Figure 51 shows the maximum weld width of 6.45 mm for a pulse on time of 50% and a pulse frequency of 2 Hz. The weld widths for pulse frequency values of 5 and 10 Hz with a pulse on time of 50% are 5.71 and 6.17 mm, respectively, as shown in Figs. 52 and 53. The weld widths are found to be 5.43 and 6.24 mm for pulse on time of 40% and 60% with a pulse frequency of 5 Hz, which is depicted in Figs. 54 and 55. All the above weld width values are found at a maximum peak current of 160 A and a base current of 60 A. A pulse frequency of 5 Hz shows the minimum weld width; an increase or decrease in pulse frequency other than 5 Hz shows an increase in weld width.

Fig. 46 Weld depth (pulse on time = 50% and pulse frequency = 2 Hz)

Precipitation in
Al–Mg–Si–Quench Factor

Fig. 47 Weld depth (pulse on time = 50% and pulse frequency = 5 Hz)

Fig. 48 Weld depth (pulse on time = 50% and pulse frequency = 10 Hz)

Fig. 49 Weld depth (pulse on time = 40% and pulse frequency = 5 Hz)

Fig. 50 Weld depth (pulse on time = 60% and pulse frequency = 5 Hz)

Fig. 51 Weld width (pulse on time = 50% and pulse frequency = 2 Hz)

Fig. 52 Weld width (pulse on time = 50% and pulse frequency = 5 Hz)

Fig. 53 Weld width (pulse on time = 50% and pulse frequency = 10 Hz)

From Figs. 51–55, it is clear that the weld width is directly proportional to the heat input.

Cooling Rate

Figure 56 shows a maximum cooling rate of 16°C/s for a pulse on time of 50%, a pulse frequency of 2 Hz, a peak current of 140 A, and a base current of 40 A. This shows that a pulse frequency of 2 Hz has very little effect on the cooling rate of the weld zone. When the pulse frequency is changed into 5 Hz for a pulse on time of 50%, a peak current of 140 A, and a base current of 40 A, the cooling rate obtained is 26°C/s. With the same pulse frequency and pulse on time, but a peak current of 160 A and a base current of 60 A, the cooling rate observed is 22°C/s as shown in Fig. 57. Figure 58 shows the cooling rate of 19°C/s for

a pulse frequency of 10 Hz with a pulse on time of 50%, a peak current of 140 A, and a base current of 40 A. This shows that a further increase in pulse frequency of >5 Hz does not have any significant influence on the cooling rate of the weld zone. With a pulse on time of 40%, a pulse frequency of 5 Hz, a peak current of 140 A, and a base current of 40 A, the cooling rate value obtained is 23°C/s as depicted in Fig. 59. This shows that the cooling rate is influenced by a difference in peak current and base current. During the higher values of difference between the peak current and the base current, the cooling rate is significantly higher. In Fig. 60, the cooling rate of 17°C/s is obtained when a peak current supplies a large amount of heat as it does not have sufficient time to cool down. This is because of a higher pulse on time of 60%. This reduces the base current effect during the cooling rate of the weld

Fig. 54 Weld width (pulse on time = 40% and pulse frequency = 5 Hz)

Fig. 55 Weld width (pulse on time = 60% and pulse frequency = 5 Hz)

Fig. 56 Cooling rate (pulse on time = 50% and pulse frequency = 2 Hz)

Fig. 57 Cooling rate (pulse on time = 50% and pulse frequency = 5 Hz)

Fig. 58 Cooling rate (pulse on time = 50% and pulse frequency = 10 Hz)

zone, and thus, the heat generated in the weld zone and the heat-affected zone is considerably higher compared other conditions.

Peak Temperature

In Fig. 61, with a pulse on time of 50% and a pulse frequency of 2 Hz, the maximum peak temperature observed is 407°C. Figure 62 shows a maximum peak temperature of 461°C for a pulse frequency of 5 Hz and a pulse on time of 50%. A peak temperature of 457°C is obtained with the same pulse on time and a pulse frequency of 10 Hz as depicted in Fig. 63. With a pulse on time of 40% and a pulse frequency of 5 Hz, the maximum peak temperature value obtained is 421°C as shown in Fig. 64. Figure 65

shows that the pulse on time of 60% and the pulse frequency of 5 Hz give a peak temperature of 430°C. The maximum peak temperatures in Figs. 61–65 are obtained with a peak current of 160 A and a base current of 60 A. Higher values of peak temperature result in higher cooling rate, which is due to higher temperature difference.

Interaction Effect

Ultimate Strength

An interaction plot shown in Fig. 66 depicts the effect of peak current, base current, pulse on time, and pulse frequency on the ultimate tensile strength. Figure 66 depicts the combined effect of the pulsed current parameters on the

Fig. 59 Cooling rate (pulse on time=40% and pulse frequency = 5 Hz)

Fig. 60 Cooling rate (pulse on time = 60% and pulse frequency = 5 Hz)

Fig. 61 Peak temperature (pulse on time = 50% and pulse frequency = 2 Hz)

Fig. 62 Peak temperature (pulse on time = 50% and pulse frequency = 5 Hz)

Fig. 63 Peak temperature (pulse on time = 50% and pulse frequency = 10 Hz)

Fig. 64 Peak temperature (pulse on time = 40% and pulse frequency = 5 Hz)

Fig. 65 Peak temperature (pulse on time = 60% and pulse frequency = 5 Hz)

Fig. 66 Interaction effect plot for ultimate strength

ultimate tensile strength and also the best combination of parameters yielding the highest ultimate tensile strength. With a peak current of 160 A, a base current of 60 A, a pulse on time of 50%, and a pulse frequency of 5 Hz, the figure shows the maximum value of >130 MPa; but the actual value found in this condition is 129 MPa. From this result, it is clear that the interaction effect predicts the values of the tensile strength value of the weldment consistently.

Yield Strength

The interaction plot for yield strength is plotted in Fig. 67. In this figure, the effect of pulsed current parameters such

as peak current, base current, pulse on time, and pulse frequency on the yield strength is observed. It depicts the best combination of parameters yielding a higher yield strength value. With a peak current of 160 A, a base current of 60 A, a pulse on time of 50%, and a pulse frequency of 5 Hz, the figure shows a maximized yield strength value of >115 MPa; but the actual value found in this condition is 110 MPa. This is confirmed from the interaction effect graph.

Elongation (%)

Elongation (%) interaction plot against the peak current, base current, pulse on time, and pulse frequency is shown in

Fig. 67 Interaction effect plot for yield strength

Fig. 68. The figure depicts the interaction effect of the pulsed current parameters on elongation (%) and also the best combination of parameters yielding maximized elongation (%). It shows that a peak current of 160 A, a base current of 60 A, a pulse on time of 50%, and a pulse frequency of 5 Hz give a maximized elongation (%) value of >12%; the actual value found in this condition is 12.33%. From this result, it is clear that the interaction effect predicts consistently.

Bending Load

The interaction plot for the bending load is plotted in Fig. 69. In the figure, the effect of the pulsed current parameters such as peak current, base current, pulse on time, and pulse frequency on the bending load is observed. The figure depicts the best combination of parameters yielding a higher bending load value. With a peak current of 160 A, a base current of 60 A, a pulse on time of 50%, and a pulse frequency of 5 Hz, the figure shows a maximized bending load of >1400 N; but the actual value found in this condition is 1460 N. This is confirmed from the interaction effect graph.

Micro Hardness

The interaction plot for micro hardness against the peak current, base current, pulse on time, and pulse frequency is shown in Fig. 70. This figure depicts the combined effect of the pulsed current parameters on micro hardness and also

the best combination of parameters yielding a higher micro hardness value. With a peak current of 160 A, a base current of 60 A, a pulse on time of 50%, and a pulse frequency of 5 Hz, the figure shows a maximized hardness value of >72 HV; but the actual value found in this condition is 75 HV. From this result, it is clear that the interaction effect predicts micro hardness very precisely.

Weld Depth

In Fig. 71, the maximum weld penetration observed in PCTIG welding condition is 2.5 mm. An increase in peak current from 140 to 160 A and an increase in base current from 40 to 60 A lead to an increase in weld penetration. But an increase in pulse frequency of >5 Hz and a pulse on time of 50% do not have any significant effect on the weld penetration. This shows that a pulse frequency of 10 Hz and a pulse on time of 60% have no effect on weld penetration, and under some PCTIG welding conditions, it leads to a decrease in weld penetration. This shows that the values other than the desired value have a negative effect on weld penetration.

Weld Width

Weld width should be minimized for the desired weld profile to yield a higher weld width/weld depth ratio. To achieve minimum weld width, the heat input during the welding should be minimized. This can be achieved by

Fig. 68 Interaction effect plot for elongation (%)

Fig. 69 Interaction effect graph for bending load

Fig. 70 Interaction effect graph for micro hardness

Fig. 71 Interaction effect plot for weld depth

reducing the peak current, base current, and pulse on time. Minimized weld width is observed under the conditions such as a peak current of 140 A, a base current of 40 A, and a pulse on time 40%. A pulse frequency of 2 Hz leads to an increase in weld width, and pulse frequencies of 5 and 10 Hz lead to reduced weld width as observed in Fig. 72.

D/W Ratio

D/W ratio should be higher for a desired weld profile. It can be achieved through a maximized weld depth and a minimized weld width. From the interaction plot shown in Fig. 73, it is clear that there is a decrease in the D/W ratio when the difference between the peak current and the base current is less. A pulse frequency of 10 Hz does not have a significant effect on the D/W ratio. An increase in pulse on time and peak current leads to a decrease in the D/W ratio. This is due to an increase in weld width in the weld profile.

Cooling Rate

The interaction plot for the cooling rate against the peak current, base current, pulse on time, and pulse frequency is shown in Fig. 74. The figure depicts the combined effect of pulsed current parameters on the cooling rate near the weld zone and also the best combination of parameters yielding a higher cooling rate. With a peak current of 160

A, a base current of 60 A, a pulse on time of 50%, and a pulse frequency of 5 Hz, the figure shows the maximized cooling rate of $>20^{\circ}\text{C/s}$; but the actual value found in this condition is 22°C/s . From this result, it is clear that the interaction effect predicts consistently.

Peak Temperature

The interaction plot for the peak temperature near the weld zone against the peak current, base current, pulse on time, and pulse frequency is shown in Fig. 75. This figure depicts the combination effect of pulsed current parameters on the peak temperature near the weld zone and also the best combination of parameters yielding a higher peak temperature value. With a peak current of 160 A, a base current of 60 A, a pulse on time of 50%, and a pulse frequency of 5 Hz, the figure shows the highest peak temperature of $>470^{\circ}\text{C}$; but the actual value found in this condition is 465°C . From this result, it is clear that the interaction effect predicts precisely.

Mean Response and S/N Ratio Analysis

Ultimate Strength

Table 8 shows the S/N ratio analysis, and Table 9 shows the mean response analysis. From these tables, the effect

Rank	3.00	4.00	1.00	2.00
Percentage	23.36	10.04	34.66	31.94

percentage of pulsed current parameters on ultimate tensile strength is evaluated. Table 8 shows that the peak current has 23%, the pulse on time has 35%, and the pulse frequency has 31% of influences on the ultimate tensile strength of the PCTIG welded sample. The base

current has only 10% of the effect percentage, which is comparatively lower than that of the other PCTIG welding parameters. This shows that the pulse on time and pulse frequency have a higher influence on the ultimate tensile strength. S/N ratio analysis in Table 8 and

mean response analysis in Table 9 show the more or less same effect percentage of pulsed current parameters on ultimate strength.

Yield Strength

Table 10 shows the S/N ratio analysis, and Table 11 shows the mean response analysis. From these tables, the effect percentage of pulsed current parameters on peak temperature is evaluated. Table 10 shows that the pulse frequency has 27% and the pulse on time has 48% of influences on the yield strength. The peak current has 20% and the base current has 5% of the effect percentage, which is comparatively lower than that of the pulse on time and pulse frequency. Thus, a slight change in pulse frequency and pulse on time has higher influence on the yield strength than on the peak current and base current. S/N ratio analysis in Table 10 and mean response analysis in Table 11 show the more or less same effect percentage of pulsed current parameters on yield strength.

Elongation (%)

Table 12 shows the S/N ratio analysis, and Table 13 shows the mean response analysis. From these tables, the effect percentage of pulsed current parameters on elongation (%) is evaluated. Table 12 shows that the pulse frequency has 34%, the base current has 25%, and the pulse on time has 28% of influences on the elongation (%). The peak current has 13%, which is comparatively lower than that of the pulse on time and pulse frequency. Thus, a slight change in pulse frequency and pulse on time has higher influence on elongation (%) than on the peak current. S/N ratio analysis in Table 12 and mean response analysis in Table 13 show the more or less same effect percentage of pulsed current parameters on elongation (%).

Bending Load

Table 14 show the S/N ratio analysis, and Table 15 shows the mean response analysis. From these tables, the effect percentage of pulsed current parameters on bending load is

3	1.26	1.24	1.32	1.17
Delta	0.29	0.10	0.28	0.23
Rank	1.00	4.00	2.00	3.00
Percentage	32.12	11.07	31.01	25.80

evaluated. Table 14 shows that the peak current has 33%, the pulse on time has 32%, and the pulse frequency has 26% of influences on the bending load of the PCTIG welded sample. The base current has only 9.5% effect percentage, which is comparatively lower than that of the other PCTIG welding parameters. This shows that the peak current, pulse on time, and pulse frequency had a significant influence on the bending load. S/N ratio analysis in Table 14 and mean response analysis in Table 15 show the more or less same effect percentage of pulsed current parameters on bending load.

Micro Hardness

Table 16 shows the S/N ratio analysis, and Table 17 shows the mean response analysis. From these tables, the effect percentage of pulsed current parameters on micro hardness is evaluated. Table 16 shows that the pulse frequency has 50% and the pulse on time has 25% of influences on the micro hardness value. The peak current has 9.5% and the base current has 14% of the effect percentage, which are comparatively lower than that of the pulse on time and pulse frequency. Thus, the slight change in pulse frequency

and pulse on time has a higher influence on micro hardness on the peak current and base current. S/N ratio analysis in Table 16 and mean response analysis in Table 17 show the more or less same effect percentage of pulsed current parameters on micro hardness.

Weld Depth

Table 18 shows the S/N ratio analysis and Table 19 shows the mean response analysis. The peak current has 55% and the pulse on time has 22%, which are the major effects on the weld depth. The base current and pulse frequency both have 11%–12% lesser effect on the weld depth. This shows that the heat input and heat input ratio during PCTIG welding has a greater influence on the weld depth. S/N ratio analysis and mean response analysis gives consistent results.

Weld Width

The peak current has 41% and the pulse on time has 29%, which are the major effects on the weld width, similar to the weld depth. But the effect percentages of the peak

current and pulse on time are changed. For weld width, the pulse on time has an increased effect and the peak current has a decreased effect compared to the weld depth effect analysis. The base current has 13% and the pulse frequency has 15%, which are the lesser effects on the weld width. Here, a decrease in peak current and pulse on time leads to a decrease in weld width. Minimized weld width is the highly desirable result to achieve a higher D/W ratio. Table 20 shows the S/N ratio analysis and Table 21 shows

the mean response analysis. The error percentage between these two analyses is <2%, so this analysis result can be taken into account for the effect percentage analysis for PCTIG welding parameters.

D/W Ratio

The peak current of 37% has a major effect on the D/W ratio. The base current of 27% and the pulse frequency of

Table 20 S/N ratio analysis for weld width

S/N ratio

23% have a significant effect percentage on the weld D/W ratio. This shows that the pulse frequency and base current also have significant importance in the weld profile. Both the S/N ratio analysis and the mean response analysis show consistent results in Tables 22 and 23.

Cooling Rate

Table 24 shows the S/N ratio analysis and Table 25 shows the mean response analysis. From these tables, the effect percentage of pulsed current parameters on the peak temperature is evaluated. In Table 24, the pulse frequency has 27% and the pulse on time has 40% influences on the cooling rate. The peak current has 19% and the base current has 14% that are comparatively lower than that of the pulse on time and pulse frequency. Thus, the slight change in pulse frequency and pulse on time has higher influence on the cooling rate than on the peak current and base current. The S/N ratio analysis in Table 24 and the mean response analysis in Table 25 show the more or less same effect percentage of pulsed current parameters on the cooling rate.

Table 22 S/N ratio analysis for D/W ratio

S/N ratio				
Level	Peak current (A)	Base current (A)	Pulse on time (%)	Pulse frequency (Hz)
1	–10.68	–9.13	–10.12	–10.38
2	–10.12	–9.85	–9.43	–9.13
3	–8.71	–10.54	–9.96	–10.01

Rank	1.00	2.00	4.00	3.00
Percentage	36.99	26.59	12.97	23.45

Peak Temperature

Table 26 shows the S/N ratio analysis and Table 27 shows the mean response analysis. From these tables, the effect percentage of pulsed current parameters on the peak temperature is evaluated. In Table 26, the pulse frequency has 27% and the pulse on time has 40% influences on the peak temperature near the weld zone value. The peak current has 19% and the base current has 14%, which are comparatively lower than that of the pulse on time and pulse frequency. Thus, the slight change in pulse frequency and pulse on time has a higher influence on the peak temperature than on the peak current and base current. The S/N ratio analysis in Table 26 and the mean response analysis in Table 27 show the more or less same effect percentage of pulsed current parameters on the peak temperature near the weld zone.

Desirability

The chances of getting higher peak temperature, cooling rate, ultimate tensile strength, yield strength, elongation (%),

weld center micro hardness, bending load, weld depth, minimized weld width value, and desirability value should be higher. The desirability level changes with respect to pulsed current parameters such as peak current, base current, pulse on time, and pulse frequency as depicted in Fig. 76.

Figure 77 shows higher desirability to get an optimum pulsed current parameter and a specific point where pulsed current parameter conditions for maximum peak

temperature, cooling rate, ultimate tensile strength, yield strength, elongation (%), weld center micro hardness, bending load, weld depth, and minimized weld width. Lower values of peak current, base current, pulse on time, and pulse frequency give reduced peak temperature as obtained in Fig. 77.

From Fig. 78, higher values of peak current, base current, and pulse on time and lower differences in the peak

Table 27 Mean response table for peak temperature

**Fig. 76** Desirability—optimized condition**Fig. 77** Desirability (pulse on time = 40% and pulse frequency = 2 Hz)

current and base current lead to overheating of base material and reduced cooling rate. When the cooling rate is at a lower value, coarse grain structures are obtained, which leads to a reduction in ultimate tensile strength.

Pulse frequency other than 5 Hz leads to reduced peak temperature and reduced cooling rate. This is the reason for reduced ultimate tensile strength, yield strength, elongation (%), weld center micro hardness, and bending load;

Fig. 78 Desirability (pulse on time = 60% and pulse frequency = 10Hz)

as a result, a coarse grain structure is obtained in the weld zone. The pulsed current condition closer to the peak current of 155–160 A, the base current of 55–60 A, the pulse on time of 50%–60%, and the pulse frequency of 5–6 Hz has a higher desirability value.

Optimized Pulsed Current Parameters

Using ANOVA, the adequacy of the experimental model can be checked, and then regression equation can be developed for each response with coefficient of correlation to validate the regression model.

From the above experimental data and from regression equations for each response, namely, weld depth, weld width, cooling rate, peak temperature, ultimate tensile strength, and bending load, the optimized pulsed current parameter condition is obtained. This optimized pulsed current parameter condition gives the maximum weld depth, maximum peak temperature, maximum cooling rate, maximum ultimate tensile strength, maximum bending load, and minimum weld width conditions when applied using Design Expert® statistical software package.

From Table 28, the optimized condition of the pulsed current parameter for TIG welding using Design Expert®

Table 28 Optimized predicted value vs. actual experimental value

Description	Optimized condition	Actual condition		
Peak current (A)	160	160		
Base current (A)	60	60		
Pulse on time (%)	54.79	50		
Pulse frequency (Hz)	5.14	5		
	Predicted value	Experimental value		
	Desirability = 0.98	Trial 1	Trial 2	Trial 3
Ultimate strength (MPa)	136	123	131	138
Yield strength (MPa)	117	116	121	127
Bending load (kN)	1.77	1.50	1.62	1.58
Elongation (%)	15.16	14.04	12.86	11.05
Micro hardness (HV)	77	75.1	73.6	74.2
Weld depth (mm)	2.57	2.5		
Weld width (mm)	6.54	6		
Cooling rate (°C/s)	18.47	20.62		
Peak temperature (°C)	446.9	430.3		

statistical software is compared with the actual condition of pulsed current parameter for TIG welding. A desirability of 0.98 shows that experimental values have higher level of acceptance. The predicted values of ultimate tensile strength, yield strength, weld center micro hardness, bending load, weld depth, weld width, peak temperature, and cooling rate for the optimized condition show nearly equal value to the actual condition. Optimized pulsed current TIG welding condition shows the predicted values for desirability, ultimate tensile strength, yield strength, elongation (%), weld center micro hardness, bending load, weld depth, weld width cooling rate, and peak temperature are plotted as contour plot in Figs. 79–88.

CONCLUSION

The regression equation was developed using Design Expert® statistical software package to predict the weld center micro hardness, yield strength, ultimate strength, elongation (%), bending load, weld depth, weld width, cooling rate, and peak temperature near the weld zone of Al-8% SiC composite, welded using PCTIG welding. Correlation coefficient is 0.9 for all the mechanical properties. This shows that the regression equation and the mathematical model developed are adequate.

Analysis of contour plot, interaction effect, S/N ratio, and mean response are developed to evaluate the influence

of each pulsed current parameter at each level and to calculate the percentage of influence by pulsed current parameters on weld strength such as yield strength, ultimate strength, and elongation (%) during PCTIG welding of Al–SiC composite.

The pulse frequency has 27% and the pulse on time has 48% influences on the yield strength. The peak current has 20% and the base current has 5% influences, which are comparatively lower than that of the pulse on time and pulse frequency. The peak current has 23%, the pulse on time has 35%, and the pulse frequency has 31% influences on the ultimate tensile strength of the PCTIG welded sample, but the base current has only 10% effect

on the ultimate tensile strength. The pulse frequency has 34%, the base current has 25%, and the pulse on time has 28% influences on the elongation (%). The peak current has 13% influence, which is comparatively lower than that of the pulse on time and pulse frequency. An increase in the peak current from 140 to 160 A leads to an increase in the weld depth and weld width. A pulse frequency of 10 Hz did not show any significant effect on the weld depth and weld width. A pulse on time from 40% to 50% results in an increase in the weld depth, but a 60% 4172 pulse on time leads to an increase in the weld width. The pulse frequency has 50% and the pulse on time has 25% influences on the micro hardness value. The peak current has 9.5%

and the base current has 14% influences, which are comparatively lower than that of the pulse on time and pulse frequency. The peak current has 33%, the pulse on time has 32%, and the pulse frequency has 26% influences on the bending load of the PCTIG welded sample. The pulse on time has 49% influences on the cooling rate. The base current has 25%, the pulse frequency has 19%, and the peak current has 8% influences, which are comparatively lower than that of the cooling rate. The pulse frequency has 27 and the pulse on time has 40% influences on the peak temperature near weld zone value. The peak current has 19% and the base current has 14% influences, which are comparatively lower than that of the pulse on time and pulse frequency.

PCTIG welding parameters such as pulse on time, pulse frequency, peak current, and base current are closely studied. Using regression equation, an empirical model was developed to obtain the optimized results for the PCTIG welding parameters. The resultant optimized values for pulse on time, pulse frequency, peak current, and base current are 54.79%, 5.12 Hz, 160 A, and 60 A, respectively. The optimized predicted values for the weld center micro hardness, yield strength, and elongation (%) have been observed as 77 HV, 117 MPa, and 15.16% with a higher ultimate tensile strength of 138 MPa, a bending load of 1.62 kN, a higher weld depth of 2.5 mm, and a lesser weld width of 6 mm, a higher cooling rate of 20°C/s, and a higher peak temperature of 430°C with a finer grain structure in the weld zone.

1. Bend strength of 1.46 kN is considered as the actual value and 1.4 kN as the predicted value.
2. Weld center micro hardness of 75.1 HV is considered as the actual value and 72 HV as the predicted value.
3. Thermal profiles such as a peak temperature of 474°C and a cooling rate of 21.5°C/s are considered as the actual condition and 463°C and 20°C/s, respectively, as the predicted condition.
4. Tensile results such as an ultimate tensile strength of 129.58 MPa, a yield strength of 110.23 MPa, and an elongation (%) of 12.33% are considered as the actual values 130 MPa, 115 MPa, and 13%, respectively, as the predicted values.

These trial runs were performed for optimized PCTIG welding condition to check the consistency of the model. This deviation between the actual value and the desired value predicted using the interaction effect plot was very small so it showed that statistical analysis was consistent. This show that the interaction effect plot developed had consistent results between the actual values and the predicted values. So this statistical analysis on the weld strength of PCTIG welded Al–SiC composite is significant. This deviation is due to the change in the value of pulse on time of 50% instead of 54.79% and pulse frequency of 5 Hz instead of 5.12 Hz.

The effect of each PCTIG welding parameter and the interaction between two or more parameters on the weld center micro hardness were studied. Key findings of the study of PCTIG welding on Al-8%SiC composite having a 5-mm-thick plate within a chosen set of parameters are as follows:

1. Peak current and base current should be 160 and 60 A, respectively.
2. Pulse on time is recommended to be 50%–55%.
3. Recommended pulse frequency should be 5 Hz.

When the peak and base current differences is more (PC-160 A, BC-40 A) and the pulse on time is 40%, the weld depth is found to be minimum and the weld width increases. When the peak and base current difference is less (PC-140 A, BC-60 A) and the pulse frequency is 2 Hz, the cooling rate decreases because it has less temperature difference between the peak current and the base current, with a pulse on time of 60% and a pulse frequency of 10 Hz; then there will be a decreased cooling rate due to higher heat input. It results in a coarse grain structure; due to the coarse grain structure in the weld zone, poor ultimate tensile strength and bending load are obtained.

Ultimate tensile strength and bending load values depend on the microstructure. When cooling rate is higher, fine microstructures are observed due to grain refinement; higher tensile strength and bending load are also observed. Due to the decreased cooling rate, coarse microstructures are observed, resulting in poor tensile strength and bending load.

Peak temperature and cooling rate are the reasons to achieve the finer grain microstructure, which is responsible for higher ultimate tensile strength and bending load in the weld zone. PCTIG welding parameters are responsible for the change in the cooling rate of the weld zone. This shows that PCTIG welding parameters have a significant effect on the weld strength of Al–SiC metal matrix composite.

ACKNOWLEDGMENTS

The authors convey their sincere thanks with gratitude to the Vice Chancellor of SASTRA University, Thanjavur, India, for pursuing this research work by providing the facility in the School of Mechanical Engineering.

Pulsed TIG Welding of Aluminum

S. Katoh

Nippon Aluminium Mfg Co Ltd, Japan

Abstract

As a consequence of developments in the electronic control of welding power sources, there has been a trend for even inexpensive and widely used metal inert gas (MIG) and tungsten inert gas (TIG) welding machines to be equipped, as standard, with a high performance pulsed current waveform control function. Meanwhile advances in understanding of pulsed arc welding phenomena and the clarification of the associated functional effects have resulted in a gradual expansion of its scope of application and of improvements in practical performance. Thus inert gas shielded arc welding is entering an epoch when full scale pulsed arc welding will become standard. In this article, the progress of the development of pulsed TIG welding of aluminium is introduced, followed by a description of the main characteristics and finally examples of recent research concerning the improvement of weld quality are introduced.

Keywords: Arc stability; Bead formation; Pulsed arc welding; Shielding gas; TIG welding.

PREFACE

In recent years, as a consequence of developments in the electronic control of welding power sources, there has been a trend for even inexpensive and widely used MIG and TIG welding machines to be equipped, as standard, with a high performance pulsed current waveform control function. Meanwhile advances in understanding of pulsed arc welding phenomena and the clarification of the associated functional effects have resulted in a gradual expansion of its scope of application and of improvements in practical performance. Thus inert gas shielded arc welding is entering an epoch when full scale pulsed arc welding will become standard.

Already it is more than 20 years since the original development of pulsed arc welding, which is not new in principle. During those years, from the start of development until the present, it is true to say that aluminium is a material to which this technique has been applied. Improvement in aluminium welding techniques is the principal objective of the development of most pulsed arc welding processes. An example of an early process to be developed was the facilitation of spray type droplet transfer by means of pulsed MIG welding; subsequently high performance and high efficiency welding of thin plate has been achieved by arc stabilisation using direct current pulsed TIG and square wave alternating current TIG welding. Similarly the stabilisation of one side keyhole welding of thin and medium plates has been achieved by means of alternating current plasma arc welding. At present the development of pulsed arc welding follows the common pattern of developments in welding apparatus; that is to say, it seems that the

development of 'hard techniques' [equipment] precede the 'soft techniques' [procedures] for welding performance. It became evident that pulsed arc welding must be employed to solve the problems of aluminium welding performance. Amongst the various types of pulsed arc welding described above, direct current pulsed arc TIG welding is provided in machines in common use; however, its use is restricted to specific processes for aluminium welding and it has not yet reached the stage of general application.

Pulsed TIG welding uses direct current straight polarity, so it has no cleaning action and this is an obstacle to it spreading to more general applications in the welding of aluminium even though the optimum penetration can be achieved. Consequently it is thought that this is a potentially suitable welding process when the problems identified as requiring improvement have been overcome. These are the (poor) welding quality with aluminium which requires improvements such as the reduction of welding distortion in thin and medium plates and the ability to achieve high quality one sided welding.

In this study the progress of the development of pulsed TIG welding of aluminium is first introduced, then the main characteristics are described and finally examples of recent research concerning the improvement of weld quality are introduced with as much detail as possible.

PROGRESS OF THE DEVELOPMENT OF PULSED TIG WELDING

Aluminium was first used as a structural material in many fields of industry from the late 1960s to the early

1970s and at the same time welding techniques for aluminium progressed rapidly. The welding techniques used for general structures have reached the point where these are by no means inferior to those used with steel materials from aspects of both efficiency and quality. However, some technical problems remain in the welding of structures which require even higher quality such as LNG plants, nuclear power plants and defence related installations. Problems such as excessive distortion when welding thin and medium plate, the occurrence of welding cracks in thermally treated alloy materials and low welded joint efficiency were considered to be the most important of these.

Investigation into these problems concluded the causes to be related to the characteristics of MIG welding which is the leading welding process for use with aluminium structures. In other words, it is related to the types of consumable electrode (difficulties of individual control of base metal and wire fusion) and the cup shaped penetrations which are not regular in the direction of plate thickness (angular distortion is likely to occur). Thus further investigation was undertaken to find a welding process with high quality and efficiency to replace MIG welding.

DCSP TIG welding was considered as a possible answer for this requirement. In the United States it has been employed in practical applications for some time and was researched by NASA and used in practice for the welding of fuel tanks. Thus, even in Japan, it has received attention as a high quality welding process. DCSP TIG welding has no cleaning action, so the process was little employed then for aluminium in Japan. However it has superior characteristics - it is a concentrated heat source and produces a narrow weld bead. Thus research has started into its practical utilisation, making use of its superior features.

The oxide film was removed from the base metal by mechanical means, helium was used as the shielding gas and the gap between the electrode and the base metal was arranged to be very small compared with alternating current TIG welding. By this means it was possible to carry out welding of excellent quality. However, the scope for these welding conditions was limited and a mis-shapen bead with an unsatisfactory appearance was formed when the welding current was high (more than 500 A). However, when the welding current was low (less than 250 A) the development of an unusual form of blowholes was unavoidable due to the entrapment of oxides and, although there was not a high rate of defects, it was difficult to reach the prescribed grade for radiographic testing.

Under these circumstances there was little merit in changing from MIG welding to DCSP TIG welding. Thus investigations were undertaken into the causes of the problems and possible countermeasures from every angle. Subsequently it was established that the poor appearance in the high current region is similar to the phenomenon of instability of the molten pool noted also in high current MIG welding. This problem was solved by using a double

shield nozzle and arranging for helium gas flow inside and argon gas outside in the same way as in high current MIG welding and welding was possible even with 1000 A.^[1]

On the other hand, when welding with a low current insufficient arc stiffness was thought to be a major cause (of problems). Thus the introduction of pulsed TIG welding was first considered. Some 20 years ago, during the early 70s, originally a thyristor type pulse welding source was employed. The results were as expected and it became clear that not only was the entrapment of oxides prevented but also the bead appearance improved and this has now become a requirement for arc control during DCSP TIG welding of thin and medium aluminium plates.

Subsequently the welding power source for pulsed TIG welding was changed from a thyristor to a transistor control type and control functions for the various welding phenomena improved significantly in areas such as arc stiffness and stability, bead appearance and penetration control (including meeting the requirements of various welding positions such as fixed pipe welding), improvement in the solidification structure (small grain size) and thermal control of the heat affected zone (HAZ).

This turned out to be a very effective technique for pulsed TIG welding of aluminium in practical applications and was also effective in the following areas: welding distortion in structures of thin and medium aluminium plates was substantially reduced, the susceptibility to weld cracks was reduced even in heat treated alloy materials and the welded joint efficiency improved. The applications for key structures such as the 2000, 6000 and 7000 groups of heat treated alloy materials, in addition to the conventional 5000 group process hardened alloy materials, have been gradually increased.

PULSED TIG WELDING EQUIPMENT

Types of pulsed TIG welding power source

The types of welding power source employed in pulsed TIG welding are classified as in the Table by their control elements and associated control systems.^[2]

Typical current waveforms used in pulsed TIG welding

When an analogue system transistor power source is used the current waveform is optional; however, current waveforms in practical use are square, sine and sawtooth waves, as shown in Fig. 1. Different frequency bands are used for the square wave (low and medium), the sine wave (low) and the sawtooth wave (high frequency).^[2] In addition, it is possible to combine these different waveforms. For example, combinations of the high frequency pulse of the sawtooth wave and the low frequency pulse of the sine wave or square wave are often used.

Fig. 1 Typical current waveforms used in pulsed arc welding

Table 1 Type of pulsed TIG welding power source classified by control element and control system

Control element	Control system	Rate of control applications per second	Pulse frequency
Thyristor	Ignition phase control	Three-phase full wave 300/360 times	DC~10Hz
	Switched type	Chopper control 30,000 times	1~25kHz
Transistor	Inverter control	50,000 times	DC~100Hz
	Analogue type	Analogue control —	DC~15 kHz

Fig. 2 Response diagram for arc pressure

MAIN CHARACTERISTICS OF PULSED TIG WELDING

Arc stability by means of a pulsed current

The arc generally has a characteristic such that the higher the arc current the more the arc stiffness and directionality improve because of a plasma current. In pulsed TIG welding arc stability can be achieved by means of a higher frequency periodic alternation of the current value for the same effective value of current compared with DCSP TIG welding. Arc pressure on the surface of the base metal is often used as a measure of the plasma current. It is believed that the arc pressure changes in proportion to the square of the current. Consequently for a pulsed arc where the current value changes with time, if the fluctuation time is sufficiently long compared with the thermal and fluid time constants of the arc, then the arc pressure varies, as shown in Fig. 2, in response to the current fluctuation.^[2] It is important to know to what extent the arc pressure responds to the current variation.

Figure 3 shows the variation of pressure directly below the electrode where $I_{AV} = 150$ A, $I_B = 50$ A, $f = 100$ Hz. The pulsed current waveforms are square and sine waves

Fig. 3 Oscillograph of arc current and arc pressure at the centre of a TIG arc^[3]

respectively and the arc pressure is following the current waveform accurately.^[3]

Figure 4 shows the frequency response for arc pressure when sine wave current waveforms I_{AV} and I_B were set. It is evident the amplitude of pressure variations and the average pressure value were constant at least up to 300 Hz and observation of the frequency range up to the resonance frequency of the pressure transfer system (several 1 kHz in this case) indicated that the arc pressure did not vary much with pulse frequency.”

Fig. 4 Frequency response curves of arc pressure for pulsed TIG arc (for a sine wave)^[3]

Fig. 5 Abnormal arc voltage waveforms recorded during high speed low current DCSP TIG welding (base metal A5083 plate of thickness 0.5 mm, welding speed 150–200 cm/min, shielding gas Helium)^[4]

Improvement in anode formation on the base metal is thought to have the effect of stabilising the arc during pulsed TIG welding.^[2] A straight polarity arc, once the anode point is formed, has a tendency to remain fixed on that location. Subsequently, when high speed welding is performed in the low current region the arc column is deformed as a consequence of being pulled to the fixed anode point and when the arc length increases beyond a certain value the arc root jumps discontinuously and becomes unstable.

Figure 5 shows abnormal arc voltage waveforms recorded during an experiment by the authors with a low current arc during DCSP TIG welding.^[4] There was no fluctuation in the current value because of the full direct current arc generated by means of a transistor power source but the arc voltage fluctuated either continuously or discontinuously. It is considered that with such a voltage waveform the arc root jumps and a weak pulse giving a 'pat pat' sound can be identified even during practical welding.

Figure 6 shows a comparison between a direct current arc and a high frequency pulsed arc (10 kHz) for the anode point trace ratio (the percentage that the sum of the anode point trace lengths represents of a fixed weld length) on the surface of aluminium alloy (5083) base metal with a high speed straight polarity TIG arc. This figure shows that anode formation during high speed welding was notably improved by a high frequency pulsed TIG arc.^[2,3]

Bead formation during pulsed TIG welding

Several effects, as described previously, can be expected from pulsed TIG welding. On the other hand, there are many more control parameters compared with conventional welding processes and there may be a risk of very adverse influences upon welding if mistakes are made in setting these conditions.^[2]

Fig. 6 Improvement of anode formation for high frequency TIG arc

Fig. 7 Current waveform region within which sound bead can be obtained for pulsed TIG welding^[3]

Although welding parameters such as average current and welding speed are fixed for pulsed TIG welding, the pulsed current waveform has a considerable influence upon the development of defects such as humping and tunnel bead.

Figure 7 shows the region where defects developed when the pulse frequency f and the current amplitude I_a , were varied. The current amplitude at the limits of occurrence of these defects depends upon the pulse frequency and it becomes a minimum I_{ac} (critical current amplitude) with a certain frequency F_c (humping frequency).^[3]

Figure 8 shows the results of investigation into the limits for the development of defects with different base metal material under the same welding conditions. Even with

Fig. 8 The relationship between pulse frequency and current amplitude where humping bead developed during pulsed TIG welding of mild steel, stainless steel and aluminium with the same average current level^[3]

fixed welding conditions the limits for the occurrence of defects varied according to the material; mild steel plate had the highest humping frequency F_c , then stainless steel plate and last of all aluminium alloy plate.^[3] The development of such humping and tunnel bead is associated with the dynamic characteristics of the molten pool during pulsed TIG welding. It is believed that the resonance phenomena, determined by the physical properties of the base metal and the shape, contribute greatly to the frequency dependence of the molten pool instability phenomena which induce defects. Theoretical calculations were also carried out by Maruo and others.^[3]

Figure 9 shows the results of investigation into the effects of pulse conditions upon penetration shape.^[6] Even when the average current value was fixed, the penetration shape ratio (D/W) varied considerably with the pulse frequency. The bead width was large in the low frequency range less than 50 Hz. Penetration did not vary much compared with the examples where full direct current was used, so D/W was smaller than for the examples where full direct current and intermediate frequencies (100–1000 Hz) were used. As described above, the bead shape for pulsed TIG welding varies according to the pulse frequency used. Thus when setting pulse conditions it is most important to select the correct frequency range.

IMPROVEMENTS IN WELD QUALITY FOR PULSED TIG WELDING (DCSP TIG WELDING)

Reduction of welding distortion

Figure 10 shows the angular distortion when MIG welding was carried out on aluminium alloy (A5083- O material) medium plate, 8 mm thickness. Similar plates were DCSP TIG welded and the degree of angular distortion and longitudinal deformation for each is shown in Fig. 11.^[7] The angular distortion became less than 1/10 for one-side 1 pass DCSP TIG welding compared with three pass MIG welding. In the examples of MIG welding a large angular distortion developed from the first pass; subsequently it was thought that the penetration shape, rather than a smaller number of layers, is the main reason that there was notably little angular distortion for DCSP TIG welding. Thus welding distortion is substantially reduced by the employment of DCSP TIG welding which gives a uniform penetration in the direction of plate thickness rather than the cup shape of MIG welding. The reduction of distortion is the greatest benefit of using DCSP TIG welding and it is applied for seam welding of numerous structures such as base plate welding of LNG tanks.^[7]

Reduction of welding defects

During DCSP TIG welding of aluminium, hydrogen, which is a cause of blowholes in aluminium welding, was mixed

Fig. 9 The effects of pulse frequency and peak current on the penetration form ratio (D/W)^[6] (base metal A5083 alloy, plate thickness 20 mm, bead-on-plate welding, pulse shape Square wave)

Fig. 10 Angular distortion with multi-layer MIG welding (AS083-O)^[7]

at 0.5% with commonly available helium gas and used as the shielding gas. Then the effect of the pulse conditions upon the formation of blowholes was investigated. The results are shown in Fig. 12. For the full direct current case a large deformed blowhole developed. This was believed to be due to the entrapment of oxides, and also there were a large number of round blowholes. However, by employing

pulsed TIG welding the formation of blowholes was notably reduced. Pulsed TIG welding is in principle the same as DCSP TIG welding, so a cleaning action cannot be expected and it is not clear at present how the formation of blowholes can be controlled. However, the effects upon blowhole formation can be seen whether the pulsed current waveform employed is a low, intermediate or high frequency. By this

Fig. 11 Welding distortion for DCSP TIG one sided welding (A5083-O)^[7]

means it is thought that effective stiffness and stabilisation of the arc were achieved. The utilisation of pulsed TIG welding is a very simple solution but it is concluded, from judgement of the actual results of its application to various structures carried out by the authors, that this is

very effective to prevent the development of deformed blowholes of the type associated with DCSP TIG welding.

Overlap tends to occur in DCSP TIG welding in the same manner as blowholes and the effects of this upon fatigue strength, etc, are a matter of concern. However, overlap can also be controlled by selection of the pulse conditions as shown in Fig. 13.

On the other hand, undercut tends to occur when using pulsed current rather than when using full direct current; this is especially so in the low frequency range and, with increased current amplitude, intrusion of the ripple line

becomes large. Thus consideration must be given to this effect in the selection of the welding conditions.^[6]

Improvement of the solidified weld structure

For pulsed TIG welding, as shown in Fig. 14, the structure of the weld metal can be refined by choice of the combination of the base metal in use and pulse conditions.^[8] For DCSP TIG welding of 5083 alloy a feathery crystal structure tends to develop at the centre of the bead; however, radiographic testing of that area revealed a false linear flaw pattern. This is one of the problems that must be overcome for the successful practical application of DCSP TIG welding.^[9] Thus there is a potential benefit in improving the solidified structure using a pulsed arc. However, the range of welding conditions in which the structure is refined is not very wide. Consequently it is believed that there are not many cases where pulsed TIG welding can be applied for microstructural improvement in practical circumstances.

Reduction of weld cracking in heat treated alloy

When joints in plate of different thickness were welded, as shown in Fig. 15, there were many cases where the thinner plate with small heat capacity became fused irregularly and, as a result of attempts to achieve full penetration, burn

Fig. 15 Temperature distribution during welding of materials with different heat capacities using direct current welding process

Fig. 16 Temperature gradient during pulsed TIG welding of joints shown in Fig. 15 with thermal control

through resulted. When pulsed TIG welding is applied to such joints it is very effective, as shown in Fig. 16, because the heat input can be controlled so that the temperature gradient in the weld zone will increase by selection of the optimum pulse conditions.^[10]

Where there are members of different plate thickness the degree of restraint of the members during welding will be different, so weld cracking is likely to occur.

Figure 17 shows the results of investigation into conditions for which sound welds without weld cracks could be obtained using pulsed TIG welding for joints of different thickness of A6063TE-T6 material of external diameter of 120 mm and a plate thickness of 10 mm^[11] Because the joints were susceptible to cracking, welding was performed using high silicon filler metal. However, in joints without a groove, macrocracking developed with any type of filler

Fig. 17 Results of experiments on pulsed TIG welding using high silicon filler material

metal. By contrast, when there was a groove, the rate of dilution by base metal also reduced and, in addition, the weld metal composition was adjusted to the higher silicon side by the use of high silicon 4047 filler metal so that weld cracking was prevented.

For pulsed TIG welding, as described above, the fusion of both base metal and filler metal can be controlled. Thus, because it is easy to set up the appropriate countermeasures, this method is advantageous for use with joints which have susceptibility to weld cracking.

Improvements to welded joint strength

A5083 alloy thin and medium plate one-side welded joints
Fig. 18 shows the relationship between the dendrite cell size and the tensile strength for one-side single pass welded joints of A5083P-O 6 mm thickness plate material.^[12] In order to obtain a sound joint performance when welding A5083 alloy the optimum welding heat input should be selected so that the dendrite cell size does not become coarse; however, for one-side single pass welding of thin and medium plates, the welding conditions, to ensure a uniform reverse side bead is formed and that in addition the welding heat input is not excessive, may be, in many cases, very restricted. In this respect the conditions to meet both requirements are easily satisfied with DCSP TIG welding rather than with MIG welding.

Heat treated alloy welded joints

The efficiency of heat treated alloy welded joints can be significantly improved with DCSP TIG welding (compared with any other welding process) because welding can be generally carried out with a low heat input so that the degree of dilution by base metal is reduced.

When applying DCSP TIG welding to one-side single pass welded joints of A7N01P-T 8 mm plate, the welded joint efficiency shows an approximately 10 per cent higher value compared with the use of MIG welding.^[12] Similarly, from the results of investigation of the effects of welding

Fig. 18 The relationship between dendrite cell size and tensile strength for one sided single pass welded joints of Al-4.7% Mg alloy (base metal A5083P-O, Plate thickness: 6.0–6.6 mm)

process upon welded joint strength for 6061 alloy T4 and T6 materials, it was ascertained that the welded joint strength improved significantly when DCSP TIG welding was used instead of MIG welding.^[13]

As described above, there are significant effects upon heat treated alloy welded joint strength resulting from the application of DCSP TIG welding. However, it has been reported that an even lower heat input than that required for full direct current was attempted by the application of pulsed arc (welding) and subsequently the welded joint strength was improved. By joining 2219-T87 and 2014-T6 materials using high frequency pulsed TIG welding the welding heat input was reduced by about 40% and the welded joint strength increased by a few per cent compared with full direct current DCSP TIG welding.^[14]

High quality and efficiency for the welding of special joints

In pulsed TIG welding there are many control factors and precision control of the arc and molten pool is possible. Thus this process was applied to a special joint which was considered to have inherent weaknesses from the viewpoint of weld quality when welded using conventional aluminium welding processes compared with the use of other materials; significantly improved results were obtained for quality and efficiency.

High speed welding of thin plate of thickness less than 1 mm

The arc becomes stable, even at low current, by the use of pulsed arc DCSP TIG welding. Thus it is possible to weld thin plate butt joints of less than 1 mm thickness which were considered difficult with conventional aluminium welding methods. In addition, welding can be carried out at much higher speeds than with conventional methods using a pulsed arc due to the effects upon the base metal of the improvements of anode formation.^[3,4,15]

When butt welding A5083 alloy plate of thickness 0.5 mm, a joint strength almost equal to that of the base metal was obtained. Thus it was confirmed that not only is high speed welding possible but also the resulting joints have good efficiency and weld quality.^[4]

Automatic welding of thin walled small diameter fixed pipes

The physical properties of aluminium differ greatly from those of other materials such as stainless steel, titanium and steels, so it is particularly difficult to carry out full penetration welding from one side of a circumferential joint in small diameter pipes.^[16] In other words, for fixed aluminium pipe welding, even with control of the penetration possible with all position welding, characteristic aluminium welding defects occur easily at the start and

the finish of welding and at the positions of overhead and downward welding. Using conventional alternating current TIG welding it is extremely difficult to carry out high quality automated welding of fixed pipes.

Low frequency pulsed TIG welding was tried for this application and welding methods and procedures were established especially for aluminium and a system was developed for setting the welding conditions for pipes, based upon heat conduction analysis. By this means the automation of stable, full penetration welding became possible and, from the results of welding tests on small diameter pipes with external diameters of 25–85 mm fixed horizontally or perpendicularly, entirely satisfactory results were achieved. Radiographic and mechanical tests were applied to the joints.^[16–18]

This technique has given excellent results in automatic welding for the 'Tristan' scheme of the High Energy Research Laboratory of the Ministry of Education.^[18]

As described above, low frequency pulsed TIG welding is particularly suitable in maintaining molten pool stability for single sided full penetration welding. The molten pool dimensions and limits can be estimated, to a degree, by calculation from heat conduction and surface tension theories. Consequently the method of calculation required to set the welding conditions has become well established.^[2,19]

One-sided welding of long medium thickness joints

For the welding of large structures with medium plates of thickness 6–20 mm it is common to carry out conventional MIG welding on both sides. However, much time is required for edge preparation and back gouging and various countermeasures are required to ensure quality and to prevent excessive welding distortion and microfissuring during multipass welding.

For such long joints in medium thickness plate structures the welding quality and efficiency can be substantially improved by one-sided single pass welding with the pulsed TIG welding process. As described above, there is very little welding distortion and the joint strength is high. However, special attention, different from that required for MIG welding, is necessary for the control of dimensional accuracy, the removal of the oxide film near the grooved area by mechanical methods and the selection of backing plates.

Examples of applications are base plate welding for LNG tanks,^[7] seam welding for bridges^[20] and the seam welding of large diameter pipes.^[21]

IN CONCLUSION

The pulsed TIG welding of aluminium has been summarised, focusing on Japanese research and the development of its applications. The fundamental characteristics of pulsed TIG arc welding only were described, excluding the characteristics of DCSP TIG welding. However, in order to clarify

the objectives and effectiveness of utilising pulsed TIG welding, examples of improved welding quality were described, including data published for DCSP TIG welding. This may have led to some lack of consistency in the contents.

A problem with pulsed TIG welding of aluminium is the use of expensive helium as the shielding gas but it is understood that there is a possibility of a substantial reduction in the price of helium due to recent technical developments. Consequently it is believed that the opportunities for the application of pulsed TIG welding to aluminium structures will increase in the future.

Quality Parameters for High-Pressure Diecastings

Roger Lumley

Engineering, LaTrobe University, Plenty Road, Bundoora, Victoria, 3086, Australia

Abstract

Techniques of examining casting quality as it relates to high-pressure die casting (HPDC) are evaluated. The roles of some simple parameters are considered in the as-cast and heat-treated conditions. Failure of HPDCs is influenced by a complex interaction of a variety of casting defects. Complex strain localization and failure occurs in HPDCs, which results in a proportionately large fraction of defects appearing on the fracture surface. The methodology developed is expanded to evaluate industrially produced components as a means to produce a universal quality metric. The effect of heat treatment on quality is also evaluated. Of the different analyses conducted, all may differentiate casting quality, but some complimentary techniques (e.g., Weibull statistics combined with flow curve derivations based on the Ludwik–Hollomon equation) are extremely useful.

Keywords: Aluminum; Casting; Defects; Ludwik–Hollomon; Weibull analysis.

INTRODUCTION

In manufacturing, quality is defined as being a measure of excellence or a state of being free from defects, deficiencies, and significant variations, where (high) quality is brought about by the strict and consistent adherence to measurable and verifiable standards to achieve uniformity of output that satisfies specific customer or user requirements.^[1] The “cost of quality” is actually the cost of poor quality,^[2] since nonconforming products increase total product cost and lengthen (delivery) lead time.

A dual approach to product manufacturing can substantially reduce cost and therefore increase competitiveness. Advanced product development can systematically design in quality, so that problems are resolved at a preproduction stage, and then process controls can build in quality to the manufacturing method itself. Unfortunately, and in most cases, product development is solely based around component function rather than design for manufacture, which means that once a drawing of a part is accepted for manufacture by a foundry, for example, only process controls remain as a means to improve quality and therefore reduce cost.

One significant advantage of the HPDC manufacturing route is the very high production rates that may be employed. The major drive for the use of this process is its ability to be utilized in mass production and reliably produce effectively identical components over 10^4 – 10^6 cycles. Hypothetically, there should be minimal variation in properties, composition, microstructure, or dimensions. For industrially produced components, alloys within the same compositional designation should display similar levels of mechanical properties to each other irrespective of the facility in which they are produced,

although variations will occur for a wide range of reasons. Ideally, it would also be the case that as-cast test bars (e.g., Fig. 1) should display properties similar to samples machined from castings of the same alloy. This relationship is unfortunately not observed in practice because of the inherent variations in processing and microstructure (e.g., the skin effect, porosity etc.) of die-cast components and materials.

MEASURES OF COMPARATIVE QUALITY OF ALUMINUM CASTINGS

Quality Indices and the Influence of Defects on Mechanical Properties of Aluminum Castings

A range of different defect types exist in aluminum castings^[4] and all influence mechanical properties. Tensile elongation and tensile strength are particularly sensitive to the presence of casting inclusions, defects, and discontinuities and, as a result, are commonly used as measures of casting quality.

For example, the quality index (Q) was originally derived by Drouzy et al.^[5] in 1980 to describe the relative quality of permanent mold and sand cast Al–Si–Mg alloys such as A356 and A357. It was first developed as an empirical formula

$$Q = \text{UTS} + 150 \log E_f \quad (1)$$

where Q and UTS are in MPa, and E_f is the percent elongation at fracture (i.e., elastic + plastic strain).

Fig. 1 Testbars produced by high-pressure die casting (used for the tensile testing referred to in this article). The cylindrical tensile test had a total length of 100 mm with a central parallel gauge section of 33 mm long and a diameter of 5.55 ± 0.1 mm. Details for specimen production are outlined elsewhere^[3]

Quality index was later shown to have physical meaning for castings.^[6,7] An excellent description of quality index and how it relates to casting quality, microstructural modification, heat treatment, and a range of microstructural defects present in castings is given elsewhere.^[8] Although this method was developed for permanent mold and sand cast Al–Si–Mg alloys, it also has utility in HPDC Al–Si–Mg and Al–Si–Cu–Mg alloys. For HPDCs, the measure of Q may have extra importance because the endurance limits for both axial and bending fatigue have been found experimentally to be directly related to tensile strength.^[9,10] For tests conducted with a stress ratio of $R = 0.1$, the ratio of fatigue endurance limit (at 10^7 cycles) to tensile strength is close to 0.6 for HPDC alloys^[9,10] (this equates to a ratio of ~ 0.4 at a stress ratio of $R = -1$). Table 1 shows results including the fatigue properties and quality index (Q) values for the 380-type alloys, as cast or heat treated.^[9,10]

For axial fatigue conditions, alloys prepared to a T6 temper outperform those treated to a T4 temper, whereas in bending fatigue the reverse is true, presumably because ductility is higher in the latter condition.^[11] Thus, a shift

Fig. 2 Comparison of melt velocity and its effect on heat treatment for Alloy 1, using Eq. 1. Details of heat treatment procedures are outlined in^[12–15]

toward higher levels of tensile strength in HPDC alloys gives an indication that fatigue resistance will be raised. Moreover, the optimal condition of resistance to both axial and bending fatigue will exist if both tensile strength and ductility can be increased together. It can be concluded, therefore, that in addition to giving a measure of casting quality, the quality index formula (Eq. 1) for Q also provides a meaningful indication of the durability of HPDC alloys.

As an example, the utility of the quality index in the A380 alloy (similar to US alloy A383) is shown in Fig. 2 for as-cast as well as T4- and T6-treated alloys, where melt velocity is compared for as-cast, T4-, and T6-treated samples.^[12–15] Based on these initial findings, the differences in the conditions presented in Fig. 2 were evaluated in greater detail.

ADVANCED METHODS

Statistical Techniques

With regards to laboratory testing, the high production rate of die castings (e.g., the cycle time of the shot shown in Fig. 1 was close to 40 s) means that large numbers of

Table 1 Endurance limit^a at 10^7 cycles, in absolute terms and in terms of tensile properties^b

identical samples can be produced without substantial variations in properties, composition, microstructure, or dimensions. Since HPDC tensile test bars require no machining, and their gage dimensions are effectively identical, rapid determination of large numbers of tensile results is possible. This means an examination of several different techniques for casting quality may be required.

$\mu \pm 3\sigma_{(sd)}$ Analysis

It is a common method for buyers of aluminum castings to specify values of $\mu - 3\sigma_{(sd)}$ for the products they purchase from foundries. (Here the notation $\sigma_{(sd)}$ is used to differentiate from stress, σ). That is, the lower bounds are specified as the mean (μ) minus three times the standard deviation ($\sigma_{(sd)}$) of a statistically relevant number of test samples. This approach has excellent utility because $\mu \pm 1\sigma_{(sd)}$ represents 68.2% of the data, $\mu \pm 2\sigma_{(sd)}$ represents 95.4% of the data, and $\mu \pm 3\sigma_{(sd)}$ represents 99.7% of the data. Only 0.135% of the data falls below $\mu - 3\sigma_{(sd)}$. An adverse change in quality may therefore be quickly detected by comparing results against a known baseline value of $\mu - 3\sigma_{(sd)}$. The major disadvantage of this technique is that it assumes a normal distribution of data exists, which is often not true for a statistically large number of castings.

Weibull Analysis

It has been proposed that examination of the Weibull distribution is a better test of quality in aluminum castings^[16,17] than $\mu - 3\sigma_{(sd)}$. Weibull statistics were first developed for brittle ceramic materials, and they have a major advantage, in that adjustments can be implemented based on the size and scale of the product being made. Another benefit is that the Weibull modulus, “ m ,” is a useful means by which to compare components made by different processes. For castings, as the value of m gets larger, the narrower is the range of tensile strengths (and ductility), which will exist, so reliability is improved. This approach has many merits for aluminum high-pressure die castings (HPDCs). As with brittle materials, the tensile strength data of castings in practice exhibit significant scatter, and the Weibull distribution provides a simple method to determine accurately the probability of failure at any given stress. A practical method for using Weibull analysis is summarized as follows.^[18]

The Weibull analysis provides a probability of failure at a given stress, expressed by the empirical relationship

$$P = 1 - \exp \left\{ - \int_X \left(\frac{\sigma - \sigma_u}{\sigma_o} \right)^m dX \right\} \quad (2)$$

where P is the probability of failure at a stress σ , m is the Weibull modulus, σ_u is the stress at which $P = 0$ (and normally equals zero), X is the strength-limiting dimension

of the material, and σ_o is a normalizing factor, referred to as the position parameter. Therefore, for specimens with constant geometry,

$$P = 1 - \exp \left\{ - \left(\frac{\sigma}{\sigma_o} \right)^m \right\} \quad (3)$$

The simplest method of obtaining σ_o and m from a series of data is to rank the σ data from smallest to largest and assign P values so that:

$$P = \frac{i}{N + 1} \quad (4)$$

where “ i ” is the rank and N the total number of specimens. Equation 3 can then be expressed as follows:

$$y = A + Bx \quad (5)$$

where

$$y = \ln \left[\ln \left(\frac{1}{1 - P} \right) \right], A = -m \times \ln \sigma_o, B = m, \text{ and } x = \ln \sigma$$

The best estimates of σ_o and m can be obtained using the linear least squares method, i.e.,

$$A = \frac{\sum x^2 \sum y - \sum x \sum xy}{N \sum x^2 - \left(\sum x \right)^2} \quad (6)$$

$$B = \frac{N \sum xy - \sum x \sum y}{N \sum x^2 - \left(\sum x \right)^2} \quad (7)$$

where $\Sigma = \sum_{i=1}^N$

It is however simpler to plot the xy data from Eq. 5 and determine the slope of the line, which gives the value of the Weibull modulus, m . The value of position parameter, σ_o , is equal to the value at which 37% ($1 - 1/e$) of samples survive.^[17]

A theoretical physical background to the Weibull distribution has also been established,^[19] related to the probability density $f(a)$ of flaw sizes within the material, with $f(a)$ being approximated by

$$f(a) = \frac{c^{n-1}}{(n-2)!} a^{-n} e^{-c/a} \quad (8)$$

where n is the rate at which $f(a)$ tends to zero for $a \gg c/n$, and c is a scaling parameter. Assuming there are a large number of randomly oriented flaws, m and n are related through $m = 2n - 2$. (Note that “ n ” used in Eq. 8 is the same notation as the original reference^[19] and is not the same as the strain hardening exponent, n , defined later for Eqs. 13–16.)

It is therefore apparent that scatter in strength data and hence the value of the Weibull modulus is directly related to the flaw size distribution, and as a result, casting quality. Weibull modulus may also be utilized across different scales. For example, Eq. 2 may alternately be written as follows:^[20]

$$P = 1 - \exp \left\{ -V \left(\frac{\sigma - \sigma_u}{\sigma_o} \right)^m \right\} \quad (9)$$

where V is the volume of the component. Therefore, for the same probability of survival (or failure; note that probability of survival = 1 – probability of failure), the stress at failure varies with the volume of the component. For example, if $\sigma_u = 0$, and $V_1 > V_2$, then

$$V_1(\sigma_1)^m = V_2(\sigma_2)^m \quad (10)$$

And

$$\sigma_1/\sigma_2 = (V_2/V_1)^{1/m} \quad (11)$$

So for an equal probability of survival, a larger volume of the component will display a lower stress to cause failure.

Similarly, the stress ratio between bending and tension for the same probability of survival is also given by

$$\sigma_{\text{bend}}/\sigma_{\text{tensile}} = \{2(m+1)^2\}^{1/m} \quad (12)$$

Advanced Quality Methods Based on the Ludwik–Hollomon Equation

Cáceres^[6,7] has shown that for any aluminum alloy, determination of the flow curve described by the Ludwik–Hollomon equation

$$\sigma = K\varepsilon^n \quad (13)$$

(where σ is the true stress, ε is the true plastic strain, K is a constant, known as the strength coefficient, and n is the strain hardening exponent)

can provide the basis for the assignment of quality indices (q) based on proportions of what constitutes a defect-free casting, where the true strain $\varepsilon = n$. Although the Ludwik–Hollomon equation is an empirical relationship, n can be shown experimentally to be equivalent to the true strain at the onset of necking. A defect-free casting will elongate until the maximum stress is achieved and necking begins, leading to failure. It then follows that the presence of any types of defects in the material means that void growth and crack propagation occur at levels of strength and ductility, where $\varepsilon < n$, these levels being directly proportionate to the fraction of defects present.

Surappa et al.^[21] has shown that a reduction in elongation to fracture through the presence of porosity may be related to the projected area of pores on the fracture surface. Cáceres and Selling^[22] later showed that bulk volumetric porosity has almost no correlation to tensile properties, whereas the number or fraction of any type of defect present on the fracture surface was directly related to the tensile behavior and failure. Cáceres and Selling^[22] thereby proposed a model based on the relationship between a cross-sectional area not containing a defect, A_o , and the cross-sectional area containing a defect, A_i , such that $A_i = A_o(1 - f)$, where f is the area fraction covered by the defect. In this case, load equilibrium is maintained if

$$\sigma_i(1 - f)A_o e^{-\varepsilon_i} = \sigma_h A_o e^{-\varepsilon_h} \quad (14)$$

where σ_i and ε_i are the true stress and strain inside the defect, and σ_h and ε_h are the true stress and strain outside the defect.

If the material follows Eq. 13, then combining Eqs. 13 and 14 leads to

$$(1 - f)e^{-\varepsilon_i} \varepsilon_i^n = e^{-\varepsilon_h} \varepsilon_h^n \quad (15)$$

This equation relates the strain inside the defect to the strain outside the defect.

Rearranging Eq. 15 to then solve for the defect area fraction gives

$$f = 1 - (e^{-\varepsilon_h} \varepsilon_h^n / e^{-\varepsilon_i} \varepsilon_i^n) \quad (16)$$

As may be appreciated, when solving Eq. 16 for defect area fraction (f), as the area fraction present on the fracture surface f increases, for a fixed value of strain outside the defect (ε_h), the strain inside the defect-containing region (ε_i) increases more rapidly.

The model of Cáceres and Selling^[22] has also been verified experimentally using investment cast 357 alloy.^[23] Lumley and Bell^[23] quantified the projected area of carbonaceous inclusions on fracture surfaces to validate the model and found that the predicted area fraction of defects (f) present on the fracture surface of tensile test bars corresponded closely to the measured value (Table 2). What is also important to note from this result is that the quantitative analysis (by color segmentation methods) could only be conducted on the projected area fraction, rather than the actual (surface) defect fraction. As may be appreciated, this was because it was not possible to precisely measure the actual defect fractions present taking into account surface roughness. Importantly, no surface roughness factor was required in the analysis.

Statistical Analysis of Quality in Al–Si–Cu Alloy

Initial experiments were conducted to determine if meaningful results related to casting quality could be derived

Table 2 A comparison of the predicted defect fraction present on the fracture surface (from Eq. 16) and the measured defect fraction present on the fracture surface

for high-pressure die-cast components. In previous work on HPDCs,^[24,25] it has been demonstrated that differences exist in the tensile properties derived from as-cast samples produced with a velocity at the gate of 26 m/s, compared to those produced with higher velocities such as 82 m/s. This difference in properties was later shown to become more significant in heat-treated conditions,^[12] where, as would be expected, a higher quality as-cast part will result in a higher quality heat-treated one (e.g., see Fig. 2). Data for compositions of Alloys 1–3 from Table 3 were generated using 25 individual tensile tests for each of the two melt velocities. These three alloys correspond to Al–Si–Cu compositions representative of a wide range of international die casting alloys (including the US alloy A380 and the EU alloy AlSi9Cu3(Fe)(Zn)). A higher level of Cu was present in Alloy 2, and a higher level of Zn was present in Alloy 3. These alloys were tested to determine if there were any compositional differences related to quality. For example, it may be hypothesized that increasing Cu within an Al–Si–Cu alloy could produce higher levels of strength and also produce greater quantities of hard intermetallic domains (e.g., Al₂Cu) that adversely influence ductility. The susceptibility to hot tearing may also change. Similarly, increased levels of Zn may increase porosity in the casting due to its high vapor pressure above 420°C.^[26] Zn

has also been reported to stabilize needles or platelets of the Beta phase Al₅FeSi,^[27] which is detrimental to cast aluminum alloys. Alternately, either element may enhance castability as well as increasing strength, so that relative quality may instead improve.

Values of the mean (μ), one standard deviation ($\sigma_{(sd)}$), and $\mu - 3\sigma_{(sd)}$ for the tensile data of each of the two melt velocities are shown in Tables 4–6. Values of $\mu - 3\sigma_{(sd)}$ for the 82 m/s samples were consistently higher than for the 26 m/s samples.

Representative fracture surface samples from tensile samples of Alloy 1 displaying values close to the mean values of elongation and tensile strength were studied further. Figure 3a–d shows fracture surfaces of an as-cast sample with tensile properties close to the statistical mean produced with a melt velocity of 26 m/s. The fracture surface is shown as a secondary SEM image in Fig. 3a and as an equivalent backscattered electron (BSE) image in Fig. 3b. Figure 3c and d are higher magnification images

of the central region of the fracture surface, also in BSE mode. Figure 3e–h shows equivalent secondary and BSE images from a sample produced at 82 m/s, also close to the statistical mean values of tensile strength and elongation.

Initial examination of Fig. 3a suggests that no large defects were present on the fracture surface. Figure 3b, however, revealed a defect that occupies approximately 25% of the cross-sectional area. Higher magnification imaging (Fig. 3c,d) showed that this was a region where dispersed shrinkage porosity is present, and there was an almost foam-like, random dendritic structure. Hard, iron-bearing intermetallics and small oxide films able to be observed in Fig. 3d further highlight the complexity of defect clusters formed during die casting. Importantly, images of the fracture surface of an average specimen produced at the melt velocity of 82 m/s (Fig. 3e–h) also show the presence of a defect of similar type. The main difference was that it was much smaller. The microstructural differences between Fig. 3a–d and e–h also suggest that strain localization during testing is expected to be far more severe in the samples produced at 26 m/s than at 82 m/s.

Examinations were then made of the fracture surfaces of specimens of Alloy 2 that had been produced at a velocity of 26 m/s, for three different samples, which had

similar tensile properties. Images are shown in Figs. 4–6, and large, characteristic defects with significantly different origins are observed. Although the defects ranged in size, shape, and type, the tensile properties of the three samples were virtually identical. In some cases, the defects were more homogeneously distributed than others (e.g., compare Figs. 5 and 6). However, their *actual* effects on tensile properties were nevertheless similar.

Weibull distributions were then used to examine the accumulated tensile data. The Weibull modulus (m) and position parameter (σ_o) values, as they relate to tensile strength for Alloys 1–3, are presented in Table 7a. The Weibull modulus (m) and E_{fo} values as they relate to elongation at failure for Alloys 1–3 are presented in Table 7b. The results suggest that samples produced at 26 m/s were inferior to those produced at 82 m/s. Respective distributions are presented in Fig. 7, for tensile strength only. For specimens produced with a melt velocity at the gate of 26 m/s, it is clear from Table 7a and Fig. 7a that the alloys could be ranked in order of Alloy 2 > Alloy 3 > Alloy 1. This primarily reflects differences in one or both of position parameter and Weibull modulus. Table 7a suggests this to also be the case for samples produced at 82 m/s, although the relative differences in

position parameter are much less such that the probability of failure curves effectively overlap (Fig. 7b). For tensile strength in Alloy 3, m is more than doubled when going from the lower melt velocity to the higher one, whereas for Alloy 1, the increase is less. Although all alloys benefit from the higher melt velocity, Alloy 3, which contained higher Zn levels, benefits most. Additionally, despite the almost identical results of m for Alloys 1 and 2 at 26 m/s,

the differences between these two when produced at 82 m/s are more significant. Differences are also pronounced in comparisons of the Weibull distribution for elongation at the different melt velocities (Table 7b). Alloy 2 displays the same general trends as Alloy 1, where at 82 m/s the Weibull modulus is lower, and the position parameter (E_{f0}) is greater than for 26 m/s. For Alloy 3, both the Weibull modulus and the position parameter (E_{f0}) are greater for the samples produced at 82 m/s.

The consequences of these observations of Weibull modulus and position parameter are that even though the values of elongation are greater in all samples tested in the 82 m/s condition, the *distribution* of flaw sizes appears likely to be increased simply because a greater proportion of samples were of higher relative quality. As may be appreciated, tensile strength does not need to change much to result in a more significant improvement in elongation. In these cases, therefore, the Weibull modulus as well as the values of the position parameters (σ_o and E_{f0}) are also very important measures of quality.

Despite the differences due to composition that could be identified using the Weibull statistics in Tables 7a and 7b, such variations in chemistry within the compositional specification would of course be considered to be normal during production, where the metal composition may vary continually within the specification. To reduce these differences, it is not uncommon to find that diecasters will specify a tighter composition range as a means to eliminate variability. The results presented also clearly show that variability is reduced and quality improved when a higher melt velocity is employed.

Use of the Ludwik–Hollomon Equation

Further investigation of Alloys 1–3 was conducted using the techniques based on Eqs. 13–16. Values of *K* and *n* defined by Eq. 13 were determined for each of the alloys, at each velocity (i.e., the 25 samples for each alloy of the two melt velocities tested). Values of *n* were determined by first converting all tensile data to true stress and true strain values. All results for both melt velocities (150 tensile tests in total) were then used to form a portion of the average true stress–true strain curve for the alloy specification (Fig. 8). Values of *n* were then determined from the slope of the log–log plot of the line of best fit for each data set, that is, (a) 26 m/s, (b) 82 m/s, and (c) both velocities combined. The results are presented in Table 8.

Figure 9 shows the corresponding combined quality chart describing the alloy, based on the *n* value of 0.259 and the *K* value of 883 (Table 8). Points corresponding to values of *q* between 0.01 and 1 on the true stress—true strain flow curve are marked. These represent theoretical quality levels of 1%–100%. As well as describing the behavior of the Al–Si–Cu alloy, Fig. 9 also describes reasonably well the combined results from other specimen geometries, literature values for alloy test bars, and samples machined from castings,^[28–33] where converted to true stress and true strain values.

By then solving Eq. 16 for the value of strain hardening exponent *n*, a relationship between the strain outside of the defect (i.e., true plastic strain) and the strain inside the defect may be related to the fraction of features, which have an *equivalent* effect to defects present on the fracture surface. That is, it takes into account that defects have an extraordinarily complex interrelationship and normalizes it.

In Fig. 9, the equivalent fraction of defects may be examined against the spread of data present. This can be easily done by following the procedure outlined in Fig. 10.

For the samples produced at 26 m/s, the proportional spread of equivalent defects (f) present on the fracture surface ranges from around 0.32–0.44. For the samples produced at 82 m/s, these values range from 0.22 to 0.34. Although these numbers generated using Eq. 14 appear large, as pointed out by Sigworth,^[17] the defects present on the fracture surface may be of the order of three to 20 times the volume fraction of porosity present in the alloy (normally around 2% for HPDCs). Examination of Figs. 3–6 agrees with this concept and suggests that most of the fracture surface is actually part of a complex, interrelated defect structure. In addition to porosity, oxides, and Fe-bearing particles, other microstructural features such as Cu-bearing intermetallics, coarse silicon plates, heterogeneous grain sizes arising from pre-solidified grains,^[35] and reduced strength aluminum grains are also likely to be contributing to the defect equivalence. Additionally, the skin of an HPDC has tensile properties higher than the average, meaning the weaker, interior material occupies a relatively large proportion of the cross-sectional area and therefore will also play an important role in strain

localization leading to failure. In the current testing, the “skin” layer is 400–500 μm thick, and therefore accounts for approximately 1/3 of the cross-sectional area.

The chart shown in Fig. 10 permits tensile properties from any casting made from a corresponding alloy designation such as A380 alloy to be evaluated against this common baseline. What is also interesting to consider from these derivations of n and K is their relative magnitude, and the scope for improvement in the alloy. In particular, it is interesting to note that Al–Si–Cu die casting alloy typically reaches less than 20% of its relative quality potential (i.e., $q < 0.2$). If straining was not limited by defects, necking would only begin at a true stress value of 622 MPa and a true strain value (where $\varepsilon = n$) of ~ 0.26 . This would correspond to an engineering stress of 480 MPa and engineering strain of almost 30%. According to Eq. 1, this would correspond to a theoretical maximum Q value of close to 700.

Effect of Degassing

To further test these procedures and to examine one possible way to influence casting quality, an additional set of experiments were conducted with and without rotary degassing. Alloy 4 from Table 3 was manufactured at a melt velocity of

Fig. 9 Quality indices (q) plotted along the flow curve determined for the Al–Si–Cu alloy. Area fraction equivalent defects are plotted on the second Y axis, determined by solving Eq. 16 for the value of strain hardening exponent, n , shown. Symbols are the same as for Fig. 8

Fig. 10 Combined quality chart for the Al-Si-Cu alloy, derived from Fig. 9. The equivalent defect fraction (f) is shown on the second y-axis. The steps are as follows: (1) Convert engineering stress and strain for the UTS and elongation at failure to true stress and true strain. (2) The experimental value of true stress and true strain at failure is plotted on the chart (e.g., square marker). A line is drawn vertically to the line describing equivalent defect fraction, and then across to the right hand axis. In this case, the part tested would have a value of $q \approx 0.15$, and an equivalent fraction of defects present on the fracture surface of 0.23

Source: From Die Casting Engineer,^[34] © 2011, NADCA.

82 m/s from recycled runners, biscuits, and reject samples used for making Alloys 1–3. It was expected that larger proportions of oxides and other defects would simply produce a greater spread in the results and would therefore produce a quantifiable comparison. Batches of samples with or without degassing were prepared. The results of the analysis are shown in Figs. 11 and 12, following the same procedures used for derivation of Figs. 8–10.

On examination, surprisingly, it would seem that there was little or no benefit in rotary degassing of the molten metal as there is little change in the data. This tends to suggest that hydrogen did not have an adverse effect in the current sample geometry. It seems reasonable to suggest that

hydrogen porosity does not manifest until higher quantities are reached, when under the pressures encountered during HPDC. The only significant change from degassing was in the frequency of oxide flakes of the type seen in Figs. 4 and 6 appearing on the fracture surfaces of test bars, which resulted in the combined lowest four values in Figs. 11 and 12.

APPLICATION OF METHODS BASED ON THE LUDWIK–HOLLOMON EQUATION TO INDUSTRIALLY PRODUCED HPDCS

In this part of the study, 20 different Al-Si-Cu test alloys conforming to the (JIS) ADC12 specification (Al-(9.6–12)Si-(1.3max)Fe-(1.5–3.5)Cu-(0.5max)Mn-(0.3max)Mg-(0.5max)Ni-(1.0max)Zn-(0.3max)Sn) were examined. Of these, Alloys 3–20 also corresponded to alloy AlSi9Cu3(Fe)(Zn), discussed in the previous section. Five samples were tested for each alloy. The composition of all 20 alloys produced is provided in Table 9 and it will be seen that principal variations existed in Fe, Cu, Mn, Mg, and Zn content.

For the industrially produced castings, each was of a different design, weighed between 2 and 40 kg, and was made from ADC12 specification die casting alloy. Seven different casting designs (oil pan, differential housings, transmission housing, small engine block, large engine block), each from different foundries and world regions, were tested. The tensile specimen dimensions were different for each casting type, but conformed either to Australian Standard AS1391, or to manufacturer internal standards. For some castings, tensile samples were taken from thin wall sections approximately 5 mm thick,

whereas others were taken from the center of very thick sections of the largest castings (e.g., from the engine bearing journals >25 mm thick). These sections therefore embodied the coarsest microstructure and highest porosity content. Irrespective of the tensile sample dimensions, all specimens tested were considered to be comparable. One hundred specimens were tested for the as-cast test bars,

and 78 specimens were tested for the industrially produced castings. Of these 78 samples machined from industrially produced castings, three broke at the 0.2% proof stress and one broke below this value.

An investigation of quality was conducted using the same methodology detailed above. Values of n and K from Eq. 13 were determined from the experimental data (for as-cast test bars and those machined from castings). The tensile data were converted to their respective true stress and true strain. Values of n were then determined from the slope of the log–log plot of the line of best fit for each data set. The values of n were then substituted back into Eq. 13 for each data point, so as to generate values of strength coefficient, K for all 0.2% proof stress and tensile strength values. These were averaged, and the results used to generate both the model flow curve, and defect equivalence curves.

The results for the 20 Al–Si–Cu alloy test bars in the as-cast condition are presented in Fig. 13, where the average flow curve expressed by Eq. 13 is plotted on a linear scale along with the 100 data points generated by testing the 20 alloys. Figure 14 shows the same data, but now plotted with the true strain on a logarithmic axis. Figure 14 also shows points of fixed quality level between $q = 0.01$ and $q = 1$, defined earlier. The defect equivalence plot (derived from Eq. 16) is also provided, and, for the data shown, the equivalent defect area (f) appearing on the fracture surface ranges from 0.18 to 0.38, which corresponds to levels of quality (q) of between ~0.07 to 0.2 (7%–20% of theoretical maximum quality).

A similar derivation was conducted for the tensile test samples machined from industrially produced castings. As in Figs. 13 and 14, Figs. 15 and 16 show the flow curve and defect equivalence curves, now with the results for the industrially produced castings included. What is most important is that despite the differences between the as-cast test bars and the industrially produced

Fig. 13 The model true stress–true strain flow curve up to the point where $\varepsilon = n$ for the Al–Si–Cu (ADC12) as-cast test bars made from Alloys 1–20 in Table 9. All experimental data are included in the plot

Source: From Die Casting Engineer,^[34] © 2011, NADCA.

castings, the difference in strain hardening exponent, n , is negligible (test bars, $n = 0.275$; castings, $n = 0.279$). Because of this, the defect equivalence plot shown in Fig. 16 is the calculated line for the test bars only and also represents the samples machined from castings. The only true difference in the model curves is related to the value of strength coefficient, K , which is 852.8 for the test bars and 767.5 for the industrially produced castings. This difference in strength coefficient, K , is related to the microstructure alone, which is far coarser on average in the industrially produced castings and has no skin layer present.

It can be seen from the results of Figs. 15 and 16 that the results of tensile testing for the industrially produced castings corresponded reasonably well to those from the test

bar castings, essentially within the band of results, which can be extrapolated from Figs. 13 and 14.

Three points are very important to focus on from this derivation. First, the equivalent defect fraction present on the fracture surface is very high in the majority of cases, and quality is low. As may be appreciated, the fraction of defects present on the fracture surface is in general many times greater than the bulk defect content.^[17]

As for Alloys 1–3 from Table 3 discussed earlier, the results of testing the combined alloys presented in Table 9 provide a prediction of what may be achieved in any casting if the quality was improved and the defect fraction present on the fracture surfaces reduced. For example, Fig. 14 shows that the equivalent defect fraction on the fracture surface for the as-cast test bars is 0.18–0.38, with corresponding

Fig. 15 Model flow curves up to the point where $\varepsilon = n$ for as-cast test bars of Al-Si-Cu (ADC12) made from Alloys 1–20 in Table 9, (solid line) and tensile samples machined from castings (dashed line). All experimental data (0.2% proof stress and tensile strength values) are included in the plot

quality levels of $\sim q = 0.07$ – 0.2 ($\sim 7\%$ – 20%). If, for example, a casting with a defect-free microstructure where $\varepsilon = n$ was produced, then its theoretical true stress and true strain values at the onset of necking would be equal to 598 MPa and $\varepsilon = 0.275$. This would correspond to engineering tensile stress and strain values of 455 MPa and $\sim 32\%$ elongation, or a Q value of approximately 680, derived from Eq. 1.

Similarly, for the samples machined from castings, the theoretical true stress and true strain values at the onset of necking are 538 MPa and $\varepsilon = 0.28$, which would be achieved with engineering stress and strain values of 407 MPa and $\sim 32\%$ elongation, respectively. This would correspond to a Q value of around 660, derived from Eq. 1.

THE INFLUENCE OF HEAT TREATMENT ON CASTING QUALITY

Samples of Al-Si-Cu Alloy 1 from Table 3 were compared in the as-cast, as-solution treated, T4, and T6 tempers. The procedures for production of these tempers are outlined elsewhere [e.g., 12–15,33,36–38]. The results of the testing were evaluated according to the procedures outlined earlier in this article.

The average mechanical properties, one standard deviation ($\sigma_{(sd)}$), high and low values, as well as $\mu - 3\sigma_{(sd)}$ are shown for the four conditions examined in Tables 10–14. For the as-solution-treated condition, when compared

to the as-cast tensile properties, there was a decrease in mean 0.2% proof stress and mean tensile strength, but a substantial increase in mean elongation at failure E_f of more than double from 3.8% to 8.2% (compare Tables 10 and 11). Subsequent aging at 25°C to the T4 temper, caused the 0.2% proof strength and tensile strength to increase, but the mean value of E_f now decreased (compare Tables 11 and 12). All tensile properties in the T4 temper were however above those recorded for the as-cast condition (Table 10). For the T6-treated samples, the 0.2% proof strength and tensile strength were raised significantly, while the value of E_f was decreased to 3.1% (Table 13).

Table 13 T6 tensile properties, high/low values, and $\mu - 3\sigma_{(sd)}$

It is interesting first to consider the value of one standard deviation ($\sigma_{(sd)}$) in E_f for the four different conditions tested. This provides a rapid evaluation of the change in the spread of data. Solution treatment (Table 11) caused the value of $\sigma_{(sd)}$ (for E_f) to be increased from 0.52 (as-cast) to 1.6. This increase in the spread of data occurred simultaneously to the increases in average, high, and low values of E_f observed. It is important to note as well that the lowest value of the as-solution-treated condition (5.1%) was still higher than the highest value of the as-cast condition (5%) despite the increase in value of $\sigma_{(sd)}$.

For the T4 temper achieved by natural aging (Table 12), the standard deviation, $\sigma_{(sd)}$ for E_f decreased from 1.6 in the as-solution-treated condition, to 1.1 in the T4 temper. This corresponded to a decrease in the mean, high and low values of E_f for the T4-treated alloy. This trend continued in the T6 temper (Table 13), where the value of $\sigma_{(sd)}$ for E_f now decreased to 0.6, simultaneously to increases in the mean, high and low values recorded.

The trends observed for the differences in $\sigma_{(sd)}$ for E_f were somewhat different for those observed for the differences in $\sigma_{(sd)}$ for tensile strength. Here, the T6 temper displayed the lowest spread in the data for tensile strength ($\sigma_{(sd)} = 8.1$, Table 13), the T4- and as-solution-treated conditions show similar, higher values ($\sigma_{(sd)} \sim 12.2$, Tables 11 and 12), and the as-cast condition had a value of $\sigma_{(sd)} = 9$ (Table 10). Although the values of $\sigma_{(sd)}$ do show a small variability for 0.2% proof stress, the differences were not significant.

Weibull Analysis

The tensile data were evaluated using Weibull statistics, and a summary of the values for Weibull modulus and position parameter for all results is provided in Table 14.

When the material was solution treated, the Weibull modulus decreased for both tensile strength and E_f . This means that in this as-solution-treated condition, the spread of results increased and hence the flaw size distribution increased. The results suggest that although all elongation results were improved, the best quality

Table 14 Values for Weibull modulus, position parameter, strain hardening exponent, and strength coefficient, for evaluating casting quality

Parameter	As-cast	As-solution treated	T4	T6
Weibull modulus m , for tensile strength, σ_{UTS}	42.3	30	37	61
Position parameter, σ_o (MPa)	355.7	332.6	391.3	438.2
Weibull modulus m , for E_f	7.9	5.9	5.6	5.5
Position parameter, E_{f0} (%)	4	8.9	5.8	3.3
Strain hardening exponent, n	0.261	0.282	0.195	0.095
Strength coefficient, K	872.1	729.2	729.1	635.8

Source: From International Journal of Metalcasting, [38] © 2011, Springer.

samples would appear to be improved *proportionately more*. For example, examining only the highest and lowest values, Tables 10 and 11 show that the lowest value of E_f for the as-cast condition was raised from 2.7% to 5.1% (1.9 $\times$) by solution treating, whereas the highest value was raised from 5% as-cast to 13% in the as-solution-treated condition (2.6 $\times$).

For the T4 and T6 tempers, the values of Weibull modulus for both tensile strength and E_f were improved following aging from the as-solution-treated condition, meaning the flaw size distribution decreased. For the fully hardened T6 temper tensile strengths, for example, m was equal to 61 and the position parameter σ_o was 438 MPa. This represents an improvement to Weibull modulus (m) above the as-cast (42.3), as-solution treated (30), and T4 (37) conditions, and hence a substantial reduction in the flaw size distribution. For E_f , the values of Weibull modulus and position parameters were decreased only slightly from as-solution treated to T4, and to T6 conditions, as summarized in Table 14.

Quality Charts and Equivalent Defect Fractions Derived from the Ludwik–Hollomon Equation

All tensile data were converted to true stress and true strain values, and the strain hardening exponent n was calculated from the slope of the log–log plot of the average stress–strain curve, based on this data. This value of n was then used to find the average strength coefficient, K , in the same manner described earlier in this article. The model flow curve was determined, and the experimental true stress–true strain data are overlaid with these model curves in Fig. 17. Values of the strain hardening exponent, n , and the strength coefficient, K , for each of the conditions are provided in Table 14.

The Solution-Treated Condition

Quality curves based on the data in Fig. 17 for the as-cast and as-solution-treated condition are compared directly in Fig. 18. These two conditions display only a small

**Fig. 17** Model flow curves derived using the Ludwik–Hollomon equation for the values of strain hardening exponent, n , and strength coefficient, K , presented in Table 14

difference in the values of strain hardening exponent n , at 0.261 and 0.282, respectively. The values of strength coefficient K do however display greater differences; the as-cast value was 872.1, but the as-solution-treated material displayed a value of 729.2. This change in strength coefficient has offset the entire flow curve downwards (Fig. 18). What is perhaps most significant was the change in relative quality, and therefore the corresponding equivalent defect fraction present on the fracture surface, determined by solving Eq. 16. In regards to quality (q) for the as-cast material, most values were between $q = 0.1$ and $q = 0.2$. For the as-solution-treated condition, the values were mostly between $q = 0.2$ and $q = 0.4$. The equivalent defect fraction present on the fracture surface derived using Eq. 16 is 0.21–0.32 for the as-cast condition; this was reduced to 0.07–0.23 for the as-solution-treated condition.

This change in the equivalent defect fraction present on the fracture surface was a particularly interesting result, because the amount of features such as porosity, Fe-bearing particles, and oxide flakes, for example, is not decreased by solution treatment. Although there is clearly the potential to increase porosity by blistering during long times or high temperatures of solution treatment, the procedures used in the current work produce little, if any, change in porosity fraction.^[12–15,39] Since it is relatively easy to characterize what has actually changed within the microstructure during solution treatment, those features which are directly influencing quality are easily understood. In summary, solution treatment causes four main changes in HPDCs that influence quality.^[39] These are as follows:

1. Fragmentation, spheroidization, and Ostwald Ripening of the Si phase.
2. Dissolution of the Cu-bearing intermetallic phases.
3. Homogenization of the aluminum grains.
4. Elimination of residual stresses.

The T4 and T6 conditions

Further analysis was conducted for the T4 and T6 conditions. Figure 19 shows the flow curves and experimental data from Figs. 17 and 18, now plotted on a quality chart, for the as-solution-treated, T4, and T6 conditions. Here, because the relative quality of the different heat-treated conditions was expected to be the same, constant quality (iso- q) lines are included, to show the entire scope of properties that may be derived via age-hardening heat treatments. As may be appreciated, varying the time and temperature of the age-hardening heat treatment for strengthening will move the range of properties within these lines. The relative quality was similar for each of the three tempers and most values fall between the iso- q values of 0.2 and 0.4. Plotting the equivalent defect fraction present on the fracture surface from Eq. 16 for the respective values of strain hardening exponent, n , in Fig. 19, reveals additional information. For the as-solution-treated condition, the equivalent defect fraction (f) was 0.07–0.23. For the T4 temper, the values of (f) were very close to the as-solution-treated conditions, at 0.06–0.22. The similarities in these results are to be expected, because it follows that the only difference between the as-solution-treated and T4 tempers is related to strengthening within the aluminum grains by very fine GP zones. Casting defects such as porosity, inclusions, or oxides, etc., may be considered to be constant. However, this trend does not continue for the T6-treated material, where the equivalent defect fraction present on the fracture surface now decreased and ranged from 0.03 to 0.09. This result was particularly interesting because the T6 temper also displayed the highest value of Weibull modulus, m , and therefore the lowest flaw size distribution. A summary of the respective equivalent defect fractions and Weibull modulus values for all conditions examined are shown in Fig. 20. Here, it is also of note that the equivalent fraction of defects present on

Fig. 19 Quality chart for heat-treated conditions (as-solution treated, T4, and T6) showing model flow curves, calculated from $\sigma = K\epsilon^n$, Eq. 13, and the equivalent defect fraction on the fracture surface (dashed lines, derived from solving $f = 1 - (e^{-\epsilon h} \epsilon_h^n / e^{-\epsilon i} \epsilon_i^n)$, Eq. 16) for the values of n shown. Fig. 20 A summary of the area fraction equivalent defects on the fracture surface (average is circles (O), with high-low ranges shown), derived from Fig. 19. The respective values of Weibull modulus, m , for tensile strength (◆) from Table 14 are shown on the second y-axis and provide a comparative measure of the flaw size distribution in the material (i.e., the lower the Weibull modulus, the greater the flaw size distribution)

Source: From International Journal of Metalcasting,^[38] © 2011, Springer.

the fracture surface does not follow the same trend as the Weibull modulus. For example, compared to the as-cast condition, the as-solution-treated material displays a greater flaw size distribution (i.e., lower value of m), but a lower defect fraction present on the fracture surface. That is, the range of defect sizes was broader, but the total defect fraction decreased. The T4-treated material displays a slightly higher value of m and a similar equivalent defect fraction to the as-solution-treated material. For the T6 samples, the flaw size distribution was reduced, and

the equivalent defect fraction was also reduced. It would therefore appear clear that the relative quality for the T6-treated material was significantly improved.

One possible contribution to the changes in relative quality for the T6 temper is derived from the earlier discussion related to the microstructural characteristics of the as-solution-treated condition. One feature identified that contributed to the equivalent defect fraction, and that was present on all fracture surfaces, is the hard Si phase. Importantly, the strength of the Si present in Al-Si

castings may only be 200–330 MPa.^[40,41] This is less than the 0.2% proof stress of the T6-treated HPDC material (351 MPa), but is between the 0.2% proof stress and tensile strength of the T4-treated material (217 and 386 MPa, respectively). Therefore, it may be suggested that as the strength of the Al grains was increased by heat treatment, such that the strength of the bulk material approached or exceeded that of the Si particles, the Si phase may actually have had less relative influence on the fracture process. This follows because fracture and de-bonding of the hard Si phase occurs on the assumption that the matrix Al surrounding the Si particles undergoes deformation in the crack tip plastic zone, leading to the accumulation of dislocations at the Si particles and their subsequent fracture. As may be appreciated, the plastic zone in the crack tip of the T6 material is expected to be smaller than that present in the more ductile T4 or as-solution-treated material, influencing crack propagation.^[41] Another reason for both the low ranges of equivalent defect fractions and high Weibull modulus values for the T6 condition follows on from the observation that no large oxide flake defects were observed on the fracture surfaces of these samples, a feature that was particularly prevalent in the lowest results for T4-treated material.^[38]

SUMMARY AND CONCLUSIONS

Here, it is important to comment on the different measures of what constitutes casting quality, and the various ways in which it can be evaluated. The techniques used in this current work all provide excellent information regarding casting quality and all can clearly identify what constitutes a “better” casting. The methods may be considered to be robust, in that they can represent different casting geometries from different sources, for a single alloy specification, and allow them to be compared against a unified measure of casting quality. An even more powerful tool for analysis of HPDCs is to use these different methods for complimentary quality analysis.

In the current work, it has been demonstrated conclusively that casting quality may be improved by increasing the melt velocity at the gate, which has the effect of decreasing the size of defect clusters appearing on the fracture surfaces. Casting quality is also influenced by alloy composition, but this effect is complex, and further investigation regarding the actual basis of the differences may be warranted. Rotary degassing to remove hydrogen and oxides from the melt does not influence quality in the same way as melt velocity at the gate.

Defects with substantially different size, shape, and distribution may have similar or equivalent effects on the tensile failure. In HPDCs, defects are usually present in complex clusters where many different features have an interrelationship, and, as a result, these clusters may behave as singular defects with a substantially different size.

There is a hierarchy of defect types that appear to influence tensile properties that have been identified. Clearly, size or scale and part geometry is also critical. The hierarchy identified so far utilizing this technique (note: not exhaustive) has been given as follows:

1. Massive porosity
2. Large oxides
3. Foamy porosity clusters
4. Small oxides
5. Fe bearing particles
6. Homogeneity of microstructure (scale, composition, and strength)
7. Si morphology
8. Distribution of Cu
9. Small, isolated porosity
10. Hydrogen content

The charts that have been derived by the technique used here are able to provide a method by which to compare casting quality from any HPDC manufactured from Al–Si–Cu alloy. In addition, the predicted maximum values for tensile mechanical properties are surprisingly high compared to the levels, which are currently achieved in foundry practice. As mentioned, most HPDCs made from Al–Si–Cu alloys in the as-cast state are currently reaching *less than 20% of their potential*. This means that large advances in quality and hence mechanical performance of HPDCs are available. The predictions of maximum theoretical properties should be viewed as a target of what the future should hold in HPDC through improvements in process development and material quality.

Finally, it is important to point out that it is not necessary to make a perfect, defect-free casting to attain major improvements in production castings. If, for example, the value of quality q , was raised to 0.5 (50%), corresponding to a defect fraction present on the fracture surfaces of around 5%, then the engineering tensile strength in an alloy like ADC12 (AlSi9Cu3(Fe)(Zn)) would be ~430 MPa with an elongation value of 15% (true stress and strain = 495 MPa and ~0.14, respectively). As may be appreciated, this achievement would reflect a paradigm shift in the potential utilization of conventional, as-cast HPDC alloy products.

Abstract

One of the steps of the heat treatment process of age-hardenable aluminum alloys is the quenching process in which the alloy is cooled from the solutionizing temperature. The objective is to quench sufficiently fast to avoid undesirable concentration of alloying elements in the defect and grain boundary structure while at the same time not quenching faster than necessary to minimize residual stresses, which may lead to excessive distortion, or cracking. Various studies have been conducted to predict the relative quench rate sensitivity to yield different properties for age-hardenable alloys. Of these different predictive methods, the one that showed the more realistic results is quench factor analysis (QFA) since it involves a correlation of the cooling curve (time–temperature curve) of the cooling process throughout the quenching cycle for the desired cross-section size of interest with a C-curve (Time–Temperature–Property Curve) for the specific alloy of interest. The QFA numerical procedure has evolved since its original introduction. A review of the basic assumptions of the classical QFA model will be provided here, which will include discussion of the various improvements to the classical model that have been proposed over the intervening years since its introduction.

INTRODUCTION

When heat treatable aluminum alloys are solutionized at elevated temperatures, typically above 400°C, alloying elements are dissolved in the aluminum lattice structure of the solid solution and the objective is to maximize the concentration of hardening elements including copper, zinc, magnesium, and silicon in the solid solution.^[1] Phase equilibria, the concentration and rate of dissolution of these elements in the solid solution increase with increasing temperature.

After solutionizing, the aluminum alloy is cooled. If the cooling process is too slow, the alloying elements will diffuse through the solid solution and form second phases as well as concentrate at grain boundaries, large voids, undissolved particles, or other “defect” locations. The diffusion process is slower for some alloys than others, thus permitting slower cooling rates during quenching. For optimal properties, it is desirable to retard this diffusion process and maintain the alloying elements in solid solution. For quench-hardenable wrought alloys: 2xxx, 6xxx, and 7xxx and heat-treatable casting alloys, the quenching process accomplishes this. The objective is to quench sufficiently fast to avoid the undesirable concentration of the alloying elements in the defect and grain boundary structure while

at the same time not quenching faster than necessary to minimize residual stresses which may lead to excessive distortion, or cracking.^[2,3] After quenching, the aluminum alloy is then aged. During the aging process, hardening elements precipitate in localized areas, which significantly increases the strength of the part.

An illustration of this effect of cooling rates after solutionizing on the properties after aging is the effect of cooling rates on corrosion of AA2024-T4 (see Table 1 for composition and Table 2 for summary of terminology related to tempering treatment), where the critical temperature range and time (s) for the transition of pitting to intergranular corrosion is shown by the so-called TTP (Time-Temperature-Property) or C-curve in Fig. 1.^[4] In this case, the C-curve for 2024-T4 is used to show the change in corrosion behavior by correlating the critical temperature range where precipitation was fastest. Figure 1 shows that increased intergranular corrosion for 2024-T4 will be favored if cooling rates are excessively slow during quenching. Similar behavior can be shown for other aluminum alloys.^[5] Therefore, it is important that cooling rates during quenching be sufficiently fast to avoid this undesirable behavior.

Fink and Willey in 1948 performed an extensive study on the effects of quenching on the strength of 7075-T6^[5]

using isothermal quenching techniques. This was done by constructing C-curves shown in Fig. 2, which are plots of times required to precipitate sufficient alloy content to change the strength by a certain amount. The “critical temperature range” corresponding to the “nose” of the C-curve, which is that temperature range that provided the highest precipitation rates, was identified.^[4]

The characteristic C-shapes of the TTP curves such as the curves shown for 7075 in Fig. 2 indicate that long

times are typically required for a given amount of solute precipitation at elevated temperatures in the range of 370°C–425°C, because the amount of solute supersaturation is low, and therefore, the thermodynamic driving force for precipitate formation is low. At temperatures in the range of 275°C–350°C, the undercooling and thermodynamic driving force are high, and the time required to achieve a particular amount of solute precipitation is relatively low—typically only a few seconds in precipitation-hardenable aluminum alloys. In this temperature range, the diffusion coefficients for the solute species are reasonably high, and precipitates can nucleate and grow in short times. As discussed previously, nucleation and heterogeneous precipitation usually occur first along grain boundaries because less lattice strain is necessary therein and

Table 2 Tempering designations for aluminum alloys

Temper designation	Tempering process
T4	Solution heat treated and naturally aged.
T6	Solution heat treated and artificially aged.
T7	Solution heat treated and stabilized (overaged).
T73	Solution heat treated and then artificially overaged in order to achieve reasonable stress corrosion resistance.
T76	Solution heat treated and then artificially overaged in order to achieve a good exfoliation corrosion resistance.
T8	Solution heat treated, cold-worked, and artificially aged.

^aR. Howard, N. Bogh, D.S. MacKenzie, “Heat Treating Processes and Equipment” in Handbook of Aluminum—Volume 1, Eds. George E. Totten and D. Scott MacKenzie, 2003, CRC Press, Boca Raton, FL, p. 881–970. Specific heat treatment processes (time and temperature) for each wrought, forged, or/and extruded alloy are described in AMS 2770.

Fig. 1 C-curve indicating cooling rate dependent corrosion attack on 2024-T4 sheet

Fig. 2 C-curves illustrating the effect of alloy precipitation on tensile strength for 7075-T6 generated by Fink and Willey

diffusion rates are higher than within grains. At still lower temperatures, below 200°C, the time required for a given amount of precipitation increases to hundreds or thousands of seconds because solute diffusion coefficients are low. The thermodynamic potential for precipitation is high because of the high degree of solute supersaturation but the rate of precipitate formation is low because of the inability of atoms to diffuse and form the precipitating species.^[6]

It is important to note that although critical solute temperature may be identified from a C-curve for an alloy, for example 340°C for 7075-T73, the specific C-curve obtained will vary depending on the property being measured as illustrated in Fig. 3.^[7]

Fig. 3 C-curves for proof stress, Vickers hardness (HV20), and electrical conductivity (% IACS—International Annealed Copper Standard) for 7075-T73

Various studies were conducted after Fink and Willey's work to determine the relative quench rate sensitivity to yield different properties for various alloys. Figure 4 illustrates the effect of cooling rate on tensile strength for different aluminum alloys and tempers.^[4] The "average cooling rate" has been traditionally defined to be the time (seconds, s) to cool from 400°C to 290°C, which will yield an "average" cooling rate in °C/s. This is the range commonly referred to and applied by the aluminum heat-treating industry. The maximum attainable strength properties are dependent on the average cooling rate. Generally, faster cooling rates provide greater strengths up to a limit.

The traditional approach for modeling quench sensitivity (which refers to the amount age hardening response is reduced by slow quench cooling) to quantitatively correlate quenching cooling rate with mechanical properties of aluminum alloys presumes a linear, well-behaved cooling process between 400°C and 290°C. However, this is seldom the case, and therefore, the classical method of determining the average cooling rate of aluminum alloys can provide only an approximation of the effect of a quenching process on properties and, in fact, may fail when the quenching process is nonlinear such as an interrupted or delayed quenching process. Therefore, it is desirable to utilize an alternative process, **quench factor analysis (QFA)**, that correlates actual cooling pathway by using a cooling curve (time–temperature curve) of the actual cooling process throughout the quenching cycle for the quenching process and cross-section size being used with a C-curve (TTP curve) for the specific alloy of interest.^[8,9]

QFA is now used routinely by many researchers in the aluminum thermal processing industry. Staley et al., one of the pioneers in developing the QFA model and

Fig. 4 Tensile strength as a function of average cooling rate

its application, has provided numerous references on experimental model validation.^[9–11] Bates successfully used QFA to model strength for AA356^[12] and 7075 and 2024.^[6] Rometsch et al. have evaluated QFA model predictions against published data and have recommended various model refinements.^[13] Liu et al. obtained excellent results using QFA to predict hardness of a 7055 aluminum alloy.^[14] Mudawar and coworkers have used QFA to spray quench 2024-T6 aluminum extrusions and have experimentally validated their results.^[15–17] Flynn and Robinson obtained excellent results using QFA to model properties of a 7010 aluminum alloy.^[18] Kim used QFA to study the properties obtain by spray quenching of aluminum alloys.^[19] In addition to aluminum alloys, QFA has been successfully applied to predict as-quenched hardness for AISI 1045 and 4140 steel alloys^[19] and 5140 steel^[20] (Table 3).

QFA has been embraced by industry in an attempt to capitalize on the beneficial properties of aluminum alloys. Specifically, Flynn and Robinson^[18] cite the use of 7000 series Al-Zn-Mg-Cu alloys in the aerospace and

automotive industries in structural applications due to high strength-to-weight ratio as well as low specific gravity. The development and application of 7010 series Zirconium containing modifications of the 7000 series alloys by aerospace part manufacturers such as Metis Aerospace and large-scale aluminum manufacturers like Alcan International improved stress corrosion cracking resistance as well as fracture toughness and strength.

The QFA was introduced well over 40 years ago.^[4] The original model has undergone considerable evolution and improvement. The objective of this paper is to review the basic assumptions of the classical model and to highlight its more significant potential deficiencies. This discussion will be followed by a summary of the various improvements to the classical QFA model that has been proposed over the intervening years since its introduction.

DISCUSSION

Calculation of Quench Factors from Precipitation Kinetic Data

Avrami used isothermal kinetics to study transformation during continuous cooling processes.^[21,22] The Avrami equation, commonly designated as the Johnson–Mehl–Avrami–Kolmogorov (JMAK) equation, is typically used to calculate a property evolution as a function of time $F(t)$ and takes the following form:

$$F(t) = 1 - \exp[-Kt^n]$$
 (1)

where
 t = time (s)
 K = temperature-dependent rate constant (s^{-1})
 n = 1–4 (Avrami exponent)

The Avrami Eq. 1 may be written in the form of volume fraction developed V_f at time t :

$$F(t) = V_f = (1 - X) \quad (2)$$

where

X = the volume fraction transformed

The volume fraction V_f may be written in the form of a property ρ ,

$$V_f = \frac{\rho_i - \rho_f}{\rho_f - \rho_i} \quad (3)$$

where

ρ_i = property after time t

ρ_i = initial value of the property being measured

ρ_f = final value of the property being measured

The properties of aluminum alloys are dependent on the amount of alloy precipitation that occurs during cooling, regardless of the cooling pathway in subsequent treatment. The Avrami equation for isothermal precipitation kinetics is^[4] as follows:

$$\zeta = 1 - \exp\left[\frac{-t}{k}\right] \quad (4)$$

where

ζ = fraction of precipitation that has occurred in time t during the quench

k = temperature-independent constant (s)

The value of k depends on the degree of supersaturation and the rate of diffusion, and it is estimated from the following equation developed by Evancho and Staley:^[4]

$$k = \frac{C_T}{k_1} = k_2 \cdot \exp\left[\frac{k_3 \cdot k_4^2}{R \cdot T \cdot (k_4 - T)^2}\right] \cdot \exp\frac{k_5}{RT} \quad (5)$$

where

C_T = critical time (s) required to precipitate a constant fraction (the equation of the C-curve)

k_1 = constant that equals the natural logarithm of the fraction untransformed (1-fraction defined by the C-curve); if 0.5% is untransformed, then $k_1 = -\ln(\sigma/\sigma_{\max}) = -0.005013$

k_2 = constant related to the reciprocal of the number of nucleation sites (s)

k_3 = constant related to the energy required to form a nucleus (J/mol)

k_4 = constant related to the solvus temperature (K)

k_5 Δ constant related to the activation energy for diffusion, (J/mol)

R = ideal gas constant = 8.3143 J.K⁻¹.mol⁻¹

T = temperature (K)

Numerical values of each of the constants $k_1, k_2, \dots, k_5$ define the C-curve for the alloy composition and temper condition. Values of $k_1, k_2, \dots, k_5$ for selected alloys for prediction of yield strength that have reported to date are provided in Table 4.^[23] Additional C-curves for alloys not shown in Table 4 that have been published, but whose k -values have not, are shown in Reference.^[24]

The earliest references to deriving k values reported using multiple linear regression analysis to fit the k_2 to k_5 values to the C_T equation and repeat the iterations until minimum computational error is obtained.^[4] Using this method, k values are readily attainable from published C-curves.^[4,25,26] However, Shuey et al.^[25] and Tiryakioğlu^[26] have studied this approach and found that although C-curves can indeed be fitted, their physical meaning was

^a k_1 is a unitless value which corresponds to the unprecipitated fraction. For this analysis, it is usually 0.995 and $\ln 0.995$ is -0.00501.

often questionable. Instead, they recommended, when possible, that the number of variables (k -values) being fitted should be reduced by using independently reported data such as solvus temperature, solute diffusivity, and enthalpy of precipitation.

From these relationships, it is possible to redefine the equation for the amount of solute precipitated during the quench, which is called the “Quench Factor” and is typically designated by “ Q .” Cahn showed that transformations that nucleate heterogeneously, such as aluminum alloys, obey the rule of additivity, which states that reactions are additive. Therefore, transformation kinetics for non-isothermal conditions, such as those that would be present during a typical quenching process may be described by:^[27]

$$Q = \int_{t_0}^{t_f} \frac{1}{C_T} dt \quad (6)$$

where

Q = measure of the amount transformed (“quench factor”)

C_T = critical time (s) from the C-curve and is calculated from Eq. 5

t = time from the cooling curve (s)

t_0 = time at the start of the quench (s)

t_f = time at the finish of the quench (s)

When $Q = 1$, the fraction transformed equals the fraction represented by the C-curve.

The Rule of Additivity permits discretization of the temperature–time curve discretized into a series of isothermal steps as described by Evancho and Staley.^[4] For each step, the volume fraction of the new phase that is formed during this time step is calculated by isothermal kinetics (Avrami Equation). This is shown in Fig. 5, where the quench factor Q is obtained by combining the cooling curve for the quenching process with the C-curve and the value for Q is obtained by:^[4,19]

$$Q = \frac{\Delta t_1}{C_{T1}} + \frac{\Delta t_2}{C_{T2}} + \dots + \frac{\Delta t_{n-1}}{C_{Tn-1}} = \sum_1^{n-1} \frac{\Delta t_i}{C_{Ti}} \quad (7)$$

In the original classical approach, properties were predicted from the quench factor by:^[4,6]

$$\sigma_y = \sigma_{\max} e^{k_1 Q} \quad (8)$$

where

σ_y = predicted yield strength (MPa)

$\sigma_{\max}$ = yield strength after an infinite quench (and aging cycle) (MPa)

e = base of the natural logarithm

$k_1 = -\ln(0.995) = -0.00501$

Q = quench factor

The relationship between quench factor and yield strength for 7075-T73 is shown in Fig. 6.^[6]

In their 1974 paper, Evancho and Staley showed that from the Avrami equation, the attainable strength is a function of the amount of solute remaining in solution after the quench and is related to k_1 as follows:^[4]

$$k_1 = -\ln \left[\frac{\sigma_x - \sigma_{\min}}{\sigma_{\max} - \sigma_{\min}} \right] \quad (9)$$

where

$\sigma_x = 0.995 \sigma_{\max}$

$\sigma_{\max}$ = maximum level of σ

$\sigma_{\min}$ = minimum level of σ

When Evancho and Staley analyzed 7075-T6 and 2024-T4 interrupted quenching data previously published by Fink and Willey, they obtained a linear correlation for $\log(\sigma/\sigma_{\min})$ versus isothermal holding time and the slope was equal to 1. Based on this observation, they concluded that the Avrami exponent was equal to 1 ($n = 1$). Therefore, Evancho and Staley set $\sigma_{\min} = 0$ in Eq. 9 to facilitate the use of Cahn’s model to predict the extent of transformation in their early work.^[4,18] In their

Fig. 5 Determination of quench factor Q by the combination of a quenchant cooling curve and a C-curve

Fig. 6 Yield strength of aluminum 7075-T73 as a function of quench factor of the material

1974 paper, Staley and Evancho further noted that the simplified equation for k_1 could be used for high-strength alloys because $\sigma_{\min} \ll \sigma_{\max}$.^[4] Staley et al. also subsequently stated that this assumption for $\sigma_{\min}$ was made because the strength of aluminum alloys held for infinitely long times below the solvus temperature would be zero.^[10] Furthermore, this simplification was validated by the excellent fit that the simplified value for k_1 provided for C-curve data developed for 7075-T6 and 2024-T4.^[4] For many industrial applications, this provides adequate results when the loss in properties is less than 10%.^[18] However, Swartzendruber et al. subsequently recommended that Eq. 9 was necessary to minimize predictive errors.^[28]

Schwartzendruber et al. also determined k -values for C-curves developed based on different mechanical

properties, which are shown in Table 5. These data show that in addition to the use of Eq. 9, it is necessary to obtain the correct C-curves for the property of interest if reliable predictions are to be made. It is not correct to use one C-curve and simply vary the property ($\sigma_{\max}$ and $\sigma_{\min}$) using the same quench factor (Q) to obtain the most reliable prediction with minimum error.

From these equations, a number of observations regarding the quenching process showing the power of QFA in quench process design and analysis are described as follows:

1. Low values of Q are associated with high quench rates, minimum precipitation during cooling, and high yield strengths.

Table 5 C—Curve parameters for aluminum alloy 2219-T87*^{b,d}

^a k_1 is a unitless value which corresponds to the unprecipitated fraction. For this analysis, it is usually 0.995 and $\ln 0.995$ is −0.00501. ^bT-87* indicates that a 10% stretch was applied prior to thermomechanical treatment. Usually, for T-87, a 5% or 7% stretch is applied. ^c% IACS is used to describe % of conductivity relative to copper, and IACS indicates “International Annealed Copper Standard.” ^dThese k -values were determined from 2219 plate with a thickness of 0.625 cm (1/4 in), width 1.22 m (4 ft), and length of 1.83 m (6 ft). Before thermal treatment, a 0.6 m wide sample was removed from each edge and the middle for analysis. The remaining 0.625 cm thick plate was cut into 2.5 cm wide $\times$ 17 cm long test bars. The test bars were solutionized at 535°C for 75 min, and then transferred directly to a salt bath and heated from 2 to 3600 s at which time the test bar was water quenched, mechanical stretch to 5%, and aged for 16 h at 172°C.

2. Conversely, higher Q values are obtained with slower quench rates and are associated with lower strength values.
3. An alloy with a low rate of precipitation will produce a lower quench factor Q than an alloy with a high precipitation rate at the same cooling rate.
4. Quench factors calculated for different alloys might be different even if similar section sizes are cooled in the same quenchant, because quench factors take into account individual alloy precipitation kinetics by means of the equation describing the C-curve (C_T function) for each alloy.
5. Solute elements are precipitated during cooling from the solution treating temperature at “high” Q values. As a consequence, an improperly quenched alloy may not properly harden during aging, and it may be susceptible to intergranular corrosion, stress corrosion, or exfoliation.

Staley et al. subsequently found that $\sigma_{\min}$ varied strongly with the isothermal hold temperature. Therefore, an alternative property predictive equation was developed, which includes the temperature dependence of $\sigma_{\min}$ and is therefore more appropriate for use with continuous cooling processes as $\Delta t_i \rightarrow 0$, the equation for $d\sigma/dt$ becomes^[10]

$$\frac{d\sigma}{dt} = -\frac{1}{C_T} [\sigma - \sigma_{\min}(T)] \quad (10)$$

where

C_T is defined in Eq. 5

σ = strength after time t at temperature T

FUTURE WORK

Property Predictions

Recently, improvements over the initial approach reported by Evancho and Staley^[4] have extended the ability of QFA to predict post-quenched physical properties of wrought and cast aluminum alloys. The classical approach was limited to the ability to predict properties when the maximum loss did not exceed 10%–15%.^[18]

As discussed previously, the classical QFA approach was based on the use of isothermal kinetics to model transformations occurring under non-isothermal conditions. However, it has been shown that Cahn's additivity model is not adequate for modeling all quench paths used for the thermal processing of aluminum alloys. The reason is that diffusion-controlled growth following site saturation and dissolution of single particles during reheating both satisfy the additivity condition used to model the isokinetic reaction if long soft impingement effects can be ignored. The process becomes even more complicated if nucleation and growth processes are considered as well.^[29] This means

that the precipitation rate is a function of the amount of solute remaining in the matrix and therefore the amount of precipitation that can occur at that temperature. Cahn's model assumes that the precipitation rate is dependent only on the temperature and the amount transformed.^[18] This problem was addressed by Staley and Tiryakioğlu using a non-isokinetic model.^[30]

Cahn's model assumes that $\sigma_{\min} = 0$, which means that QFA predicts properties in the upper portion of the C-curve approaching 0 as the fraction of the maximum property value decreases. This limitation was addressed with a non-isokinetic model where $\sigma_{\min}$ is related to the slope of the solvus.^[18] This model is based on the assumption that strength and solute content exhibit a linear relationship and that the ability of an alloy to produce properties decreases incrementally ($\Delta\sigma_j$) over each individual time interval (Δt_j).

$$\Delta\sigma_j = \left(\sigma_{j-1} - \sigma_{\min}(T_j) \right) \cdot \left[1 - \exp \left[-\frac{\Delta t_j}{C_i(T)} \right] \right] \quad (11)$$

where

$\Delta\sigma_j$ = loss of incremental strengthening capability (MPa)

Δt_j = time interval (s)

$C_i(T)$ = critical time (s)

$\sigma_{\min}(T)$ = minimum $Rp_{0.2}$ (MPa)

σ_{j-1} = Eq. 12 (MPa)

$$\sigma_{j-1} = \sigma_{\max}(T_j) = \sigma_{\max} - \sum_{n=1}^{n=j-1} \Delta\sigma_n \quad (12)$$

The $Rp_{0.2}$, strength after quenching (σ), is defined as $\sigma_{\max}$ —sum of incremental losses as shown in Eq. 13:^[18]

$$\sigma = \sigma_{\max} - \sum_{j=1}^{j=n} \Delta\sigma_j \quad (13)$$

Since it is assumed that $Rp_{0.2}$ and the solute content exhibit a linear relationship, the $Rp_{0.2}$ of the alloy will be equivalent to the intrinsic annealed $Rp_{0.2}$ of the alloy plus a strength factor related to the solute content (s):

$$\sigma = \sigma_{\text{int}} + A \cdot s \quad (14)$$

T_{int} is the temperature below which the driving force for precipitation is insufficient, and the solute content at this temperature is s_{int} and is related to $\sigma_{\min}$ by^[18]

$$\sigma_{\min} = \sigma_{\text{int}} + A \cdot (s - s_{\text{int}}) \quad (15)$$

Equation 16 defines the change in solubility of the solute (s) with respect to temperature (T):

$$s = \exp\left(-\frac{\Delta H_0}{R \cdot T}\right) \cdot \exp\left(\frac{\Delta S}{R}\right) \quad (16)$$

where

ΔH_0 = standard enthalpy (J/mol)

ΔS = standard entropy (J/mol K)

R = universal gas constant (J/mol K)

T = temperature K

Flynn and Robinson^[18] combined Eqs. 15 and 16 to derive Eq. 17 as follows:

$$\sigma_{\min} = \sigma_{\text{int}} + k_6 \cdot \left[\exp\left(-\frac{k_7}{T}\right) - \exp\left(-\frac{k_7}{T_{\text{int}}}\right) \right] \quad (17)$$

where k_6 and k_7 are constants.

If values for $\sigma_{\min}$ are obtained experimentally for $Rp_{0.2}$ from different isothermal hold temperatures followed by cold water quenching and then aging, it is then possible to plot $\sigma_{\min}$ versus temperature as shown in Fig. 7.^[18] The locus of the curve for this data follows the same trend as the equilibrium diagram. From these data, it is possible to obtain values for k_6 and k_7 in addition to T_{int} . Then with these data, it is possible to calculate $\sigma_{\min}$ at each incremental time step, Δt_j . If these relationships for $\sigma_{\min}$ as a function of temperature are associated with Eq. 5, then k_1 is not used since the C-curve no longer represents an isothermal process.

The application of this non-isokinetic model especially is significant since it extends the capability of the use of QFA for property prediction from up to a loss of 10%–15% to approximately 70% loss of properties^[18] reported by Evancho and Staley.^[4]

Fig. 7 Variation of $\sigma_{\min}$ with temperature (7010-T76)

C-Curve Generation—Derivation from Jominy Curve Data

One of the reasons for relatively limited use of quench factors up to the present time is the relative unavailability of C-curves for the alloy of interest. The principle reason for this is that experimental determination of C-curves is a time-consuming process. This is illustrated by the following example of the experimental procedure used by Robinson et. al. to obtain C-curves for 7010-T6 forgings involved heating a test specimen, typically multiple as many as ten, test specimens of the alloy of interest in a forced air furnace at the appropriate solutionizing temperature and soaking time with respect to section size of the alloy being studied.^[31] A test specimen could be a tensile bar obtained from a forging or casting of the alloy of interest. Typically, the test specimen is sufficiently small to assure temperature uniformity during isothermal heat treatment. After solution treatment of 7010 forgings for 2 h at 475°C at which point, the test specimens were rapidly transferred, within approximately 5 s, to a salt bath composed of potassium nitrate and sodium nitrite mixture and maintained within $\pm 5^\circ\text{C}$ of the desired isothermal holding time and temperature. The isothermal holding time begins when the temperature is within 5°C of the desired aging temperature. For 7010 forgings, isothermal heat treatments were performed between 210°C and 450°C. (These are a series of isothermal anneals or “pre-aging” treatments.^[32]) The test specimens are manually agitated in the molten salt bath.

After the test specimens have been held at the isothermal holding temperature for the desired time, they are quenched to room temperature. Cooling rates are determined on selected test specimens by inserting a Type K thermocouple to the geometric center of the test bar and data acquisition was performed at a 1 Hz sampling rate over the duration of the test. After quenching, the test specimens were aged as required for the temper designation of interest. For example, for an artificial aging (T6) process, the test specimen is heated for 24 h at 120°C in a forced air oven. After cooling, the test specimens were tested for the property of interest in order to construct a C-curve. If the test specimen could not be tested immediately, it was stored at -20°C to delay natural aging.^[31]

This example illustrates the time-consuming and labor-intensive nature of the experimental procedure used to obtain C-curves to date. Therefore, it would be highly desirable to identify an alternative procedure to acquire C-curves. This is particularly important the C-curve produced is alloy composition dependent. Fortunately, in addition, to determining C-curve constants experimentally,^[31] an alternative procedure has been recently developed that permits the determination of C-curves experimentally by modeling Jominy data obtained for the aluminum alloy.^[23,33–35] A brief, but reasonably detailed, overview of this procedure will be outlined in this section.

Hardness measurements were taken on a -22°C aluminum slab, so that the temperature of the Jominy bar did not exceed 0°C during hardness testing. Hardness measurements were taken at 2 mm from the edge of the flats and at 4 mm increments from the quenched end. After hardness measurements were taken, the test bar was refrigerated again.

Another Jominy test bar was machined with a 1.5 mm diameter holes at the center in which 1.5 mm diameter Type K thermocouples were inserted as shown in Fig. 9. These thermocouples were used to obtain cooling curve data. The data acquisition rates for temperature was 3.3 Hz, and one set of data was obtained at 10Hz for the thermocouple located 3 mm from the quenched end. The heating and quenching process was the same as that described for the test specimen used for hardness measurements.^[33]

Ma et al.^[34] used Jominy test bar with more Type K thermocouples than the bar used by Tanner and Robinson.^[33] Thermocouple positions used in Ma's study at positions shown in Table 6. The 356 aluminum casting alloy used in their study was solutionized at 540°C for 4 h. The time-temperature (cooling curve) and cooling rate curves obtained are shown in Fig. 10. At 3.2 mm from the quench end, the maximum cooling rate is approximately 150°C/s, which is equivalent to a water quench. The maximum cooling rate decreases to approximately 5°C/s at 63.5 mm from the quench end, which is similar to the cooling rate attainable from an air quench. These data show that with

MacKenzie,^[23] Tanner and Robinson,^[36] and Ma et al.^[34] have described Jominy end-quench test procedures to determine hardness and cooling rate as a function of distance from the quenched end of the Jominy test specimen. The Jominy end-quench test specimen was typically a round bar which was machined to 25 mm diameter $\times$ 100 mm long with a head at the top end of the bar of 31 mm diameter $\times$ 3 mm thick. Flats of 1 mm depth were machined on opposite sides of the test bar prior to conducting the test: a standard Jominy end-quench test rig such as one described in ASTM A255-07 “Standard Test Methods for Determining Hardenability of Steel.” The head of the test bar was supported by a plate in the Jominy test rig, a schematic of which is shown in Fig. 8.^[34] The water spray is emitted from a 12.7 mm diameter orifice, which is located 12.7 mm from the end of the Jominy test bar. The heat transfer occurring in the test bar was assumed to be one-dimensional because only one end of the bar

one experiment using a single thermocouple-instrumented Jominy test probe, it is possible to obtain a wide range of cooling rates.

Tanner—Robinson’s approach to obtaining cooling curves using fewer thermocouples can also be used to obtain cooling curves and cooling rate curves at any point on the Jominy bar by using a finite element analysis (FEA).^[33] In this case, heat transfer model of the Jominy end-quench bar is constructed using a platform such as ABAQUS. The symmetry of Jominy end quench test bar may be modeled using one-quarter of the test bar with heat diffusion elements of type DC3D4 (four-noded linear tetrahedron) for the head of the sample and DC3D8 (eight-noded quadratic brick) elements for the main shaft of the sample.^[33] Properties for thermal conductivity, density, and specific heat were obtained from literature. The main boundary condition was established from cooling curves measured at 3 mm from the end of the Jominy end-quench bar. Radial heat transfer from the unquenched sides of the specimen was ignored, as previous work has indicated that any heat transfer that occurs to the surrounding air does not affect the hardness measured.^[33,37]

The next step is to develop a correlation between strength and hardness. Good linear correlations between hardness and strength may be obtained if the same aging treatment is used after different continuous cooling quench rates.^[13] However, since QFA was originally derived based on actual strength measurements, it has been recommended that if any property other than strength is used, then a linear correlation exists between that property and strength.^[34,38]

An often-used alternative to strength is hardness, which is typically based on the depth of indentation. These hardness values, like Rockwell hardness, are based on an arbitrary number. However, an alternative is Meyer hardness (which may be referred to as “mean pressure”) that is proposed to possess a physical meaning and is defined

as the “work to create a unit volume of elastoplastic residual impression”.^[38] Meyer hardness, P bar, is defined numerically as follows:

$$\bar{P} = \frac{4 \cdot L}{\pi \cdot d^2} \quad (18)$$

where

$\bar{P}$ = Meyer hardness (kg/mm²)

L = load on the indenter (kg)

D = diameter of the indentation (mm)

The correlation between Rockwell B hardness (RHB) and Meyer hardness was developed by Tiryakioglu and Campbell:^[38]

$$d = 1,263 - 5,270 \cdot 10^{-3} \text{RHB} \quad (19)$$

From Eqs. 18 and 19, Meyer hardness from Rockwell B hardness can be calculated.

For the work described by Ma et al., Meyer hardness was calculated from RHB measurements and then plotted as a function of distance from the quenched end of the Jominy bar to yield the curve shown in Fig. 11.^[34]

Ma et al. used Eq. 20 to determine the relationship between the quench factor Q and Meyer hardness:^[34]

$$\frac{\sigma - \sigma_{\min}}{\sigma_{\max} - \sigma_{\min}} = \exp(k_1 \cdot Q) \quad (20)$$

The value for $\sigma_{\max}$ was taken as the Meyer hardness at the quenched end of the Jominy bar since only limited precipitation will occur under these conditions and, as abovementioned, Meyer hardness is known to exhibit a correlation with strength. The value for $\sigma_{\min}$ was established by solutionizing the Jominy bar at 540°C in a conventional furnace and then transferring the bar to a preheated fluidized furnace also at 540°C at the time when burners are

Fig. 11 Meyer hardness as a function of distance from the quenched end of a Jominy bar of a cast aluminum 356 alloy^[36]

turned off but the blowers left on and then cooling for 20 h to allow precipitation to reach equilibrium. Then, the bar is quenched in water followed by aging at 165°C for 6 h. The bar is sectioned and ten hardness readings were taken across the section and averaged. This value was used as the minimum Meyer hardness. Values for σ are the incremental Meyer hardnesses along the Jominy bar.

At this point, the natural logarithm is taken on both sides of Eq. 20, which yields Eq. 21:

$$\ln \left[\frac{1}{k_1} \cdot \ln \left(\frac{\sigma - \sigma_{\min}}{\sigma_{\max} - \sigma_{\min}} \right) \right] = n \cdot \ln Q \quad (21)$$

It was previously demonstrated that a plot of the left side of Eq. 21 using yield strength instead of Meyer hardness versus the $\ln(Q)$ from the calculated quench factor using measured cooling curves with the C_T constants with

Eqs. 5 and 6 would yield a linear relationship for aluminum cast alloys 356 and 357. The slope or Avrami constants were determined to be $n = 45$ and $n = 63$ for aluminum alloys 356 and 357, respectively.^[39] Although there was considerable scatter in the data, the linearity of this relationship is shown in Fig. 12.^[39] Since Meyer hardness was shown to correlate with strength, it is expected that a similar linear correlation would result.

As discussed previously, multiple linear regression analysis is used to iteratively determine the best set of values for k_2 to k_5 . (The value for k_1 was equal to the logarithm of the % transformed (-0.00501) which is assumed to be 0.5% transformed.) Ma et al. minimized the difference between the predicted and measured property using a least-squares routine to obtain the best linear relationship between a function of experimentally measured properties and calculated quench factors (Eq. 21).^[34] Quench factors were calculated according to Eq. 5 using the cooling curves shown in Fig. 10 that correspond to the different Jominy position for which Meyer hardnesses were obtained. In this study, initial values for k_2 to k_5 were assumed and then iteratively varied until a minimum error was obtained. A plot of the data as shown in Fig. 13 was obtained and this process was repeated until the fitted line passes as close as possible through the origin as shown in Fig. 13.^[34]

Using these computational methods and Jominy end-quench experiments, it is possible to utilize QFA to identify the best alloy and quench rate for a given application. Using either a database of cooling curves for different section sizes or by utilizing FEA simulations as discussed here, it is possible to calculate cooling curves at any point in a section or to examine section size effects when coupled with QFA. Finally, by obtaining Jominy data as discussed here for different alloy chemistries, it is possible to examine the effect of compositional variation of a particular alloy on properties using QFA.

Fig. 13 An example best-fit curve for QFA of cast aluminum alloy A356^[36]

Limitations of QFA

Although QFA has been, and continues to be, used successfully for property prediction of heat treatable aluminum alloys, there are limitations to the predictive accuracy, which are attributable to the assumptions made in the theoretical development.^[13] Three of these limitations, as addressed by Rometsch et al. include the following:

1. Classical QFA assumes that strength varies linearly with solute concentration. However, it is now known that strengthening contributions are due to both shearable and non-shearable precipitates, which are proportional to the square root of the volume fraction, which is contrary to the original QFA assumption. Rometsch et al. proposed that Eq. 5 from the classical QFA approach should be replaced by Eq. 22 to account for this nonlinearity.^[13]

$$\frac{\sigma - \sigma_{\min}}{\sigma_{\max} - \sigma_{\min}} = \left[\exp(k_1 \cdot Q) \right]^{1/2} \quad (22)$$

2. Classical QFA assumes that transformational kinetics are described by a special case of the Avrami equation where the Avrami coefficient is $n = 1$. When Evancho and Staley analyzed the 7075-T6 and 2024-T4 interrupted quenching data of Fink and Willey, they obtained linear correlations with slope of 1 for plots of $-\log[\sigma/\sigma_{\max}]$ versus isothermal hold time. However, diffusion-controlled nucleation and growth theories indicate that $n < 1.5$ is not possible for reactions that involve growth in three dimensions (precipitates nucleating and growing within grains).^[13] Therefore $n = 1$ is mostly related to formation of nonhardening precipitates within grains during quenching. Rometsch et al. have proposed using Eq. 23, a form of the Starink–Zahra equation as an alternative to the

Avrami approach to describing transformation kinetics to accommodate values of $n \neq 1$, as an alternative to Eq. 22.^[13]

$$\frac{\sigma - \sigma_{\min}}{\sigma_{\max} - \sigma_{\min}} = \left[\frac{(-k_1 Q)^n}{\eta_i} + 1 \right]^{\eta_i/2} \quad (23)$$

where

n = Avrami coefficient

η_i = impingement factor^[40]

3. The minimum strength in the Avrami Equation—by neglecting minimum strength ($\sigma_{\min}$), the ability to successfully predict strength loses accuracy. As discussed above, Staley showed that at lower values of $\sigma/\sigma_{\min}$, the predictions are improved by introducing $\sigma_{\min}$ as a constant related to strength in the absence of hardening precipitates. However, Rometsch developed an alternative non-alloy-specific approach to address this problem based on temperature-dependent solubility to describe the variation of $\sigma_{\min}$ with temperature. The reader is directed to Reference^[13] for a rigorous treatment of this approach that permits the inclusion of aging temperature variation, solution treatment temperature, and alloy composition to be included in the model.

Tiryakioğlu and Shuey have developed a new QFA model that addresses many of the deficiencies of the classical model or even the various improvements like establishing process–structure–property relationships, includes multiple quench precipitates, and utilizes thermodynamic and calculated data for some coefficients.^[41] In this new model, the amount of each quench precipitate is represented by a dimensionless microstructural state variable S (volume fraction). For arbitrarily long

isothermal hold, in the absence of competing precipitates, the limiting value, S_{eq} is defined as

$$S_{eq}(T) = 1 - \exp\left[\frac{\Delta H}{R}\left(\frac{1}{k_4} - \frac{1}{T}\right)\right]; T \leq k_4 \quad (24)$$

where

k_4 = solvus temperature (K)

ΔH = precipitation enthalpy for quench precipitate (J/mol)

S_{eq} = Limiting value of a dimensionless microstructural variable specifying the amount of quench precipitate (S) at equilibrium after an arbitrarily long isothermal holding time at a given temperature

Note: A “state variable” is an element of the set of variables that describe the state of a dynamic system. Typical state variables in a thermodynamic system include: temperature, pressure, enthalpy, entropy, and specific volume.

The evolution of quench precipitates (dS/dt) is modeled by

$$\frac{dS}{dt} = \frac{S_{eq} - S}{t_c} \quad (25)$$

where

t_c = critical time (s) to nucleate and grow quench precipitates and is determined from

$$t_c = k_2 \exp\left[\frac{k_3 k_4^2}{RT(k_4 - T)^2} + \frac{k_5}{RT}\right] \quad (26)$$

where

k_2 = coefficient related inversely to number of nucleation sites (s)

k_3 = coefficient related to energy barrier to heterogeneous nucleation (J/mol)

k_5 = stoichiometrically averaged activation energy for diffusion (J/mol)

R = gas constant, 8.3143 J/(mol K)

T = temperature (K)

The change in the precipitates that are formed is calculated from

$$\Delta S_i = (S_{eq} - S_{i-1}) \left[1 - \exp\left(\frac{-\Delta t_i}{t_c}\right) \right] \quad (27)$$

At the conclusion of the quenching process, the total precipitates formed is determined by summing the incremental amounts:

$$S = \sum_i \Delta S_i \quad (28)$$

The yield strength is calculated from

$$\sigma_y = \sigma_{\max} - \sum_j k_j S_j \quad (29)$$

where

j = quench precipitates modeled

$\sigma_{\max}$ = strength obtained at an infinite quench rate (ksi)

k_j = strength coefficient

Equation 29 assumes that yield strength depends linearly on the amount of solute available after quench, which is consistent with the classical model.^[4,10] This new Tiryakioğlu and Shuey model is an expansion of the classical versions that considered only one type of quench precipitate (same stoichiometry and site) by using similar equations.^[41] If only one precipitate is considered with a single quench precipitate, Eqs. 24–29 are equivalent to the classical equations discussed above.

CONCLUSIONS

To achieve the ideal quench, low values of Q are desirable because they are associated with high quench rates, minimum precipitation during cooling, and high yield strengths. High values of Q can lead to an improperly quenched alloy that may not properly harden during aging and may be susceptible to intergranular corrosion, stress corrosion, or exfoliation. Some improvements in the modeling of the QFA have been developed although classical QFA has been used successfully for property prediction of heat treatable aluminum alloys.

However, there are limitations to the predictive accuracy of the classical quench factor equations which are attributable to the assumptions made in the theoretical development. A brief overview of newer predictive methodologies that address these limitations and expand the potential utility of QFA have been provided here.

Abstract

The application properties of metallic materials are frequently adjusted by heat treatments utilizing controlled microstructural changes—i.e., solid–solid phase transformations like nondiffusional martensitic transformation or diffusional secondary phase precipitation and/or dissolution. For technical application, knowledge about the characteristic temperatures and times but moreover about their time dependence (kinetics) is required. As the relevant solid–solid phase transformations all show a heat effect (e.g., precipitation → exothermic; dissolution → endothermic), one outstanding measurement technique to follow these phase transformations is calorimetry, particularly differential scanning calorimetry (DSC). Appropriate combinations of DSC methods and devices to cover nine orders of magnitude in heating and cooling rates (10^{-4} – 10^5 K/s) will be introduced, using dissolution and precipitation reactions in aluminum alloys as examples. Basically, these techniques allow one to record time–temperature transformation (or precipitation/dissolution) diagrams for various materials during heating, isothermal annealing, and even during continuous cooling, making DSC a very powerful tool for the investigation of solid–solid phase transformations. Nowadays, physically based models verified with DSC results moreover allow one to predict precipitation volume fractions and solute mass fractions.

INTRODUCTION

Aluminum as (Base) Material for Structural Components

Aluminum alloys have a large range of applications. They are also widely used as a structural material for lightweight applications in transportation, i.e., for structural parts of vessels, trains, and cars. Reference^[1] provides a detailed overview of these applications. For decades, the lightweight materials of choice for the structure of air planes were aluminum alloys. Although composites are now used to a certain extent, aluminum alloys still play an important

role in this field. Aluminum alloys are typically used in the form of extruded profiles or sheets, while castings and forgings are also common. In general, appropriate material properties are needed to allow the application of a certain material as a structural component—i.e., any structural component must possess a certain level of strength and ductility and—beside others—corrosion also plays an important role, e.g., for vessels.

Pure aluminum possesses a relatively low strength. To allow the application of aluminum-based material as structural components, the strength must be increased significantly. To increase the strength, different mechanisms are available. The dominating mechanism utilized for aluminum alloys is particle strengthening—alloying element atoms form nanoscaled secondary phase crystal particles which hinder the dislocation movement in the aluminum lattice and thereby increase the strength. To enable the required precipitation (growth of secondary crystal particles), alloying elements typically with a few percent

Originally published as “Precipitation and Dissolution Kinetics in Metallic Alloys with Focus on Aluminium Alloys by Calorimetry in a Wide Scanning Rate Range” © Springer International Publishing Switzerland 2016C. of the mass fraction are added to the aluminum base metal (in the liquid state during primary forming). The nanometer-sized precipitates, which increase the strength of the aluminum alloys, are adjusted at the end of the production chain by a heat treatment, called *age hardening*.

Precipitation Hardening of Aluminum Alloys by Heat Treatment

The basic requirement to allow age hardening is the solubility of at least one alloying element in the aluminum matrix lattice. This solubility must moreover increase significantly with increasing temperature. One appropriate example is shown in Fig. 1 for quasi-binary Al-Mg₂Si alloys. Following the solvus line, the solubility for Mg₂Si increases with increasing temperature—i.e., at 595°C a maximum solubility of 1.85 mass % Mg₂Si in the aluminum matrix is reached. The age hardening treatment comprises three steps: solution annealing, quenching, and aging. These steps will be explained using the example of the composition Al-1 mass % Mg₂Si, as shown in Fig. 1.

Let us assume to start with an equilibrium microstructure containing two phases— α -aluminum and β -Mg₂Si. At room temperature, nearly nothing of the Mg₂Si phase is dissolved in the aluminum matrix. If this composition is heated, the solubility of the Mg₂Si increases and reaches its *solvus temperature* at about 500°C—i.e., during slow heating, the whole amount of alloying elements of Mg and Si will dissolve in solid solution. Dissolution is a diffusion-driven process and therefore needs time (depending on the applied temperature). To optimize this process step in practical application, it is of great importance to know the dissolution kinetics. However, the alloy will be heated to some 10 K above the solvus temperature—to the solution annealing temperature, and held there for a while (soaking) to allow homogeneous distribution of the alloying element atoms. At the end of the solution annealing, the aim is to

reach a homogeneous solid solution, ideally possessing only one microstructural phase, based on the aluminum face-centered cubic lattice structure, with all alloying elements dissolved (for wrought alloys).

During the second process step, the solid solution is rapidly cooled (quenched). This quenching aims to “freeze” the solid solution and to avoid precipitation of alloying elements—a completely supersaturated solid solution is intended. If we cool the alloy extremely slowly and close to equilibrium conditions, β -Mg₂Si would precipitate, starting when the temperature falls below the solvus temperature. As precipitation is also a diffusion-controlled process, it depends on temperature and significantly on time (which must be regarded on logarithmic timescales in this case). Extremely slow cooling would lead to very coarse secondary particles (dimensions: several micrometers) embedded in a nearly pure aluminum lattice. The strength would be about as poor as for pure aluminum. As this is not the aim, the solid solution obtained during solution annealing is instead cooled down rapidly to room temperature—the resulting microstructural state is far from equilibrium—and this state in particular is unstable. However, this metastability is used during the final aging step to allow the precipitation of particles out of the supersaturated solid solution, causing the required strengthening. The quenched material will be aged at temperatures near to room temperature for several days (up to a month) or at temperatures up to about 200°C for a period of several tens of minutes to some hours. Depending on the chosen temperature and time, nano-sized precipitates grow, starting from clusters (= arrangement of a few to about 1000 atoms without regular structure) up to precursor phases (possessing their own crystal structure) with (partially) coherent interfaces to the aluminum lattice. Finally, the precipitation sequence will end with coarse equilibrium particles. Depending on the volume fraction and size, the nano-sized precipitates hinder the dislocation movement effectively and will increase the strength of the alloy significantly.

Fig. 1 Pseudo-binary phase diagram for Al-Mg₂Si and schematic temperature–time profile of an age hardening procedure
Source: Adapted from.^[1]

The following alloying systems based on aluminum are suitable for precipitation strengthening: AlCu(-Mg), Al-Mg-Si, Al-Zn-Mg(-Cu), and (rarely used) Al-Li(-xy) alloys.^[1] The most frequently used are Al-Mg-Si alloys, while Al-Zn-Mg(-Cu) alloys obtain the highest strength values.

The first heating step in Fig. 1 is primarily thought to allow dissolution of all the alloying elements, which may be completed during solution annealing. In reality, the processes are much more complex, and several dissolution and precipitation reactions may occur sequentially. Studying these processes is of technological interest too. The importance of understanding the heating behavior and thereby the kinetics of dissolution and precipitation during heating of aluminum alloys will be demonstrated by a few examples: aluminum sheet materials are coiled, and solution annealing is performed in continuous annealing furnaces with very short solution annealing times (a few minutes, allowing production to remain fast and cost-efficient). Knowledge of the dissolution behavior over a wide dynamic range will help to select an appropriate heating rate, generating a full solution already during heating and hence exploiting the full age hardening potential. Another important application field of dissolution is retrogression annealing, which leads to an increase in plastic formability. This holds for forming processes like tailored heat-treated blanks (e.g., Ref. [2]) but also for joining processes like laser-assisted clinching.^[3]

As described above, one crucial step for the success of *age hardening* is to “freeze” the dissolved alloying element atoms in a supersaturated solid solution by rapid cooling from solution annealing. However, the driving force for precipitation during cooling—which must be avoided—varies significantly between different alloys and different alloying systems. Therefore, the kinetics of precipitation, which we intend to avoid, varies significantly too. Of course, the optimal cooling rate—just freezing all the alloying elements to a completely supersaturated solid solution—also varies significantly with the chemical composition. The liability to “lose” solute atoms to coarse (micrometer-sized), undesired quench-induced precipitates is called *quench sensitivity*. (It must be mentioned that there are different ways to define quench sensitivity.) If an alloy is highly quench sensitive, it tends to lose a significant amount of solutes during conventional cooling procedures. These “lost” atoms are then no longer available to form the desired hardening nano-sized precipitates. In contrast, an alloy that possesses a low quench sensitivity might freeze all the alloying elements to a completely supersaturated solid solution during the same quenching path. The latter alloy will finally be able to transform all the alloying elements into hardening nano-sized precipitates, exploiting its full age hardening potential. Thereby the strength increase by aging is called the hardening response. Obviously, this will be low

if an appreciable amount of solutes is wasted in coarse, quench-induced precipitates. Considering the quenching step, we will focus here on the particular cooling rate that is needed to freeze the full fraction of dissolved alloying elements. Besides, for a full understanding of precipitation, one should also know at which slow cooling rate precipitation might already be completed during cooling from solution annealing.

To understand all the relevant solid–solid phase transformations and their kinetics, one obviously has to consider heating, isothermal soaking, and cooling steps. Due to the kinetics of the relevant transformations, these investigations require a very wide dynamic range.

Kinetics of Solid–solid Phase Transformations and Its Measurement

As the relevant solid–solid phase transformations all show a heat effect (e.g., precipitation → exothermic; dissolution → endothermic), one outstanding measurement technique to follow these phase transformations is calorimetry, particularly differential scanning calorimetry (DSC). During recent years, advanced calorimetric techniques to analyze solid–solid phase transformations in a very wide dynamic range have become available (e.g., Refs. [4–10]). These techniques will be introduced, using the dissolution and precipitation reactions of secondary phase precipitates in aluminum alloys as examples. DSC can give information about the relevant temperature ranges and reaction intensities. The latter can be quantified by the heat or enthalpy transformed. The reaction enthalpy can be precisely measured by DSC. Moreover, the precipitation enthalpy gives a direct link to the mass fraction of grown precipitates and the kinetics of this phase transformation.

For a full physical understanding, the required high dynamic range is bounded by very slow transformations close to equilibrium conditions on the one hand, and on the other hand, by relatively fast cooling beyond the critical cooling rates of the relevant transitions. For instance, for aluminum alloys the adjustment of maximum strength values requires the complete suppression of any precipitation reaction upon cooling from solution annealing (typically at about 470°C–550°C). The slowest cooling rate that just retains all alloying elements dissolved during solution annealing in solid solution is called the upper critical cooling rate.^[11] For highly alloyed Al-Zn-Mg-Cu wrought, or Al-Si-Mg cast alloys, this upper critical cooling rate can easily reach several 100 K/s.^[8,12] The lower critical cooling rate defines the fastest cooling rate at which all the alloying elements (compared to the equilibrium solubility) precipitate during cooling from solution annealing, yielding enthalpy changes on a saturation level. For an Al-0.72Si alloy, this lower critical cooling rate is about 10⁻⁴ K/s (for less concentrated alloys, this will be even slower^[9]). To identify both critical cooling rates, one has to exceed

them experimentally by at least one order of magnitude toward both slower and faster cooling, which requires a dynamic range of about 10^{-5} – 10^3 K/s. Today such a wide dynamic range is available in scanning calorimetry, in particular concerning cooling.

To achieve the required high dynamic range during cooling, a combination of three different (indirect and direct) measuring techniques and five types of DSC devices is needed. However, to be able to perform precise qualitative and quantitative data evaluation, one has to ensure a close to zero base level of the measured curves (subsequently termed “zero-level”), since the studied effects in aluminum alloys show only small heat effects. In any case, it is preferable to measure the excess specific heat capacity by scanning a sample versus an inert reference sample of comparable heat capacity. Baseline measurements are performed back to back. Moreover, samples are shielded properly and, if possible, unavoidable remaining zero-level bending is eliminated by subtraction of polynomial functions, as detailed below.

The described indirect reheating techniques (see Sections 3.1.2 and 3.2.2) allow one to obtain enthalpy data only, while by direct in situ cooling experiments also characteristic temperatures and times can be evaluated. The basic metrological considerations are summarized below, providing a guideline to perform high-precision DSC experiments on solid–solid phase transformations in metals. Basically, these techniques allow one to record time temperature transformation (or precipitation/dissolution) diagrams for various materials during heating, isothermal annealing, and even during continuous cooling, making DSC a very powerful tool for the investigation of solid–solid phase transformations. Nowadays, physically based models verified with DSC results (e.g., Refs. [9,13,14]) moreover allow one to predict precipitation volume fractions and solute mass fractions for a wide range of alloys

and processing conditions. In this contribution, different aluminum alloys covering a wide range of critical cooling rates were chosen.

The following Table 1 shows the mass fractions of the alloying elements contained in the aluminum alloys investigated. In addition, the alloy designations corresponding to EN 573-1 and EN 573-2 as well as the standard composition ranges according to EN 573-3 are given.

DSC INVESTIGATION OF DISSOLUTION AND PRECIPITATION IN METALLIC ALLOYS IN A WIDE DYNAMIC RANGE

Basics for Calorimetric Measurements of Precipitation (and Dissolution) in (Al-) Alloys

Commonly, precipitation reactions in metal alloys are exothermic, and dissolution is endothermic. Despite their relatively small heat effects (compared to heat effects of a first-order phase transition like melting), they can therefore be analyzed by DSC. However, if one aims to analyze these relatively small heat effects and this moreover in a wide dynamic range, one needs to take care of several issues and employ a specified measurement setup. First, the excess specific heat capacity should be evaluated.^[7]

Figure 2 compares two DSC cooling curves of the same alloy in the same device at the same cooling rate—the only difference is that in (a) the sample (packed in a standard aluminum pan) was measured versus an empty pan. After normalization for sample mass and scanning rate, this results in a measurement of the specific heat capacity, c_p (during cooling in this case!). The specific heat capacity of this alloy decreases with decreasing temperature—despite the peak at about 350°C. This peak results from

Fig. 2 Comparison of a specific heat capacity measurement (a) and an excess heat capacity measurement (b) for the precipitation reaction in EN AW-Al SiMg(A) during cooling at 50 K/min from solution annealing^[7]

an exothermic precipitation reaction inside the sample—but this is the only particular item of interest. Within the measured specific heat capacity (Fig. 2a), these two effects are apparently superimposed. To simplify the evaluation, it makes sense to eliminate this superposition. Generally, the basic idea of the symmetry of the DSC device is also simply transferred to the measurement setup. Therefore, the alloyed sample is measured versus an inert reference sample. This reference sample must be thermodynamically inert in the temperature range of interest. Moreover, it should possess a highly similar specific heat capacity over the whole relevant temperature range compared to the sample under investigation. Ideally, the surface condition should also be very similar. For measurements on precipitation in wrought aluminum alloys (possessing only a few mass % alloying elements), this holds in a very good approximation for pure aluminum. Hence, high purity aluminum is commonly used as a reference for DSC measurements on aluminum alloys. For details, see references.^[7,15] Each DSC device possesses a certain deviation from the ideal symmetry—a bent baseline results—i.e., the zero level of the heat flow is commonly not zero but instead a bent curve. This device-dependent baseline bending can be eliminated by performing a baseline measurement and subtracting this from the original sample measurement. Consequently, the symmetry should be retained here also, and the baseline measurement should hence be performed by measuring an inert sample versus an inert reference sample—both again with similar dimensions and heat capacities to the original sample. If done so, after baseline subtraction and standard normalization by sample mass and scanning rate, excess specific heat capacity curves result. In an ideal case, this excess c_p is zero as long as no reaction occurs in the sample which is analyzed. The only asymmetry that can occur

is a heat effect inside the alloyed sample (i.e., exothermic precipitation during cooling or heating, but also—only during heating—endothermic dissolution). Therefore, the remaining signal peaks correspond directly and only to the reactions that are intended to be investigated (see Fig. 2b). Comparing the scaling of the ordinate, one can see that it differs by about one order of magnitude, making the peak much more easily detectable. As one further benefit, this now basically straight and flat zero level gives the opportunity to allow integration and quantitative evaluation of the heat released during precipitation.

Possible Reasons for Remaining Zero-level Curvature and Its Elimination

Although the device-dependent zero-level bending is essentially eliminated by a baseline subtraction, at larger magnification, the zero level is still bent, for reasons which are different for each measurement. Höhne et al.^[16] reported that, for instance, the exact position of the furnace lid or sample inside the micro-furnace will affect the measurement precision. However, if one aims to perform quantitative evaluation, for example, of the transformation heat or enthalpy change, one has to ensure that the zero level for curve integration is truly zero.

One characteristic of the measurements of precipitation reactions in metallic aluminum alloy samples is the relatively broad temperature range. In particular, relatively high temperatures also need to be considered. The solution annealing of aluminum alloys typically ranges from about 470 °C to 550 °C. Other metallic systems showing similar precipitation reactions might also be of interest—and would require even higher temperatures. However, with increasing temperature the heat exchange by radiation increases.

This leads to instrument-specific problems of measurements on precipitation reactions in metallic systems.

Before the measurements, a freshly machined metallic sample typically possesses a shiny metallic surface. During the measurement (at high temperatures), the surface of the sample typically changes its color slightly, e.g., due to oxidation of the alloying elements accumulated at the surface. That is, in contrast to the pure aluminum reference samples, the surface of the alloyed sample gets darker. Compared to a shiny metallic surface, a darker surface increases its potential of heat exchange by radiation. This leads to a metrological problem caused by the related radiation heat losses. At solution annealing temperature (about 500°C), the furnace of a heat flow DSC stabilizes at isothermal conditions. Heat flow DSCs typically possess just one furnace, containing both measuring cells,^[17] which should now be at the same equilibrated temperature. However, if the sample surface is darker than the shiny surface of the pure aluminum reference sample, the alloyed sample will instead have a slightly lower temperature. As in heat flow DSC devices the difference of the sample temperatures serves as the measuring signal,^[17] this slight asymmetry will affect the differential heat flow. Besides, the baseline measurement is performed with two shiny metallic pure aluminum samples which will finally be at nearly the same temperature without the above-mentioned asymmetry. Therefore, the heat flow values of sample and baseline measurement might differ, in particular at high temperatures, even in reaction-free temperature regions (see Fig. 3a).

Packing the samples in shiny pure aluminum crucibles helps to avoid this radiation problem (see Fig. 3c). Nevertheless, a slight difference between the sample and baseline heat flow typically remains—and causes a small difference particularly at the high temperature isotherm. This effect gives rise to a remaining bent nonzero heat flow outside the transition regions. Nevertheless, for a proper qualitative and quantitative evaluation, the zero level is crucial and one has to ensure that it is close to zero and at least straight prior to evaluation. In this respect, the difference of the high temperature isotherms is a measure for the heat loss differences between the inert baseline sample and the sample under investigation. Even when temperatures are not extremely high, with 540°C as in Fig. 3, it is remarkable how sensitive a DSC instrument is regarding radiation losses. One would expect that a fully aluminum foil covered sample in a three-dimensional (3-D) measuring system of the Calvet calorimeter Setaram DSC 121 should not show such effects. Since these differences in radiation losses are unavoidable, a strategy is needed for reliable data treatment.

To illustrate the power of the suggested data treatment, a reasonable measurement (Fig. 4a–c) and a really bad example as shown in Fig. 4d–f are chosen. Due to ice formation from humid air on the cooled calorimeter block, the instrument is extremely asymmetric, resulting in a

Fig. 3 Influence of sample packing on the measured heat flow signal in a Calvet-type Setaram 121 DSC
Adapted from Milkereit et al.^[17]

more than 150 mW difference between the start and end isotherms and serious curvature already for the baseline measurement (Fig. 4d). Commonly, one would not use such a bad measurement for further data analysis. Nevertheless, since the conditions are reproducible between the baseline and sample measurement, as confirmed by the difference between the high temperature isotherms of only approximately 0.2 mW, the measurement was evaluated. It can be seen that the curve values after baseline subtraction are not necessarily zero even if the reactions seem to be finished in the sample. This remaining zero-level curvature can potentially be eliminated by subtracting a polynomial (zero-level polynomial). However, for this, the start and end of the measured curves should exhibit sections where no heat has been exchanged by microstructural changes within the sample—i.e., reaction-free zones are urgently required to allow fitting of a zero-level polynomial. It might need

Fig. 4 Elimination of remaining zero-level curvature on DSC heating curves of an EN AW-Al Si1Mg0.8 alloy (initially in a naturally aged condition) in two different devices at similar heating rates by subtraction of a third-order polynomial function^[18]

several measurements with varying parameters to obtain knowledge and confidence about the appearance of such reaction-free zones. One possibility to ensure the latter is to measure samples at different scanning rates. All the microstructural solid–solid effects should depend on time and therefore the corresponding peaks should change.

The data evaluation procedure is shown in Fig. 4 with raw data from two DSC devices by means of EN AW-Al Si1Mg0.8. In order to indicate the comparability of both DSC types, similar heating rates of 0.1 K/s (Fig. 4a–c) and 0.3 K/s (Fig. 4d–f) were chosen. While 0.1 K/s is already fast for the Setaram DSC 121, 0.3 K/s is common for the Pyris 1 DSC. The excess specific heat capacity is obtained from the difference between the sample heat flow ($\dot{Q}_{\text{sample}}$) and baseline heat flow ($\dot{Q}_{\text{baseline}}$) (Fig. 4a,d) and after normalizing by sample mass (m) and scan rate (β).

$$c_p = \frac{\dot{Q}_{\text{sample}} - \dot{Q}_{\text{baseline}}}{m \cdot \beta} \quad (1)$$

The remaining zero-level curvature was corrected by subtracting a polynomial of third order (see Fig. 4b,e). This method to calculate the excess specific heat capacity is generally applied to compare different heating rates and different sample masses.^[19] The zero-level polynomial is fitted to the reaction-free zones. This curve correction should be performed for multiple samples on curves in the same scale. Moreover, the correction should always start on curves with the largest measuring effects to allow proper estimation of the curvature. However, this procedure

should only be used if one can distinguish with certainty between reactions and reaction-free sections, e.g., in comparing other curves of slightly different heating rates. Nevertheless, this method is a subjective procedure and must be handled with care.

Another important fact during evaluation is shown in Fig. 4a,b,d, and e. Changing the heating rate during one DSC experiment significantly, e.g., from a constant heating rate to the isothermal soaking at high temperatures, unavoidably leads to heat flow artifacts. Depending on the DSC device, a so-called overshoot peak can be seen. These artifacts must be excluded from evaluation.

Subsequently, the resulting de-bent curve can be displayed as a function of temperature (Fig. 4c,f). The differences between the start isothermal and end isothermal for the PerkinElmer Pyris 1 DSC (Fig. 4d) have a greater magnitude than for the Setaram 121 DSC due to initially unrecognized ice on the measuring block of the PerkinElmer device. Nevertheless, even the PerkinElmer device was used under unfavorable conditions, both of the finally evaluated excess heat capacity curves show a similar behavior, indicating a proper data treatment and good comparability of the two DSC devices used.

Alloy-Specific Requirements on the Scanning Rate Range

The requirements on the dynamic range will first be explained based on the example of the investigation of precipitation during cooling from solution annealing.

For this precipitation process, a lower critical cooling rate is defined as the highest cooling rate at which practically complete precipitation takes place. Additionally, an upper critical cooling rate is defined as the slowest cooling rate at which completion of supersaturation in solid solution is reached during cooling.^[11] The precipitation kinetics depends on the alloy composition, diffusion coefficients of the alloying elements, and the amount of nucleation sites available. In contrast to most steels (e.g., Ref. [20]), a higher alloying element content increases the quench sensitivity by increasing the precipitation rate, i.e., the upper and lower critical cooling rates increase. The critical cooling rates of different alloys might vary by several orders of magnitude. For instance, a highly alloyed Al-Zn-Mg-Cu alloy can possess an upper critical cooling rate of some 100 K/s,^[8,21,22] while the lower critical cooling rate of an Al-Si alloy might be below 10^{-4} K/s.^[9] Besides, the upper and lower critical cooling rates of one particular alloy also differ significantly within the standard tolerance range of chemical composition. Apart from this, as mentioned above, the cooling rates which may be achieved during technological application also vary dramatically with the cooling technology or media used but also with component dimensions. If one aims to gain a full understanding of precipitation and dissolution kinetics during heating to and cooling from solution annealing of age hardening aluminum alloys, one has to consider a very wide dynamic range. This will significantly contribute to select the appropriate alloy and the appropriate corresponding technological process.

As implied above, a dynamic range of about seven orders of magnitude, ranging from about 10^{-4} to 10^3 K/s, is of interest. This dynamic range is set by the lower and upper critical cooling rates. However, to confirm the saturation levels beyond these boundaries, one has also to measure beyond these critical rates—in both directions. That is, about nine orders of magnitude are required as the dynamic range.

If one is interested in the application of the relevant alloys, one will hardly see the relevance of determining the lower critical cooling rate. The lower critical cooling rate is already some orders of magnitude below the cooling rates at which nearly all age hardening potential is lost in coarse quench-induced precipitates. Therefore, the lower critical cooling rate plays no important role in technical applications. Nevertheless, the physical understanding of the precipitation kinetics will only be complete if one also knows the fastest cooling rate at which effectively all the alloying elements are precipitated from the aluminum matrix (with respect to the equilibrium solubility) to quench-induced precipitates (termed the lower critical cooling rate). In particular, the saturation enthalpy level even at lower cooling rates can be considered as the equilibrium level of precipitation enthalpy change. This value is of essential importance for the setup or testing of any reliable physically based models to describe the precipitation enthalpy

or precipitate volume fractions as a function of cooling rate—i.e., models that describe quench sensitivity (e.g., Refs. [9,13]). Therefore, of course, we aim to cover the full dynamic range of physical interest: from slow transformations close to equilibrium conditions up to above the upper critical cooling rate far away from equilibrium.

This has so far not been investigated systematically for dissolution and precipitation during heating. Also, for the kinetics of dissolution, certain critical heating rates exist. For instance, one could define a lower critical heating rate as the fastest heating rate at which a certain initial microstructural state will be dissolved completely in the solid matrix at a certain temperature.

DSC Devices and Sample Geometries Utilized to Achieve Nine Orders of Magnitude in Cooling Rate

From an experimental point of view, cooling must be considered the more critical step and device limitations are hence discussed for cooling. In general, fast heating even for large samples can be realized by a sufficiently large heat input, i.e., by laser or inductive volume heating. Fast, controlled cooling requires large heat losses to the surroundings by heat conduction, convection, or radiation. In all cases, contrary to heating, the heat has to be exchanged through the surface of the sample. Therefore, a large surface to volume ratio, as realized by small samples, is preferable.

Most calorimeters are limited to about two orders of magnitude in cooling rate—i.e., to investigate the high dynamic range of nine orders of magnitude, one has to combine several DSC devices. Höhne, Hemminger, and Flammershaim published a detailed description of the different DSC device types.^[17] Moreover, some further limitations make it necessary to employ different measurement techniques—in particular, direct and indirect techniques. Thereby the direct DSC cooling measurements (e.g., Ref. [7]) allow one to evaluate both characteristic temperatures/times and also enthalpies of the relevant reactions, whereas the indirect techniques by reheating after cooling (e.g., Refs. [8,9]) in the first evaluation allow one to evaluate the enthalpy changes only. These techniques will be introduced in detail below.

The study of slow cooling rates provides the opportunity to follow near-equilibrium phase changes. This is an essential requirement for a physical approach to describe the enthalpy and solute state during cooling.^[9,13] Recently the accessible cooling rate could be extended to very low values below 0.0003 K/s using the Setaram C600 DSC device with the following specific boundary conditions: the Setaram C600 calorimeter is a heat flux DSC with a cylinder-type measuring system and is equipped with a high-precision 3-D Calvet sensor,^[23] which totally surrounds the sample and reference cell. This setup enables nearly all the heat exchanged to be

Fig. 5 Optimal cooling rate ranges of all DSC devices available at the Rostock DSC laboratory ($^{\circ}\text{CALOR}$) and corresponding measurement techniques. The exact limits depend on the specific setting of the measurement system (DSC device and applied cooling device), sample mass and alloy concentration

measured. Measurements comprising a temperature range from -20°C up to 600°C can be realized. A closed cooling circuit was implemented using a refrigerated circulator Julabo F34-ED and the whole device is operated inside a refrigerator, set to -20°C . Beside the cooling capability of the refrigerator, an effective decoupling between the ambient and the measuring system is realized, which is essential for long-lasting measurements. Optimal results were achieved by using cylindrical samples with curved edges—see Figs. 5 and 6.

The samples have dimensions of 13.8 mm in diameter and 60.5 mm in length, which results in a sample mass of approximately 24,000 mg for aluminum alloys. The samples as well as the references were covered with conventional aluminum foil (about 110 mg) to minimize radiation losses caused by surface reactions of the samples (unfortunately, standard pure aluminum crucibles are not available for this type of sample).

As one metrological feature of the Setaram C600, at high temperature—i.e., during solution annealing—it requires 120 min to reach thermal equilibrium regarding

the measured heat flow signal due to the large heat capacity of the sample and measuring block, resulting in a large time constant. A well-stabilized heat flow signal at solution annealing is needed for high-quality specific heat capacity measurements. Note that one has to check for possible undesired microstructural changes like grain growth during prolonged solution treatment times.

Experiments in the range of about 0.01–0.1 K/s are performed in another Calvet-type DSC, the Setaram DSC 121, with a circulating water bath for cooling and stabilization. The temperature of the cooling jacket is 5°C . The device is positioned below a box which is purged by dry air to prevent water condensation on the cooled parts of the electronics and the measuring block. The sample is covered on both sides by two aluminum crucibles. Depending on the dimensions of the 300 μl standard pure aluminum crucibles, the samples have a cylindrical geometry, with dimensions of $\varnothing 6.0 \times 21.65$ mm. The sample mass thereby is about 1600 mg for aluminum alloys.

Cooling rates in the intermediate range from about 0.1 to 0.5 K/s are performed employing the heat flow-type Mettler-Toledo 823 DSC with a disk-shaped sensor. The optimal samples for these rates and this device have dimensions of 5.4 mm in diameter and 1.4 mm in height, which results in a sample mass of approximately 90 mg for aluminum alloys. The samples are placed in the standard aluminum crucibles (49 mg). These crucibles have a positioning pin for exact and equal positioning on the sensing area. The crucibles can be tightly closed by a press. If done so, a small hole is placed in the lid in order to avoid buckling of the crucible due to overpressure. Buckling would disturb the heat flow between the sample and sensor and could result from air expansion caused by the large temperature range. Another frequently used option to avoid buckling is to put the lid loosely on the pan. Heating in this device is typically performed with 0.5 K/s. A pure nitrogen

Fig. 6 Samples of different DSC devices: (a) Setaram C600 DSC, (b) Setaram 121 DSC, (c) Mettler-Toledo 823 DSC, (d) PerkinElmer Pyris DSC, and (e) DFSC sample on chip sensor

purge is used, and cooling is realized by a two-stage mechanical cooler.

The fastest conventional DSC experiments (0.3 to about 6 K/s) are performed in a power-compensated Perkin-Elmer Pyris 1 DSC. Samples are placed in standard pure aluminum pans possessing dimensions of $\varnothing 6.4 \times 1$ mm. The sample mass for aluminum alloys thereby is about 90 mg. For different specific purposes (heating or cooling experiments) and calibrations, different mechanical cooling systems are installed on different devices, ranging from a Lauda circulating bath realizing a block temperature of 5°C for heating experiments over an Intracooler II with a block temperature of about -60°C to a three-stage mechanical cooler-type Intracooler III with a block temperature of -136°C. Nitrogen with lower heat conductivity is used instead of helium as the purge gas because of the high temperatures required and the better stability of the devices. For the fastest cooling experiments, instead of the star-shaped guard ring inserts between the ovens and the cold block, self-made massive guard rings were used increasing heat losses to the cold block for faster cooling in a wider temperature range. The devices working with block temperatures below 0°C are placed under a glove box and purged with dry air to reduce the formation of frost ice. Due to the high drift sensitivity of these devices, sample and baseline measurements are recommended in the sequence of sample–baseline–sample.

The fastest DSC experiments nowadays can be performed using chip–sensor-based differential fast scanning calorimeter (DFSC) devices. We therefore utilize different DFSC devices developed in house (e.g., Ref. [24]). In addition, the first commercially available DFSC Mettler-Toledo Flash DSC 1 is used. The sample size depends on the exact sensor utilized. However, cuboid samples, possessing lateral dimensions of about 100 μ m and about 10 μ m thickness, are used (Fig. 6e).

Typically, six measurements with identical parameters (six sample measurements and three corresponding baselines) are performed in the faster conventional DSC devices and commonly four runs under the same conditions were executed in the Setaram 121 DSC. In the very slow Setaram C600 DSC, typically only one or two experiments for each cooling rate are carried out due to the

extensive test durations. Table 2 summarizes devices used and their measuring principles.

Some Peculiarities of DSC Cooling Experiments—Temperature Control Limitations and Determination of the Upper Critical Cooling Rate

As indicated in Fig. 5, every DSC device possesses its own limited heating rate and cooling rate range, while the cooling rates are typically limited to a narrower range. This limitation is basically set by the absolute heat capacity of the measuring system and the possible sample masses (or heat capacities).

During cooling with a device-specific relatively high cooling rate, each DSC will run out of control on approaching a certain temperature. For proper evaluation, one has to be aware of this issue. Taking this into account during experiment preparation is a further metrological way to ensure the lowest possible zero-level bending, i.e., the highest quality DSC curves. Therefore, one should at least check the program-, furnace-, and sample temperature and in particular the actually applied scanning rate.

Figure 7 gives an example of a device-specific relatively fast cooling and shows the raw heat flow curves of a cooling experiment on 1700 mg samples of EN AW-Al Zn6CuMgZr(A) (and pure aluminum). Moreover, the sample temperature and accordingly the applied cooling rate are plotted on additional ordinates. As already discussed for Fig. 4, the change between isothermal holding and cooling leads to a heat flow overshoot artifact. The cooling rate then quickly stabilizes to the desired value of 0.05 K/s. However, with decreasing temperature—as the temperature difference between the cold block and sample decreases—the ability to control the cooling process unavoidably decreases too. At a certain temperature, the device might be unable to control cooling any more—leading again to an artifact in the heat flow curves. In the example shown in Fig. 7, this happens at about 8700 s. Of course, the following part of the raw data must not be included in further evaluation. Therefore, one has to be urgently aware of this issue; otherwise, one might fail with the interpretation of the results.

Table 2 Overview of devices used and their measuring principles

Device	Measuring principle	Cooling rate range (for in situ experiments)	Sample dimensions
Setaram C600	Calvet-type heat flux DSC	$\approx 0.0004\text{--}0.01$ K/s	Cylindrical sample: diameter 13.8 mm, length 60.5 mm
Setaram 121 DSC	Calvet-type heat flux DSC	$\approx 0.01\text{--}0.1$ K/s	Cylindrical sample: diameter 6 mm, length 21.5 mm
Mettler-Toledo 823 DSC	Heat flux DSC	$\approx 0.1\text{--}0.5$ K/s	Disc sample: diameter 5.4 mm, height 1.4 mm
PerkinElmer Pyris 1 & Pyris Diamond DSC	Power compensated DSC	$\approx 0.3\text{--}6$ K/s	Disc sample: diameter 6 mm, height 1 mm
DFSC	Chip-based sensor	$\approx > 1000$ K/s	Cuboid sample $\approx 100 \times 100 \times 30$ μ m

Fig. 7 Heat flow raw data during device-specific relatively fast cooling of about 1700 mg EN AW-Al Zn6CuMgZr(A) in a Calvet-type heat flow DSC Setaram 121 DSC showing evaluation limits

The latter metrological issue is more pronounced for large sample masses and large addenda^{*} heat capacities of the DSC device, which is basically most critical for the high-precision Calvet-type DSC devices. Beside the metrological reliability, one has to ensure that the interesting reactions in the sample are already finished before losing cooling control. Otherwise, one has, for instance, to use the next faster DSC device if available.

As will be demonstrated later, the amount of precipitation heat released decreases with increasing cooling rate when approaching the upper critical cooling rate. This is because precipitation reactions are driven by diffusion, and precipitation is increasingly suppressed if the time available for diffusion shortens. One technologically very important aim of these studies is the detection of the upper critical cooling rate at which precipitation during cooling is suppressed completely. All alloying elements dissolved during previous solution annealing will remain in supersaturated solid solution. For the DSC analysis, the measure of the precipitation intensity is the specific heat (or enthalpy) released by the precipitation. Reaching the upper critical cooling rate, of course the enthalpy change by precipitation

is zero. This leads to a metrological problem: in the cooling rate range close to the upper critical cooling rate, one has to determine if no precipitation heat is detectable in the measured curves. The challenge is to decide when a precipitation peak is above the noise level. Therefore, an objective criterion is needed, and the detection limit was defined in the following way:^[7]

- The reaction is detectable in at least three repeated experiments.
- The reaction is detectable also at the next slower cooling rate.
- The specific precipitation heat is at least 0.1 J/g.
- Peak temperatures are in the same region as for the next slower rate.

For correct curve interpretation, the evaluation must be done starting from the slowest to faster cooling.

DIRECT AND INDIRECT MEASUREMENT OF PRECIPITATION ENTHALPIES

Heating Experiments

In Situ Investigation of Dissolution and Precipitation Behavior during Heating of a Certain Initial Microstructural State

Figure 8 displays a direct comparison of the initial conditions: EN AW-Al SiMg(A) “naturally aged” (T4), “artificially aged” (T6), and overaged by means of DSC heating curves at 0.1 K/s. The dotted straight line represents the zero level. In general, deviations exceeding this

^{*}The addenda heat capacity is the heat capacity of the heated part of the sample platform and other heated parts of the measuring system, e.g., the oven in conventional DSCs or even the heated gas in the surrounding of a chip sensor. Unfortunately, the addenda heat capacity of the calorimeter may depend on the sample itself. This is particularly true for chip calorimeters, where the addenda heat capacity depends on the area of the chip covered by the sample. In conventional DSCs, the sample heat capacity is generally smaller than the addenda heat capacity and the sample is only a small perturbation to the whole measuring system. For chip calorimeters, this may be no longer true and additional problems occur.

Fig. 8 Comparison of initial conditions T4, T6, and overaged of EN AW-Al SiMg(A) during heating with 0.1 K/s^[25]

level upward indicate endothermic dissolution reactions and downward exothermic precipitation reactions. For the interpretation, one must be aware of the fact that a DSC measures the sum of all running reactions. This means that if one exothermic and one endothermic reaction with the same enthalpy change run in parallel the sum signal will be zero. Therefore, interpreting the DSC heating curves of aluminum alloys quantitatively is difficult and must be handled with care.

There is an obvious alternation of endothermic and exothermic peaks corresponding to the dominating microstructural dissolution and precipitation processes, respectively. For initial condition T4 (quenched in water, stored at 25°C for 8 days), an endothermic peak A starts at about 140°C. This endothermic effect should correspond to dissolution of GP zones (e.g., Ref. [26]), precipitated during initial natural aging. Peak A₁ is followed by two exothermic processes b and c. According to the generally accepted precipitation sequence,^[1] peak b very likely corresponds to precipitation of β'' . In T6 (quenched in water, aged at 180°C for 4 h) and overaged (quenched in water, aged at 200°C for 10 h), initial condition peak A₁ and peak b are not present. Therefore, another endothermic dissolution peak A₂ occurs at about the same temperatures as the precipitation peak b in T4. Here, β'' should already have been precipitated during the initial artificial aging. Hence (at least almost), no β'' precipitation occurs during heating of T6 and the overaged initial condition. Instead, there is a dissolution reaction A₂ at higher temperatures compared to A₁ in the T4 condition. Here, the precipitates present in T6 and the overaged state are very likely at least partially dissolved. At temperatures higher than about 280°C, the reactions of all the initial conditions behave similarly, going on with an exothermic peak c, which very likely corresponds to precipitation of phases like β' and B'.^[1,27] Above about 320°C, the DSC curves show a sequence of endothermic peak D, exothermic peak e, and endothermic peak F. The peak area of peak e is much smaller than the peak area of peak F. This indicates a superposition of several reactions.

According to the precipitation sequence,^[1] exothermic peak e should correspond to the precipitation of equilibrium phase β -Mg₂Si and excess Si. Endothermic peak F should be the final dissolution. Due to the fact that, during endothermic peak D, precipitates remaining from initial treatment and/or grown during exothermic reactions b or c should already be dissolved, it is assumed that the peaks D, e, and F are a superposition of coexisting dissolution and precipitation. Also, it might be possible that precipitates like β' from low-temperature precipitation processes directly transform to β .^[1] In any case, in the high-temperature region above 320°C, the endothermic reactions dominate.

Figure 9 shows heating rate-dependent DSC curves of the four different initial conditions of the investigated alloy EN AW-Al SiMg(A): (a) T4, (b) T6, (c) overaged, and (d) soft annealed. All the diagrams in Fig. 9 have the same scaling. The DSC curves are shifted and arranged in order of increasing heating rate, starting with the slowest rate on top. In condition T4 at the slowest heating rate of 0.01 K/s, an endothermic peak A₁ starts at about 140°C, shifting to about 195°C at 5 K/s. Peak A₁ is followed by two exothermic processes b and c, which increasingly overlap with increasing rate, and at rates higher than 1 K/s, they cannot be distinguished any more. One unexpected fact is that the endothermic peak A₁ increases in intensity, which can be measured by means of the peak area, with increasing heating rate. Because the endothermic processes running here are diffusion-controlled dissolution reactions, it is not likely that such a process increases with increasing rate or decreasing reaction time. One possible explanation of the increase of the peak A₁ area with increasing heating rate is that the overlapping exothermic effect b (and c) is suppressed much stronger with increasing heating rate than the endothermic effect. This highlights the problem of overlapping reactions and one has to state that a peak in the DSC signal is not necessarily equivalent to the intensity maximum of a microstructural reaction. However, at least exothermic DSC signals indicate the domination of precipitation, while endothermic DSC signals indicate the domination of dissolution reactions in the microstructure. The overlapping and superposition issue implies that the evaluation of kinetic parameters, e.g., for precipitation reactions based on DSC heating curves, must be handled with care. Some of the evaluation methods for kinetic parameters, like the Kissinger method, utilize a single peak for evaluation—which, based on the above results, obviously brings with it the danger of misinterpretation. Moreover, all the methods to evaluate kinetic data from DSC heating curves are based on the assumption that the transformed fraction of alloying element atoms is constant and independent of the varying heating rates.^[28–30] This basic assumption also does not hold—in particular for a variation of heating rates in a wide dynamic range. This leads to the future task to develop new methods for the evaluation of kinetic parameters of microstructural reactions

Continuous heating of different initial conditions of EN AW-Al SiMg(A) to 580 °C

Fig. 9 DSC heating curves of four different initial conditions: (a) T4, (b) T6, (c) overaged, and (d) soft annealed of alloy EN AW-Al SiMg(A)^[25]

in aluminum alloys. Kinetic modeling might solve that task. Some available models already make it possible to combine both precipitation and dissolution to describe the whole DSC heating curve from room temperature up to the solvus temperature (e.g., Refs. [31–35]).

At higher temperatures in Fig. 9a, during heating with 0.01 K/s at about 275°C, an endothermic peak D starts. It is shifted about 140 K to 420°C at 5 K/s. Next, an exothermic peak e occurs, followed by the final endothermic peak F. At rate 0.01 K/s, peak F finishes at about 525°C, which is the solution temperature of this heating rate. Peak F and its finishing temperature could be observed up to about 1K/s. The finishing temperature shifts to about 560°C. At faster rates than 1K/s, there is no peak F detectable.

Figure 9b shows the DSC heating curves of the T6 initial condition. The peak shifts are similar to those observed in the T4 condition. This also applies for the overaged initial state, presented in Fig. 9c. The temperature difference of the peak shifts up to 170 K indicates that thermal lag does not dominate. In the PerkinElmer Pyris 1 used, the DSC

thermal lag should be in the order of about 10 K for the highest investigated heating rate of 5 K/s.^[36]

Heating of the initial soft annealed condition is presented in Fig. 9d. It shows significant differences from all the other initial conditions investigated. In the soft annealed state, most of the mass fraction of alloying element atoms is precipitated in very coarse Mg_2Si precipitates with dimensions up to about 10 μm .^[11,37] According to,^[11] a smaller part of the mass fraction is bound in relatively large needlelike β' and or B' precipitates with lengths up to about 1000 nm or more. Based on the results of,^[37] it is to be expected that these coarse precipitates bind the whole alloying element content. Hence, during heating of the soft annealed samples, no obvious exothermic effect but two endothermic dissolution processes have been detected. For a heating rate of 0.05 K/s, the dissolution is probably completely finished at 580°C—it can be seen in Fig. 9d that the excess heat capacity beyond the final dissolution peak drops back to zero. At least for the faster heating rates investigated, the dissolution reaction is incomplete. Thus, a critical heating

rate that applies for complete dissolution at a certain temperature exists. After faster heating to this particular temperature, soaking will be needed additionally to solve all the relevant alloying elements.

The integral of the heating curves—covering the full temperature range—gives information about the heat consumed by dissolution of the preexisting initial microstructural state. Integration is performed by the numeric approximation using the Origin software. The course of enthalpy change indicates running dissolution and precipitation reactions. The development of enthalpy change during heating with different heating rates is displayed in Fig. 10a using the example of EN AW-Al SiMg(A) T4. Therein the enthalpy levels at temperatures above the solution temperature are defined to be zero. The curves start at approximately -6 J/g (gray line) and run to zero (dotted line) caused by complete dissolution of all phases. The flatter course of the curves with increasing heating rates shows that more and more precipitation reactions are being suppressed. Nevertheless, the total amount of enthalpy change is identical.

The value of the total enthalpy change can help to assess the initial condition. If heating is performed slowly enough, the initial microstructure will dissolve completely. The characteristic enthalpy change in such cases can be defined as the enthalpy level of the initial condition. The value is expected to be constant as long as all phases are dissolved completely. In this example, this holds for the initial conditions T4, T6, and overaged. For these conditions, precipitates with a relatively low stability such

as clusters, GP zones, and β'' and/or β' form. In contrast, soft annealing leads to relatively stable precipitates—predominantly coarse (up to some $10\ \mu\text{m}$) equilibrium β (Mg_2Si) plates. These coarse precipitates cannot dissolve in short heating times. Therefore, in the investigated heating rate range of 0.01 – $5\ \text{K/s}$, the dissolution of these coarse secondary particles is not finished even at 600°C (Fig. 9d). The slower the heating, the more will be dissolved and the values of enthalpy change increase. However, the enthalpy level of the initial soft annealed state remains unknown since the slowest heating rate applied is still too fast. It is definitely larger than $15\ \text{J/g}$, as seen from Fig. 10e.

Figure 10b–d displays the average enthalpy change of each heating rate indicated by a scatter bar. Each heating rate has been repeated two to six times. Therefore, the error bars show the minimum and maximum value of all sample measurements from one heating rate. In addition, the average values of the enthalpy changes of all the investigated heating rates for any initial conditions T4, T6, and overaged are plotted as a straight line and an overall scatter band indicating the standard deviation. In this context, it should also be pointed out again that the elimination of the zero-level curvature has a significant effect on the enthalpy change. Hence, it is extremely important to proceed very carefully with elimination of bending. The enthalpy change increases in the order T4, T6, overaged, soft annealed from 6 , 10 , 12 up to $>15\ \text{J/g}$, respectively. This enthalpy change indicates the stability of the initial microstructure, which increases in the order T4, T6, overaged, soft annealed.

Fig. 10 Enthalpy change during heating of EN AW-Al SiMg(A): (a) T4, total enthalpy change at different heating rates (b) T4, (c) T6, (d) overaged, and (e) soft annealed^[18]

Fig. 11 Time-temperature profile and basic enthalpy changes of the reheating method

Indirect Determination of Precipitation Enthalpies during Slow Cooling by *Reheating*

A detailed analysis of alloys with very slow precipitation kinetics is hard to achieve with direct DSC cooling experiments, because an adequate statistical basis is very hard to obtain due to the extensive test durations. In order to determine the saturation value of enthalpy change for near-equilibrium phase changes in such alloys, an expansion of the cooling rate range to even lower rates than 0.0001 K/s is necessary. This is hard to achieve using any direct DSC cooling experiment with state-of-the-art devices due to the low signal-to-noise ratio. Instead several samples can be cooled in parallel in a controlled furnace and afterward an indirect DSC reheating approach is used to deal with the mentioned difficulties. With implementation of the reheating method, information on enthalpy changes caused by precipitation during cooling can be derived from the DSC experiments. Even though DSC heating curves of aluminum alloys are often difficult to interpret, quantitative information can be obtained, provided the zero level is determined accurately. The reheating method takes as a basis that the total enthalpy change in a closed thermodynamic loop equals zero under the premise that the starting and end points are in equilibrium. The schematic temperature-time profile, indicating the enthalpy changes for the reheating method, is shown in Fig. 11. For the given problem, the complete solid solution at the end of the solution annealing process can be defined as such an equilibrium state with a precipitation enthalpy value of $H_0 = 0$.

During slow cooling from solution annealing, exothermic precipitation reactions take place, causing a negative enthalpy change ΔH_C . Provided that the same equilibrium state H_0 as before is achieved after a reheating cycle (with a higher rate) following the cooling process, the sum of enthalpy changes of the cooling step ΔH_C and the reheating step ΔH_{RH} must be zero ($\Delta H_C + \Delta H_{RH} = 0$). For a sample cooled at a specific rate, a defined sequence of exothermic and endothermic reactions is detectable during the reheating cycle (Fig. 12). The equilibrium state is achieved when all reactions are completed (at the solution temperature)

before the annealing temperature T_{an} is reached, i.e., the temperature exceeds the solution temperature of the applied scanning rate. For equilibrium like slow cooling, the solution temperature equals the solvus temperature. If this is the case, all the precipitated particles that have been formed during previous cooling and during the reheating step are redissolved, and a complete solid solution and the enthalpy value H_0 are restored.

On the condition that the equilibrium state is achieved after reheating, ΔH_C can be calculated directly from the DSC curves of the heating step. For optimal control and evaluation of the corresponding zero level, it is recommended that the sample temperature exceeds the corresponding solution temperature by some 10 K. In that case, after baseline-measurement subtraction, zero-level bending correction can be performed (see Fig. 4). The essential benefit of this reheating method is the possibility to study the phase transformations for cooling rates, which is unattainable with direct DSC measurements. Another significant advantage is the reduced duration of experiments directly performed in DSC devices because the first thermal cycle comprising solution annealing and the cooling process can be executed simultaneously on various samples in an appropriate furnace. Therefore, solution annealing and slow cooling at a nearly constant rate are realized in a chamber furnace Carbolite CWF 11/13 equipped with an Invensys Eurotherm nanodac™ recorder/controller for cascade control. Prior to heat treatment, the samples are commonly sealed in quartz glass tubes under vacuum in order to prevent surface reactions and thus changes in chemical composition. In addition to near-equilibrium slow cooling rates, the as-quenched condition after cooling in water is typically analyzed as a reference and control measurement. After the cooling process, samples are stored at about -80°C to suppress further potential precipitation reactions before they are reheated in the Setaram C600 DSC. A heating rate of 0.003 K/s is optimal for this DSC device. At least two experiments should be carried out for each material condition.

Figure 12 schematically shows the excess specific heat capacity (a) and corresponding enthalpy change (b) as a function of temperature on the example of reheating an Al-0.72Si sample after cooling at 0.005 K/s. The enthalpy curve is obtained by integrating the excess heat capacity. Above the solution temperature, all previously existing (and basically solvable) precipitates are dissolved, and the alloying elements are in solid solution with the aluminum matrix—i.e., the enthalpy state H_0 is reached. The enthalpy difference between the starting and the end values in Fig. 12 corresponds to the initial enthalpy state of the initial microstructural state. If the cooling rate is now varied to adjust different initial states, one can follow the enthalpy evolution of the initial states of interest.

The variation of cooling rates in the furnace can theoretically be extremely slow. This matter depends more on how long one wants to wait. In any case, one has to

Fig. 12 Excess c_p and excess enthalpy during reheating of a previously slow-cooled sample

ensure that the coarse precipitates grown during slow cooling can be dissolved during the much faster reheating. This will require a certain overheating, i.e., heating above the equilibrium solvus temperature and some tens of K above. However, not every alloying system allows a large overheating temperature interval. In this respect, for example, lower concentrated Al-Si and Al-Mg-Si alloys are typically uncritical. Higher concentrated Al-Zn-Mg(-Cu) and Al-Cu alloys typically possess annealing temperatures much closer to the solidus respectively eutectic temperatures. Therefore, overheating of the latter brings with it the danger of (partial) melting, which must be avoided. However, the reheating approach might be very efficient, as the investment costs of the furnace are only about 10% of the DSC device. Moreover, several samples can be treated at the same time, allowing a reasonable statistical validation in the DSC in reasonable experimental times for very slow cooling rates.

Determination of Precipitation Enthalpy and Characteristic Temperatures/Times from Cooling Experiments

In Situ Cooling Experiments with Constant Cooling rates (Linear Cooling)

Measurement of excess c_p during cooling, as explained above, allows one to determine the characteristic start and end times/temperatures of reactions. The results will be demonstrated in the “Precipitation behaviour during cooling from solution annealing for three aluminium alloys with very different precipitation kinetics” section.

In several cases, different reactions overlap and add some heat contribution to the DSC signal. During cooling, only precipitation reactions are expected—this generally makes the interpretation of DSC cooling curves much easier compared to heating curves. Nevertheless, to distinguish several overlapping reactions might still be a difficult task. As a relatively simple approach, one can use the local minima between two peaks to estimate the start and end of the related microstructural reactions. Figure 13a shows an example

dividing the DSC curve into two dominating reactions. Limited by these characteristic temperatures, integration determines the enthalpy changes—Fig. 13b. A more detailed separation between all the enthalpy changes of the underlying reactions and their detailed start and end temperatures would require intensive knowledge of the microstructural evolution (which requires transmission electron microscopy (TEM) work on a large amount of samples). Moreover, only physically based and temperature-dependent models will be able in future to make further progress in DSC peak separation. Up-to-date models that are able to predict whole DSC curves exist only for heating curves, and their validation is typically limited to a narrow experimental heating rate range (e.g., Refs. [31–35]).

Determination of Precipitation Enthalpy during Fast Cooling by Differential Reheating

Currently, “conventional” DSC for controlled cooling is limited to somewhere below 10 K/s. For significantly faster cooling rates, nowadays chip-based differential fast

Fig. 13 Evaluation of cooling curves by section-wise integration^[13]

scanning calorimeters (DFSC) exist (e.g., Refs. [38,39]). Very fast cooling and heating can only be achieved using extremely small samples. Sensors which are used in the DFSC are based on silicon nitride membranes because they have a low addenda heat capacity. Scanning rates up to 1,000,000 K/s can be realized,^[38] but the devices have low sensitivity below about 1,000 K/s. Therefore, the particularly interesting cooling rate range between 5 K/s and some 100 K/s is still too slow for in situ investigations in these devices. Appropriate samples typically possess dimensions in the micrometer range and therefore the signal-to-noise ratio at rates below about 1000 K/s is bad. Unfortunately, the cooling rate range between about 10 K/s and some 100 K/s particularly seems to be about the range for the upper critical cooling rates of highly concentrated technical aluminum alloys and is therefore of special interest for our work. To overcome this metrological problem, we developed an indirect *differential reheating method* (DRM),^[8] which allows us to determine the enthalpy of precipitation on cooling from reheating scans at an appropriate scanning rate for the DFSC device (e.g., 1000 K/s).

The basic idea of the DRM is to study the dissolution of precipitates formed on previous cooling by a reheating experiment similar to the method described in “Heating Experiments” section. While the method described in “Heating Experiments” section requires the integration of a baseline-corrected excess heat capacity curve, the method discussed here uses a reference scan from the same sample to obtain the enthalpy change on cooling. This is required since sample preparation issues in DFSC do not allow unambiguous determination of excess heat capacity.

If certain conditions apply, the enthalpy change caused by quench-induced precipitation can be determined from a subsequent reheating experiment. This holds for a thermodynamically closed loop in enthalpy, which starts at a certain equilibrium enthalpy level. For the relevant aluminum alloys, the end of the solution annealing can be considered as such an equilibrium state and its enthalpy can again be defined as H_0 . In Fig. 14a, the time–temperature profile of the DRM is shown schematically, consisting of two closed loops in temperature—starting and ending at the solution annealing temperature.

For validation of the DRM method, a comparable direct measurement of an EN AW-Al Mg0.7Si sample versus a pure aluminum in a PerkinElmer Pyris 1 DSC is presented in Fig. 14. In Fig. 14b, the corresponding progress of the excess heat capacity and in Fig. 14c the related enthalpy changes are plotted.

If we assume that, independently of the temperature path, the same thermodynamic state H_0 is reached at the annealing temperature after reheating, then the total enthalpy change for both cooling–reheating cycles equals zero (closed loop). When the system is cooled undercritically from the solution annealing temperature, precipitation occurs—causing an enthalpy change ΔH_c —which is of particular interest. For the temperature equilibration at low temperatures, one has to ensure that no further enthalpy change occurs. Therefore, temperature equilibration can be done, e.g., at -20°C for 10 ms. After this temperature equilibration, the sample is reheated back to the annealing temperature (completing the first closed loop). Thereby, additional precipitation may occur but finally all

Fig. 14 (a) Time–temperature profile and enthalpy difference scheme of the DRM. (b) Measured excess heat capacity curves from Pyris-1 DSC (PerkinElmer) for two closed thermal loops for EN AW-Al Mg0.7Si. Adapted from Zohrabyan et al.^[8]

precipitates, including those formed during first cooling, dissolve. (For the correctness of this method, it is important to ensure the latter.) This first reheating causes a total enthalpy change ΔH_{HI} . Considering the closed loop idea, this enthalpy change has to possess the same value as the amount of enthalpy change during slow cooling ΔH_C . If one is able to precisely determine this enthalpy change during the reheating step, one can evaluate the interesting enthalpy change of relatively slow cooling. However, as handmade samples are still commonly used in DFSC, the basic attempt to measure excess heat capacity fails in this case—normally only one sensor of the differential chip system is loaded with a sample. Nevertheless, the integral of the heat capacity gives the desired enthalpy change. In this case, the first reheating DFSC curve contains not only the enthalpy change caused by the precipitation during slow cooling but also device-dependent deviations (abbreviated BL for baseline in Fig. 14a) and further deviations resulting from the increase of the sample heat capacity (abbreviated c_p in Fig. 14a).

Therefore, another way of achieving the enthalpy change must be utilized. The closed loop idea is utilized again and a second closed loop is added, acting as “baseline-measurement.” After the second solution annealing, the sample is therefore cooled with an overcritical cooling rate (i.e., applying a very fast cooling rate between about 10^4 – 10^5 K/s). During this overcritical cooling, nothing is precipitating because there is not enough time for nucleation and growth of the precipitates. The related enthalpy change is $\Delta H_{OC} = 0$. The subsequent reheating (performed with identical parameters to the first one) back to the annealing temperature shows some thermal effects due to precipitation and dissolution on relatively slow heating (1000 K/s). Besides, the DFSC curve also contains the undesired baseline and sample- c_p contributions mentioned above. Hence, this second closed loop acts perfectly as a baseline measurement. If one subtracts this from the first reheating curve, the differential curve now only contains those enthalpy changes caused by precipitation during slow cooling. However, the resulting differential curve is only suitable for quantitative interpretation of the total enthalpy change, that is, the integral over the whole curve. Integration thereby determines the desired ΔH_C . Reference^[8] describes the method in more detail.

Precipitation Behavior during Cooling from Solution Annealing for Three Aluminum Alloys with Very Different Precipitation Kinetics

Alloy with Relatively Slow Precipitation Kinetics—Pure Binary Al-0.72Si

Pure binary Al-Si has a low technical importance. Nevertheless, Si as an alloying element is used frequently. For an understanding of the influence of Si in the aluminum alloying systems, it is worthwhile to consider pure Al-Si.

Figure 15 shows characteristic excess specific heat capacity curves for an Al-0.72Si alloy during cooling after solution annealing. The curves are shifted vertically and arranged in order of increasing cooling rate. DSC devices used for different cooling rate ranges are displayed. Exothermic precipitation reactions are shown by deviations exceeding the zero level, which are given by a dashed line for each curve.

It can be seen that the precipitation temperatures and precipitation intensities depend on the cooling rate. This can be explained by the suppression of diffusion processes. As only the diamond cubic Si-rich phase ($a = 0.542$ nm) is likely to occur,^[1,40] the occurrence of two reaction peaks for the alloy Al-0.72Si within the analyzed cooling rate range is surprising. However, in the microstructure we clearly found two different precipitate particles possessing significantly different morphologies.^[9] Both are the diamond cubic Si-rich phase. For the slowest cooling rate investigated by direct cooling DSC, precipitation reactions in Al-0.72Si start at about 475°C, which is very close to the solvus temperature regarding the simple eutectic phase diagram^[41] of this binary alloy system. A high temperature precipitation peak is dominant at this cooling condition, but is suppressed significantly in its intensity and shifted toward lower temperatures as the cooling rate increases. While the high-temperature reaction (HTR) is suppressed, another peak at lower temperatures rises to a maximum and shifts to higher temperatures. Further increase in the cooling rate results in a decrease in this low temperature peak area as well. Simultaneously, the peak of these low-temperature reactions (LTRs) changes its shifting direction to lower temperatures. The upper critical cooling rate of Al-0.72Si is about 1 K/s. One reason for the urgent need to investigate very slow cooling rates becomes obvious when even slower cooling than 0.01 K/s is investigated (about the slowest rate of the Calvet-type Setaram 121 DSC). While the cooling

Fig. 15 Selected DSC curves of cooling Al-0.72Si from 540°C 20 min^[9]

curve for 0.01 K/s already shows indications that at least two reaction peaks overlap in the temperature range around 400°C, this precipitation behavior can only be proven with investigation of slower cooling rates. With the extension of the cooling rate range with the Setaram C600 DSC possessing high precision Calvet detectors, the existence of a HTR and a LTR peak is revealed.

In order to establish the saturation level of enthalpy change for near-equilibrium phase changes, DSC reheating experiments after cooling with rates down to 0.0001 K/s (60 days cooling from solution annealing) were carried out. Figure 16a shows DSC reheating curves of alloy Al-0.72Si in different initial conditions. The precipitation and dissolution sequence during the heating cycle is heavily dependent on the preceding cooling condition. In general, the sequence comprises exothermic precipitation reactions and endothermic reactions at higher temperature, which can be attributed to the dissolution of particles. The lower the cooling rate chosen in the previous heat treatment, the more alloying elements are already precipitated during the cooling step. Consequently, supersaturation of the solid solution reduces, and less Si can precipitate upon reheating. Hence, the intensity of the exothermic peak (a) decreases with a reduction of the cooling rate. Peak (a) disappears when supersaturation after cooling becomes sufficiently small for precipitation upon heating.

The criterion for the completion of precipitation during cooling should be to maximize the integral of dissolution heat during heating. In that case, all alloying elements that are insoluble in equilibrium condition at room temperature have been precipitated during previous cooling. In practice, this should be quite close to the case when peak (a) disappears completely. Therefore, from the DSC reheating results a lower critical cooling rate of about 0.0001 K/s can be estimated for Al-0.72Si. However, validation of a stable saturation level enthalpy change is still missing—the next slower experiment with 3×10^{-5} K/s (cooling duration about ½ year) revealed a slightly increased enthalpy change.

Endothermic dissolution peaks (B_1 and B_2) are present at higher temperatures. These peaks are shifted to higher temperatures with decreasing cooling rate. This indicates

that particles formed at low cooling rates dissolve more slowly than those precipitated in faster cooling conditions. However, the DSC reheating curves show that all dissolution reactions are completed before 570°C for all initial conditions and thus a complete solid solution is reached. As a result, the enthalpy change ΔH_c evoked by the cooling step can be evaluated from the DSC reheating curves.

In Fig. 16b, the enthalpy change ΔH of the different conditions in Fig. 16a during reheating with a heating rate of 0.003 K/s is plotted. At high temperatures, the equilibrium condition H_0 is reached, and this enthalpy level is defined as zero. As no precipitation reactions take place during water quenching, the enthalpy level should be equal in both the initial and annealing conditions. When the water-quenched condition is reheated, the enthalpy evolution indeed starts at the zero level. The precipitation reactions that occur on heating lead to a decrease in enthalpy first. At higher temperatures, the dissolution of precipitated particles causes endothermic reactions. This results in an increase in enthalpy until the equilibrium level is reached again. The high-temperature equilibrium level is also achieved after heating of all other initial conditions to 570°C. However, in these states, quench-induced precipitates exist initially and the initial enthalpy state is therefore negative compared to equilibrium, and this moreover differs in dependence on the cooling rate. The initial value of enthalpy change therefore equals ΔH_c .

Figure 17 shows the enthalpy change $|\Delta H_c|$, after cooling to RT from solution annealing as a function of the cooling rate. Both data from direct DSC cooling experiments and the values derived with the reheating method are plotted. The error of 10% results from the uncertainty in the determination of the peak area from DSC data. The data obtained from both methods are in good agreement, verifying the feasibility of the reheating method.

With DSC reheating experiments, the examinable cooling rate range can thereby be extended significantly, covering a dynamic width of five orders of magnitude between 2 and 0.0001 K/s in this example. However, if one has time to wait for the results, even much slower cooling is accessible

Fig. 16 (a) DSC reheating curves of previously slow cooled Al-0.72Si samples and (b) corresponding enthalpy development^[9]

Fig. 17 Precipitation enthalpy for cooling of Al-0.72Si from 540°C 20 min over five orders of magnitude. The model used for fitting is given in^[9]

with this method. Beside the experimental results, a model fit is plotted. This model further allows one to determine the amount of Si dissolved in solid solution^[9] and thereby makes it possible to adjust the precise material conditions, which is particularly helpful if one wishes to investigate the influence of dissolved Si on the mechanical properties of the alloy.

Figure 18 exemplarily shows the enthalpy change during cooling with two different cooling rates out of Fig. 15. We here aimed to adjust two material conditions of Al-0.72Si which possess a mass fraction of 0.26% Si dissolved in solid solution: a condition with finer precipitates resulted from cooling with 0.01 K/s to room temperature, and a condition with coarser precipitates from cooling with 0.001 K/s to 400°C and further rapid quenching.

The two chosen cooling rates are each dominated by one of the different peaks—0.001 K/s is dominated by the HTR, while 0.01 K/s is dominated by the LTR. Thereby, samples having an equal amount of solute Si but different precipitation states can be tested in order to investigate their influence on the mechanical behavior. A big advantage of this method is that the strengthening contribution of solutes and precipitates can be determined separately, and in particular without the need to assume any—potentially inaccurate—superposition law between particle and solute

Fig. 18 Enthalpy change of Al-0.72Si for two cooling rates and corresponding mass fraction of Si in solid solution as function of temperature

strengthening. Figure 19 plots stress–strain curves of different Al-Si alloys in different microstructural states. The precipitate-free conditions of both alloys show different flow characteristics (Fig. 19a). A higher amount of solute Si enhances the yield strength of Al-Si alloys. However, comparison to pure Al 99.99 shows that the strengthening effect of Si is rather small. While a higher solute Si amount results only in a slight increase in yield strength, work hardening is strongly influenced by the Si content. Increased work hardening compared to Al 99.99 was observed in both Al-Si alloys.

By comparison of conditions having an equal solute Si content of 0.26 mass % but different precipitation states, identical yield strengths were observed for all conditions (Fig. 19b). This indicates that both precipitate types formed during cooling have no impact on yield strength. However, the influence of precipitated particles becomes significant as the strain increases. Higher strain hardening at the initial stage of plastic deformation was observed for samples containing precipitates. Interestingly, work hardening is much stronger in Al-0.72Si samples with small rod-/platelet-like particles, which are formed during cooling at lower temperatures. The strength of this condition even exceeds the precipitate-free Al-0.72Si state (Fig. 19a) in the strain range between 0.01 and 0.06. The results clearly show that quench-induced precipitates in Al-Si can influence the mechanical properties despite their relatively large sizes. While coarse high temperature precipitates with low aspect ratios seem to have a very low strength contribution, the smaller rod-/platelet-shaped precipitates formed at lower temperatures clearly influence work hardening.

Alloy with Medium Quench Sensitivity—EN AW-Al SiMg(A) and Brief Comparison with Other Al-Mg-Si Alloys

The next example of EN AW-Al SiMg(A) is of much higher technical importance. Polmear states in:^[1] “Al-Mg-Si alloys are widely used as medium-strength structural alloys which have the additional advantages of good weldability, corrosion resistance, and immunity to stress-corrosion cracking. (...) The Al-Mg-Si alloys are used for the majority of extrusions, with smaller quantities being available as sheet and plate.”

Figure 20a plots selected DSC cooling curves of a commercially extruded EN AW-Al SiMg(A) wrought alloy (plot setup similar to Fig. 15). Exothermic precipitation occurs in two dominating reactions: HTR and LTR. It can be seen that in also this alloy the precipitation reactions are significantly influenced by the cooling rate. The HTR cannot be detected any more at 100 K/min, whereas the LTRs are still present. At 375 K/min (6.25 K/s), no reaction at all can be detected and the critical cooling rate suppressing all precipitation during cooling is reached.

Fig. 19 Comparison of stress–strain curves of Al-0.26Si and Al-0.72Si at 30°C to investigate strengthening contribution of (a) solute Si and (b) quench-induced precipitates in Al-Si alloys (strain rate: 10^{-1}s^{-1})

Fig. 20 (a) Selected DSC curves of cooling EN AW-Al SiMg(A) from 540°C 20 min.^[13] (b) Corresponding enthalpy change and hardness after additional artificial peak aging. Adapted from Milkereit and Starink.^[13]

The section of the curve measured with 375 K/min shown here possesses a relatively narrow temperature range. Due to this—with respect to the limitations of the particular DSC device used—very fast cooling rate, at higher temperatures the overshoot artifact disturbs the DSC signal (overshoot cut and not plotted). At lower temperatures, the device runs out of control (out of control section cut and not plotted). For the particular setup used, this rate is already close to the experimental limit. It is known that one driving factor for the quench sensitivity and the critical cooling rate of an aluminum alloy is its concentration of alloying elements. The higher this concentration, the higher the quench sensitivity will generally be.^[1,11,13,21,42] As the investigated alloy EN AW-Al SiMg(A) is a medium-concentrated aluminum alloy, one can conclude that some alloys will need much faster cooling rates than can be studied by “conventional” DSC.

It was shown that the HTRs dominantly correspond to the precipitation of Mg_2Si , while the LTRs are dominated by the precipitation of Mg_2Si precursor phases.^[11,37] Selected area electron diffraction analysis in a TEM showed a diffraction pattern from which the precipitation of β' and B' can be concluded.^[11] Recent work showed evidence that mainly B' is involved in the LTR.^[13] Figure 20b plots the corresponding enthalpy changes for the total amount of precipitation, as well as for the HTR and the LTR, evaluated according to Fig. 13. Besides, the resulting hardness after cooling and additional artificial aging (25°C 7 min + 180°C 4 h) is plotted. At the upper critical cooling rate, the total enthalpy change reaches zero and the hardness reaches a saturation level.

Recently, a new physically based model was introduced by Milkereit and Starink.^[13] The model allows one to predict the quench sensitivity for the technologically

important step of cooling from solution annealing during the age hardening procedure of Al-Mg-Si alloys. The model considers two consecutive precipitation reactions during cooling: β -Mg₂Si and B'. The model predicts the volume fraction of precipitates formed with the corresponding enthalpy changes, and both yield strength and hardness in the quenched and in the quenched + aged condition. For its setup, the model combines moreover the latest findings in the modeling of diffusion-controlled phase transformations and in modeling of the thermodynamics of technically important complex alloy systems,^[43,44] including first principles modeling.^[45] For the setup and testing of the model, an extensive set of experimental results from DSC, optical and electron microscopy, and X-ray diffraction was considered. Selected parts of the model predictions for enthalpy and hardness values are shown in Fig. 20b. Comparing the experimental results in a very wide dynamic range for enthalpy change, Mg₂Si volume fractions (not shown here), and T6 hardness, the model delivers generally excellent fits. Application of the model will help to optimize the exploitation of the age hardening potential of the widely used Al-Mg-Si alloys. See reference^[13] for model details and further results.

Considering the total precipitation enthalpy progress in Fig. 20b, it is worthwhile to briefly discuss the steplike increase, which was measured and predicted. Initially, we expected a sigmoidal progress, as shown above for Al-0.72Si, rather than trusting this stepwise measured progress. However, in developing the new model approach, we learned that this stepwise progress can be considered to be true. The explanation is astonishingly simple: the total precipitation enthalpy is the sum of the HTR and LTR. Referred to as a mol of atoms, the precipitation of the equilibrium phase Mg₂Si (HTR) possesses a significantly higher precipitation enthalpy than its precursor phase B' (LTR).^[13] For example, the second step in the total enthalpy change curve, starting at about 1 K/min, is simply related to the fact that at slower rates the precipitation of Mg₂Si dominates.

In heat treatment shops, appropriate heat-treatment parameters must frequently be chosen. This also holds for the optimal quenching rate or quenching media, respectively. Ostermann^[46] assessed different literature sources and plots a figure which gives the average cooling rate between 400°C and 290°C in dependence on the material thickness for the use of cold and warm water, glycol–water mixtures, calm and moved air (Bild 3.2.43 on page 179 in^[46]). This can give a hint on how fast the use of a certain medium will be for the relevant part. However, one has also to know how fast the alloy needs to be cooled. Therefore, the essentials of the above-described DSC results, relevant for the technical practitioner, are typically summarized in continuous cooling precipitation diagrams. Precipitation start and end temperatures from several cooling rates were plotted together in one temperature/time diagram. Such diagrams correspond to the continuous

cooling transformations diagrams of steels. The latter have been known for several decades and are available today for nearly every technically important steel. For aluminum alloys, these diagrams could first be recorded to a meaningful extent by the described DSC techniques.^[7]

Figure 21 plots one example of such a diagram. One has to mention that these diagrams are only valid for the detailed investigated batch (chemical composition, grain structure ...) and solution annealing parameters. To date, such continuous cooling precipitation diagrams measured by DSC are available only for a relatively small range of different alloys: five different Al-Mg-Si wrought alloys,^[11] one Al-Si-Mg cast alloy,^[12] and three Al-Zn-Mg(-Cu) alloys.^[21,22] Nevertheless, so far we have not managed to apply the full range of DSC devices available and thereby cooling rates to one single batch. Therefore, there is still some potential for completing these diagrams.

Figure 22 demonstrates that slight variation in the chemical composition might affect the critical cooling rate dramatically. It compares five different Al-Mg-Si alloys in terms of the enthalpy changes during cooling and the resulting hardness after additional aging. The upper critical cooling rate of the alloys is reached when the enthalpy change during cooling is zero and simultaneously the hardness just reaches its saturation level. Faster quenching will not enhance the mechanical properties but might induce significant residual stresses.^[47,48] Two particularly remarkable aspects are addressed: first, just within the standard composition window of EN-AW-6082, the upper critical cooling rate can already vary by a factor of 10. This demonstrates the “batch sensitivity” of this quenching issue. Second, sometimes one might be restricted to use a certain limited cooling process. Then a lower alloyed composition might lead to higher final hardness and strength.

For instance, if one is restricted to about 100 K/min (or 2 K/s), EN AW-Al SiMg(A) will reach the maximum hardness, whereas the hardness of the highest alloyed EN AW-Al SiMgMn_{high} (EN AW-6082_{high}) is significantly

Fig. 21 Continuous cooling precipitation diagram of one batch of EN AW-Al SiMg(A) (= EN AW-6005A)^[11]

Fig. 22 Comparison of five different Al-Mg-Si alloys by specific precipitation heat after cooling following solution annealing at 540°C 20 min (a) and Vickers hardness after artificial aging (b) as functions of cooling rate^[11] (EN AW-6060 = EN AW-Al MgSi, EN AW-6063 = EN AW-Al Mg0.7Si, EN AW-6005A = EN AW-Al SiMg(A), EN AW-6082_{low} = EN AW-Al Si1MgMn_{low}, and EN AW-6082_{high} = EN AW-Al Si1MgMn_{high})

lower. Of course, the latter would reach a significantly higher hardness than EN AW-Al SiMg(A) if its full potential were exploited by quenching with more than 130 K/s.

Highly Quench-sensitive Aluminum Alloy: EN AW-Al Zn8MgCu

As a further experimental outcome, one can also conclude from Fig. 22 that conventional DSC, limited for cooling somewhere below 10 K/s or 600 K/min, is not able to investigate the full range of technically relevant and highly concentrated alloys. Unfortunately, just these highly concentrated alloys can reach the highest mechanical values and are therefore of significant technical importance. This particularly applies to Al-Zn-Mg(-Cu) alloys, which can obtain the highest strength and are therefore utilized for aerospace applications. One example of these high-strength Al-Zn-Mg(-Cu) alloys further demonstrates the potential of the DFSC DRM in combination with conventional DSC. The excess specific heat capacity of one of the most highly concentrated aluminum wrought alloys available, EN AW-Al Zn8MgCu, during cooling from 470 °C 30 min with rates from 0.001 to 4 K/s is demonstrated in Fig. 23. This cooling rate range has been covered by

Fig. 23 Selected DSC curves of cooling EN AW-Al Zn8MgCu from 470°C 30 min^[22]

the three conventional DSC devices, Setaram 121 DSC, Mettler-Toledo 823 DSC, and PerkinElmer Pyris 1 DSC. The slowest cooling rate of 0.001 K/s is hard to evaluate—for rates slower than 0.01 K/s, the utilization of, e.g., the Setaram C600 DSC is recommended and would give much better results. This device was not available when we recorded the following results.

However, from 0.025 to 4 K/s, the excess specific heat capacity shows at least two overlapping main peaks. The first relatively sharp peak (high-temperature precipitation) starts at about 450 °C for low cooling rates. With increasing cooling rate, it shifts to lower temperatures. The second broad peak (low-temperature precipitation) is characterized by a slowly decreasing excess heat capacity down to a temperature of about 175 °C at 0.001 K/s. Separation of the two main peaks is hardly possible over the entire cooling rate range, whereas it is not possible at all cooling rates faster than 3 K/s. Precipitation reactions finish at 225 °C–250 °C for 4 K/s. The areas under the precipitation peaks become smaller with increasing cooling rate. They give the precipitation enthalpy change for the sum of all precipitates. The precipitation enthalpy change decreases steadily and continuously also at such cooling rates, where the DSC device has been changed. For low cooling rates, the precipitation heat amounts about 50 J/g. This precipitation heat is large compared to other aluminum alloys (e.g., Al-Mg-Si wrought alloys, Fig. 22^[11]), due to

the high alloying element content in EN AW-Al Zn8MgCu. With increasing cooling rate, the precipitation enthalpy change decreases down to 10–15 J/g at 4 K/s, i.e., the critical cooling rate is significantly higher. The precipitation behavior during cooling has been further investigated by DFSC and the *DRM* up to 5000 K/s.

The differential heat flow of aluminum alloy EN AW-Al Zn8MgCu during reheating after cooling is plotted in Figs. 24 and 25 for two sets of experiments. The initial cooling rates range from 0.125 to 5000 K/s.

Up to 4 K/s, they agree with experiments in the conventional DSCs. They show relatively large differential heat flow peaks that correspond to the dissolution of

quench-induced precipitation from preceding cooling. With increasing cooling rate, the differential heat flow peak areas during reheating decrease, as during the preceding cooling precipitation is increasingly suppressed. Thus, during reheating fewer precipitates are dissolved. It is remarkable that a scanning rate of 1000 K/s utilized for both reheating steps is fast enough to suppress any precipitation during reheating and only endothermic dissolution can be detected. However, it can also be seen that the differential reheating heat flow of the preceding cooling rates 0.125–1.5 K/s in Fig. 24 and 1–6 K/s in Fig. 25 does not drop back to zero when the solution annealing temperature of 470°C is reached. This shows that not all the quench-induced precipitates of the initial cooling could be dissolved, as they were too large to dissolve during the 1000 K/s reheating (= within 0.45 s). The differential heat flow at 470°C just drops back to zero for the preceding cooling rate 4 K/s (Fig. 24)/12 K/s (Fig. 25) (and faster). Thus, only the faster differential reheating curves can be used for further quantitative evaluation. The used samples have lateral dimensions of about 100 μm . This is already in the order of magnitude of the grain size. Therefore, the area of grain boundaries and other nucleation sites for precipitation but also the chemical composition between such small samples might vary. This explains not only the different states for which a full solution can be reached at 470°C but also the different critical cooling rates found. The critical cooling rates are reached if no dissolution can be detected any more during reheating, which is about 40 and 600 K/s for the examples in Figs. 24 and 25, respectively.

The area under the differential heat flow peaks has been evaluated for seven different samples, to average the chemical inhomogeneity of the very small samples. This results in seven sets of reheating experiments. Because the exact sample mass is unknown, the peak areas plotted in Fig. 26 are therefore given in arbitrary units.

Differential reheating EN AW-Al Zn8MgCu
Flash-1 DSC; 470 °C, 15 min; thermal paste: silicon oil

Fig. 24 Selected and shifted differential heat flow rates of aluminum alloy EN AW-Al Zn8MgCu during reheating after cooling with rates from 0.125 to 2000 K/s^[22]

Fig. 25 Selected differential heat flow rates of aluminum alloy EN AW-Al Zn8MgCu during reheating after cooling with rates from 1 to 5000 K/s

Fig. 26 Integrated peak areas of several DFSC DRM samples of EN AW-Al Zn8MgCu

Adapted from Zohrabayan et al.^[22]

Due to the demanding preparation of the very small DFSC samples and due to possible chemical inhomogeneity among these very small DFSC samples, the absolute peak areas differ relatively strongly. But the important result is that for all seven sets of reheating experiments, the peak areas reach the zero level at very similar cooling rates (with respect to the logarithmic scaling). This demonstrates that the DFSC experiments are reproducible. However, obviously a large number of DFSC experiments must be performed to gain statistical security.

The peak area reaches the zero level at 40–600 K/s, i.e., the average value determines the upper critical cooling rate of the alloy EN AW-Al Zn8MgCu is about 300 K/s. The remarkably high critical cooling rate is due to the very high amount of alloying elements in EN AW-Al Zn8MgCu (with respect to aluminum wrought alloys). Because of the cooling rate overlap between DSC and DFSC, the peak areas of DFSC can be normalized by the peak areas of the corresponding DSC tests. Figure 27 summarizes the precipitation heat of all DSC and DFSC experiments in the cooling rate range from 0.0005 to 2000 K/s, i.e., an investigated cooling rate range of seven orders of magnitude. The precipitation heat decreases continuously with increasing cooling rate down to the critical cooling rate

of 100–300 K/s. In addition, the hardness of cooled and additionally naturally aged samples (aging: 25°C 30 days) is plotted. Compared to the precipitation heat, the hardness after aging shows an opposite behavior and increases from about 60 HV1 at 0.0005 K/s to about 180 HV1 at 300 K/s. All the alloying element atoms lost in coarse precipitates during slow cooling cannot participate in strengthening by nanoscaled precipitates during aging.

Considering the precipitation enthalpy progress, a steplike increase of the enthalpy change can be seen, like that already measured for several Al-Mg-Si alloys,^[13] and discussed above for EN AW-Al SiMg(A). In the case of EN AW-Al Zn8MgCu, the Setaram 121 DSC was used for such slow cooling rates, at which this device normally already shows a bad signal-to-noise ratio. In this case, the very large amount of alloying elements allowed a slower use. Nevertheless, even slower cooling with the Setaram C600 DSC or with the indirect reheating method would be very interesting for the validation of thermokinetic models.^[9,13] Figure 27 again demonstrates the great potential of a combination of several DSC devices and methods. By combining all the introduced methods, the full dynamic range of physical interest is now accessible for all aluminum alloys.

Precipitation Kinetics during Controlled Nonlinear “Newtonian” Cooling

The quenching step in practical heat treatment is typically done by relatively simple methods like quenching in a water or oil bath. Cooling in calm or moved air is also common. Consequently, during real heat treatments the quenched components cool down nonlinearly rather than linearly, as typically investigated by DSC. To check if this difference in the cooling path influences the precipitation kinetics significantly, we also developed a DSC method to compare linear and controlled nonlinear cooling from solution annealing. Cooling curves of real gas

Fig. 27 Precipitation enthalpy change during cooling of EN AW-Al Zn8MgCu from 470°C and corresponding hardness after additional natural aging

Adapted from Zohrabayan et al.^[22]

Fig. 28 Heat flow curves from sample and baseline measurement and recalculated excess specific heat capacity during stepwise Newtonian cooling with $t_{[540,150]} = 5784$ s in a Setaram DSC 121. The inset shows the applied cooling rate (derivative of sample temperature) and its smooth fit, used for excess c_p calculation^[10]

cooling experiments^[49] were described mathematically^[10] by Newton's law of cooling (e.g., Ref. [50]). A method was developed to approximate these Newtonian cooling curves stepwise linearly. In two different types of DSC, overshooting problems at each stepwise change of linear cooling rate were successfully avoided, utilizing a cooling rate step size of only 5%.^[10] To allow comparison with linear experiments, the cooling duration between 540 °C and 150 °C was defined as the cooling path identifier. Figure 28 exemplarily shows one evaluation of such a controlled nonlinear Newtonian cooling experiment. For the required calculation of the excess specific heat capacity, a smooth fit to the actual applied cooling rate (derivative of sample temperature, see insert plot Fig. 28) was used. As an important outcome, the smooth heat capacity curves obtained show that it is possible to perform controlled nonlinear cooling experiments, simulating Newtonian cooling, in a DSC. Due to the smearing of sample temperature and heat flow rate signals, after switching from one rate to the next, the resulting heat capacity curves are unexpectedly

smooth. The quality of the curves is very reasonable and allows further evaluation of the precipitation reactions as discussed above. For further details, see.^[10] In principle, this method can also be transferred to nonlinear heating.

Figure 29 compares selected in situ DSC curves (a) measured with controlled nonlinear Newtonian and (b) linear cooling of an EN AW-Al Si1MgMn_{low} alloy after annealing 540 °C 20 min. Curves with relatively similar cooling durations between 540 °C and 150 °C are chosen. It is seen that the general behavior is very much the same. Figures 30 and 31 compare the enthalpy change caused by precipitation during cooling and the hardness after additional aging for Newtonian and linear cooling, respectively. Summarizing, the enthalpy changes as well as the resulting hardness values are similar for linear and Newtonian cooling. As the only difference, during Newtonian cooling for relatively short cooling durations, a slight shift of precipitation reactions to higher temperatures was detected.

Referring back to the initial question of this chapter, whether the difference in the cooling path influences the

Fig. 29 Comparison of (a) nonlinear Newtonian and (b) linear cooling in two DSCs of EN AW-Al Si1MgMn_{low}. Selected DSC curves with similar cooling durations between 540 °C and 150 °C are plotted. Adapted from Milkereit et al.^[10]

Fig. 30 Enthalpy change and Vickers hardness for Newtonian cooled EN AW-Al SiMgMn_{low} (= EN AW-6082_{low})^[10]

Fig. 31 Enthalpy change and Vickers hardness for linear cooled EN AW-Al SiMgMn_{low} (= EN AW-6082_{low})^[10]

precipitation kinetics significantly, it can be concluded that the simplification of linear DSC experiments delivers good approximations while reducing the experimental effort significantly. Nevertheless, if a precipitation and/or dissolution during a certain real and particularly nonlinear temperature regime of a heat treatment shop is to be investigated, this is now possible with controlled nonlinear in situ DSC experiments.

OUTLOOK AND FUTURE PROSPECTIVE

This article summarizes the state-of-the-art DSC techniques, which allow to investigate the kinetics and thermodynamics of solid–solid phase transformation in aluminum alloys in a wide dynamic range. A comprehensive description, for instance, of precipitation

reactions requires to analyze the complete scanning rate range physically relevant. The Rostock DSC laboratory °CALOR nowadays covers a dynamic range of about nine orders of magnitude in cooling and heating rates for such investigations (about 0.00003–10.000 K/s considering cooling of Al alloys from solution annealing). To achieve this enormous scanning rate range (particularly in cooling), it is needed to combine several DSC device types and measurement methods. Those methods are described and tested thoroughly on dissolution and precipitation reactions during heating and cooling of aluminum alloys. However, those methods can be transferred to other metallic systems.

As technologically very important output, continuous heating dissolution diagrams as well as continuous cooling precipitation diagrams can be recorded. Those diagrams help to select appropriate technological heat treatment

processes for a certain alloy or the appropriate alloy for a certain heat treatment process.

The enthalpy changes measured give a direct link to the kinetics and thermodynamics of the relevant reactions and allow concluding on the atomic fractions converted. Recently, with new physically based models verified with our DSC results, the quench sensitivity, i.e., the critical cooling rates of different alloys become predictable for Al-Mg-Si and Al-Zn-Cu-Mg alloys in dependence on the alloy composition.

For the future, we aim to broaden the field of application of DSC to reactions in other metals/materials. As one important step toward this aim, the temperature range assessable was recently increased to 1600°C (so far in a relatively narrow dynamic range).

ACKNOWLEDGMENTS

The enormous number of experiments reported here was performed by several people, and we gratefully thank R. Steuer, C. Fabry, M. Beck, D. Zohrabyan, J. Osten, Y. Zhang, H. Fröck, and P. Schumacher for performing DSC experiments. M.J. Starink (University of Southampton, UK) is gratefully acknowledged for his brilliant modeling contributions. Some parts of this work were funded. We therefore gratefully acknowledge the Deutsche Forschungsgemeinschaft DFG Mi1731/1-1, the Interdisciplinary Faculty, Department of Light, Life and Matter, University of Rostock and the German Academic Exchange Service (DAAD, sabbatical of BM at the University of Southampton within the PostDoc-program).

Quench Sensitivity of Aluminum Alloys

Barbara Rivolta and R. Gerosa

*Dipartimento di Meccanica, Politecnico di Milano, Piazza Leonardo da Vinci, 32,
Milan 20133, Italy*

Abstract

The demand of alloys with high strength-to-density ratio is continuously increasing in the engineering world. Beside very expensive materials, such as the titanium alloys and the high strength reinforced polymers, the aluminum alloys represent an excellent alternative to satisfy the challenging requirements of many mechanical and aerospace applications. Among these alloys, the heat treatable grades are much appreciated for the possibility to increase the mechanical resistance significantly after solution treatment and aging. The former aims to create a supersaturated solution that is later modified during the latter by the formation of metastable precipitates involving all or some of the alloying elements. In the technical literature, it is well known that the corrosion resistance and the mechanical properties of these alloys, especially the 7xxx grades, strongly depend on the quenching conditions after the solution treatment. This phenomenon is known as “quench sensitivity.” The main aim of this entry is to discuss the influence of the cooling rate during quenching of different commercial aluminum alloys from mechanical and corrosion points of view. The influence of the rolling direction and of the alloy temper will be considered to focusing the attention on some experimental data obtained on the 7075 aluminum alloy.

Keywords: Aluminum alloy; Corrosion resistance; Heat treatment; Mechanical properties; Quench sensitivity.

The heat treatment of aluminum alloys consists of three steps: (1) a solution treatment at high temperature, (2) a quenching from high temperature to ambient temperature, and (3) an aging treatment for creating a dispersion of fine strengthening precipitates.

Precipitation hardening during aging can be successful only after a solution treatment able to create a supersaturated solid solution at room temperature. After heating at the solution temperature, it is fundamental to quench the material with a cooling rate high enough to avoid any precipitation of phases during cooling. A solution treatment carried out with insufficient cooling rate is largely paid in terms of lower mechanical properties (especially the yield stress) and poor corrosion resistance of the final product.^[1] If some transformations are allowed to occur during the cooling after solution, at temperatures just below the solvus, the low thermodynamic driving force results in low nucleation and growth rate. These conditions result in the precipitation of coarse nonstrengthening equilibrium second phase during the aging.

The objective of quenching solution-treated components is to preserve the solid solution formed at the solution heat-treating temperature by rapidly cooling to some lower temperature, near room temperature. This applies not only for retaining solute atoms in solution but also for maintaining a certain minimum number of vacant lattice

sites to favor the low-temperature diffusion required for zone formation. As a broad generalization, the highest strengths achievable and the best combination of strength and toughness are those associated with the most rapid quench rates.

However, a rapid quench, such as in water, is able to create high-temperature gradients between the surface and the core of components. Since the yield strength of the alloy is low in the as-solutioned alloy, thermal stresses often exceed the yield strength and result in distortion and presence of residual stresses. For limiting residual stresses and distortion, lower quench rates are sometimes preferred. However, lower quench rates might produce mechanical properties below the limits requested by the international standards such as.^[2] All the heat-treatable, high-strength aluminum alloys are susceptible to losing the possibility to develop the maximum strength by a proper aging if the cooling rate from the solution temperature is decreased.

The influence of the cooling rates during quenching on the final properties of aged aluminum alloys is known in the technical literature as “quench sensitivity.”^[2–7] The quench sensitivity is attributed to loss of solute by precipitation during quenching with the nucleation of precipitates of the equilibrium phase and loss of vacancies. Quench sensitivity is higher in the more concentrated alloys and enhanced in the alloys containing incoherent precipitates

whose interfaces serve as nucleation sites for heterogeneous precipitation.

The quench sensitivity of aluminum alloys is affected by the composition of the alloy (alloying elements, homogenization, etc.) and its temper.^[8–10]

Quench sensitivity is generally documented by recording the changes produced in a given physical or mechanical property. It can be studied by time–temperature–property curves, which identify the time required to attain some fraction of the required property at a set transformation temperature.

Some data about the quench sensitivity of Al–Mg–Si alloys with different alloying elements are shown in Figs. 1 and 2, where ΔY_s represents the difference in Y_s between water-quenched and still air-quenched specimens.

Figure 3 shows other data about the quench sensitivity of 7xxx alloys taken from,^[12] expressed in terms of the difference in Vickers hardness number between the fast quenched specimen (80°C/s) and the slowly quenched specimen (2.5°C/s) of some commercial and experimental alloys. 7075 alloy can be considered the most sensitive to the quenching cooling rates, and quench sensitivity depends also on temper: the T6 peak strength alloy is more sensitive than the overaged T73 condition. Moreover, the experimental data confirm that increasing the alloying amount increases the quench sensitivity.

Other data about 7xxx aluminum alloys are available in,^[14] which are expressed in terms of transverse yield strength versus average quenching cooling rate. Figure 4 shows the data from.^[14]

Fig. 6 Cooling curves for different types of cooling media for quenching AA6082 aluminum sheet

Fig. 7 Effect of the quench rate on the yield strength of two commercial Al-Si-Mg casting alloys^[16–17]

In the technical literature, some data are available for aluminum casting alloys. Figure 7 shows the effect of the quenching rate on the yield strength of two commercial Al-Si-Mg casting alloys.

The data reported in the technical literature are mostly not complete and lacking important details, such as the metallurgical condition of the material (product type and temper parameters). Some information can be found on the relationships between the microstructure, the strength, and the toughness in 7050 aluminum alloy,^[18] while Robinson et al.^[19] studied the problem of the 7xxx quench sensitivity applied on forgings. Particularly, when considering the heat treatment of 7xxx thick plates, in which the cooling rate at the core can be very low even by water quenching, the information of the literature is missing. The aerospace world, which is the traditional field of application for the aluminum alloys, solves the problem by giving very strict standardized parameters for the quenching process and

severe limits of applications of high thickness product. Nevertheless, in many engineering fields the respect of the severe aerospace standards is not requested and hence, the cooling rates at the core of thick mechanical parts cannot be high enough to guarantee the final expected corrosion and mechanical properties. Moreover, for mechanical applications, the severity of quenching could be reduced intentionally, for decreasing the risk of quenching deformations, or accidentally due to an increase in the quenching bath temperature, or to a nonhomogeneous flow of the quenchant on the shape of the part, or to a reduced time interval between successive charges.

In Ref. [20], not only the mechanical but also the corrosion properties of 7075 aluminum alloy from plates were investigated by varying the temper condition, the rolling direction, and the quenching rate. The heat transfer conditions were simulated by finite element method analysis.

Specimens were machined in all the rolling directions—longitudinal (L), long-transverse (LT), and short-transverse (ST), out of a plate of 100 mm in thickness—and were treated according to T6, T76, and T73 tempers. The solution temperature was 480°C and the cooling rate was experimentally varied both using water at different temperatures (20°C, 50°C, and 90°C) and adding a polymer (Aqua Quench 260) to the water bath at room temperature. The amounts of polymer were 11% and 30%.

These amounts were optimized after many preliminary tests in order to obtain the cooling rates well distributed in the interval defined by the water bath at 20°C and the water bath at 90°C. The samples were finally aged to T6, T76, and T73 tempers. The temperatures during heating and cooling were measured experimentally with a thermocouple placed at the core of the sample.

The effects of the quenching rate, temper, and rolling direction were investigated by tensile and intergranular corrosion tests. The results of the tensile tests are shown

in Figs. 8 and 9. The samples for the corrosion tests, whose dimensions were 10 × 10 × 10 mm, were dipped for 6 h in a solution having the following composition:

Sodium chloride: 57 g

Hydrogen peroxide (30%): 10 mL

Deionized water: filled to 1 L

The samples were cut, mounted, and polished in order to observe and analyze the whole corroded profile by an optical microscope. Some indexes for quantifying the corrosion were introduced and defined as follows:

$$C_s = \frac{\sum_i L_i}{L_{\text{tot}}} \times 100\%$$

where L_i is the length of the i th corrosion spot and L_{tot} is the total length of the original profile (with no corrosion spots).

Fig. 8 UTS vs quenching cooling rate in different tempers

Fig. 9 Yield strength vs quenching cooling rate in different tempers

Table 2 Corroded surface and R_c index by varying the rolling direction, T6 temper, 20°C water quenched

	L	LT	ST
C_s (%)	2.8	12.0	30.9
R_c	13.5	32.8	100.2

Table 3 Corroded surface and R_c index by varying the tempers, ST direction, 20°C water quenched

	T6	T76	T73
C_s (%)	30.9	37.2	31.4
R_c	100.2	80.7	69.5

Table 4 Corroded surface and R_c index by varying the cooling rates, ST direction, T6 temper

	220°C/s	203°C/s	13°C/s
C_s (%)	30.9	43.7	100.0
R_c	100.2	116.9	815.4

$$R_c = \overline{R^*} C_s$$

where $\overline{R^*}$ is the average value of the modified roundness R_i^* calculated for each corrosion spot as follows:

$$R_i^* = R_i \frac{H_i}{L_i}$$

where R_i is the roundness of the i th corrosion spot ($R_i = p_i/4\pi S_i$, with p being the perimeter and S the area of each defect), H_i is the maximum depth of the i th corrosion spot, and L_i is the maximum width of the i th corrosion spot. The results are shown in Tables 2–4.

It is confirmed that ST is the worst direction in terms of corrosion resistance and that the temper able to give the best corrosion performances is the T73 followed by T76 and finally T6. Finally, the corrosion resistance strongly decreases at very low quenching rates as demonstrated by the experimental data reported in Table 4.

Abstract

This article aims to describe the media, procedures, and techniques applied to quenching for heat treatment of aluminum alloys besides problems related to this specific process. This article presents important topics such as quench sensitivity, cooling curves analysis, showing experimental apparatus details, influence of probe format and comparison between probe types used in quenching, and problems related to surface oxidation due quenching. Polymer quenchants types are analyzed besides quenching parameters. There is a discussion related to surface rewetting and its importance for quenching successful. Different quenching process are presented like “uphill” process comparing as cryo quenching, ultrasonic agitation, and ionic liquids besides topics related to corrosion types and residual stress after quenching.

Keywords: Cooling curve; Corrosion; Quenching; Quench media; Quench system; Racking; Surface rewetting.

INTRODUCTION

When aluminum is solution heat treated at elevated temperatures (750°F, 399°C), the alloying elements are dissolved in the aluminum lattice structure of the solid solution. The objective is to maximize the concentration of hardening elements such as copper, zinc, magnesium, or silicon in the solid solution. The concentration and rate of dissolution of these elements in solid solution increases with increasing temperature.

During slow cooling, the alloying elements diffuse through the solid solution and concentrate at the grain boundaries, large voids, undissolved particles, or other “defect” locations. To achieve optimal strength properties,

it is desirable to retard this diffusion process and maintain the alloying elements in solid solution.

This is accomplished by the quenching process. After quenching, the aluminum part is aged. During the aging process, hardening elements precipitate in localized areas significantly increasing the strength of the part. These processes are illustrated in Fig. 1.^[1]

The diffusion process is slower for some alloys than others thus permitting slower cooling rates during quenching. Figure 1 illustrates that very slow cooling will result in the concentration of the alloying elements in the grain boundaries. Figure 2 shows that intergranular corrosion (IGC) for 2024-T4 will be enhanced if cooling rates are excessively slow during quenching (See “Intergranular Corrosion” section). Similar behavior can be shown for other aluminum alloys.^[2] Therefore, it is important that cooling rates during quenching be sufficiently fast to avoid this undesirable behavior.

The cooling process of age-hardenable aluminum alloys is affected by material properties such as strength, ductility, and thermal stresses. Thermal stresses are minimized by reducing the cooling rate from the solution heat

This article is a revision of “Chapter 29—Quenching of Aluminum Alloys” by G.E. Totten, C.E. Bates and G.N. Webster, “Quenching,” in *Handbook of Aluminum: Vol. 1- Physical Metallurgy and Processes*, G.E. Totten and D.S. MacKenzie Eds. 2003, Marcel Dekker Inc., New York, NY, p. 971–1062. ISBN: 978-0-8247-0494-0

Fig. 1 Schematic illustration of the solid diffusion processes that may occur during solution heat treating

Fig. 2 C-curve indicating type of cooling rate-dependent corrosion attack on AA2024-T4 sheet

treatment temperature. As described above, if the cooling rate is too slow, undesirable alloy segregation at the grain boundaries will result. Conversely, if the cooling rate is too fast, an increased tendency for distortion may result.^[3,4] Therefore, one of the primary challenges in quench process design is to select quenching conditions that permit optimization of all important properties.

Various aspects of aluminum quenching will be discussed in this article, which will include the following: quenching and aluminum hardenability, quenching mechanisms and their effect on material properties, different quenchant and quench processes, quenchant maintenance, cooling curve analysis, property predictions, importance of racking, and quenchant media selection to reduce residual stresses and improve distortion control.

DISCUSSION

Quench Sensitivity

The physical properties of an age-hardenable aluminum alloy are dependent on many factors including the

following: alloy composition, structure, and temper. The tendency for an alloy to form non-hardenable precipitates during quenching is referred to as “quench sensitivity”.^[5] Quench sensitivity of AA6082 sheet stock (2 mm) containing varying alloy composition using different quench media summarized in Table 1 and Fig. 3 was studied by Lim and Shercliff.^[5]

Although little variation of Vickers hardness after T6 temper was observed for furnace cooling, hardnesses increased with increasing cooling rate (Table 2). Quench sensitivity increased with decreasing cooling rates and homogenization temperature. Process models have been developed that successfully predict AA6082 quench sensitivity. The development and use of these models has been reviewed by Lim and Shercliff.^[5]

Vruggink studied the effect of cooling rate on the variation of yield stress as an indicator of quench sensitivity using various commercially available aluminum alloys.^[6] The quench media used included cold water, boiling water, and still air which provided a broad range of cooling rates varying from 5000°F/s to 3°F/s. Figure 4 shows that the midplane cooling rates (750°F/s–550°F/s) of various 12 × 12 in. test specimens of 7075-T6 with varying thicknesses.^[6] The data show that the approximate average midplane cooling rates of 5000°F/s, 40°F/s, and 3°F/s would be expected if 0.064, 3.0, and 10.0 in. thick test specimens were quenched into water at 70°F. From these data, it was concluded that quench sensitivity of age-hardenable aluminum alloys could be compared by quenching 12 × 12 × 0.064 in. test specimens in cold water, boiling water, and still air and aging to the desired temper. One objective of this work was to show that decreasing cooling rates would exhibit the same effect as increasing thickness.

The quench sensitivity of various 2xxx and 7xxx series aluminum alloys using this methodology is shown in Figs. 5 and 6, respectively.^[6] Although a wide range of strengths are achievable for the 2xxx series when quenched at 5000°F/s, significant variation in quench sensitivity was observed only when decreasing the cooling rate from 40°F/s to 3°F/s (see Fig. 5). Alloy AA2618 exhibited the

least quench sensitivity, and AA2014 exhibited the greatest sensitivity. Figure 6 illustrates the results of a similar study conducted on various 7xxx series aluminum alloys. This study shows that quench sensitivity increases with increasing concentrations of Cu and Cr.

Vruggink also attempted to quantify quench sensitivity effects for thicker cross sections using a modified steel Jominy testing methodology and a 3 in. dia. and

Fig. 5 Effect of cooling rate on the properties of 2xxx series of aluminum alloy sheet in T6 temper

Fig. 6 Effect of cooling rate on the properties of 7xxx series of aluminum alloy sheet in T6 temper

13 in. long cylindrical test specimen shown in Fig. 7^[6] and also a wedge-shaped test specimen (see Fig. 8) also modified from ferrous metallurgy hardenability studies.

Fig. 7 Jominy end-quench test specimen and cooling rates at different locations along the specimen

Fig. 8 Wedge specimen and cooling rates at various locations in the specimen

Both test specimens were quenched into 70°F water. The results reported by Vrugink showed that there was no yield strength correlation for the end-quench and the wedge tests and either plate or sheet test specimens as shown in Figs. 9 and 10, respectively.^[6]

Hart et al. have used the Jominy end-quench test to evaluate the influence of quench rates on corrosion properties of AA2024-T4 and -T6 and 7075-T73.^[7] Their experimental apparatus is illustrated in Fig. 11.

A summary of cooling rates as a function of section thickness is provided in Fig. 12.^[7] For this work, aluminum extrusions were used because the more pronounced grain structure would be expected to provide greater sensitivity to stress corrosion and exfoliation corrosion (EFC). Hart's work was conducted according to ASTM A255-48T. The water quenchant temperature was 286 K, a metal screen was placed over the orifice, and the transfer time from the furnace to the quench was <5 s. It was also found that water pressure exhibited no effect on cooling rate.

Figure 13 illustrates hardness and conductivity data obtained from the experimental Jominy bar data for different aluminum alloys.^[7]

Figure 14 illustrates the sampling of specimens from the Jominy bar for stress corrosion studies. The results of this work are shown in Fig. 15:^[7]

- Naturally aged AA2024 showed the lowest stress corrosion life.
- Alloy AA2024-T6 was slightly better.
- For both naturally aged T4 and solution treated and naturally aged (T6) AA2024, there was no effect of Jominy bar distance on stress corrosion life.
- Alloy AA7075-T6 was susceptible to stress corrosion over the first 40 mm of the Jominy bar distance.
- The overaged alloy AA7075-T73 was completely stress corrosion resistant.

thermocouples at the positions shown in Fig. 16 was quenched according to ASTM A255.^[8]

A comparison of the hardness and conductivity data obtained as a function of distance from the quenched end illustrates the reduced quench sensitivity of AA7050, an alloy developed for use where thicker cross-section sizes are required is provided in Fig. 17.^[8]

Transmission electron micrographs of AA7075 and AA7050 at positions corresponding to 7, 24, 56, and 79 mm distances on the Jominy bar are shown in Figs. 18 and 19, respectively.^[9] These micrographs compare AA7075 and

AA7050 specimens that are quenched at different cooling rates but tempered under identical conditions.

Cooling Curve Analysis

Experimental Apparatus

Sheet and Bar Probe Construction To obtain experimental cooling rate data, two types of aluminum probes, constructed from bar and sheet stock of the aluminum alloy of interest, were constructed.^[10] Cylindrical bar probes were prepared as shown in Fig. 20, where the length was at least four times the diameter to approximate an infinite cylinder. A Type K thermocouple was inserted to the geometric center. Contact with the probe was maintained by the use of a spring-loaded thermocouple or by brazing. An aluminum tube was tungsten inert gas (TIG) welded to the bar probe to provide a handle and protect the thermocouple from the quenchant.

Probes to measure the cooling rates of aluminum sheet stock were prepared. As shown in Fig. 21, this probe consists of two 2 × 2 in. aluminum sheets with a combined thickness equal to the thickness being simulated. The sheets and handle were cleaned, thoroughly degreased, and the surface deoxidized. An intrinsic thermocouple was prepared^[10] using 30 gauge chromel–alumel wire by spot welding the wire to the interior of the sheet.^[10] A spacer was sandwiched between the sheets to allow the thermocouple wire to exit. The assembly was placed on a notched handle and TIG-welded watertight.

Effect of Probe Shape Croucher^[11] and Van Horn^[12] have shown that there is no simple direct correlation

specimen being used must be specified along with the cleaning process if such data are to be used for the prediction of the mechanical properties of production parts.

Comparison of Quenching Characteristics of Silver and Aluminum Probes Silver probes are often used to evaluate quench severity exhibited by different quenchants.^[13,14] Because of the similarity of the thermal characteristics of silver and aluminum and because of the significantly lower

Fig. 22 (a) Effect of surface preparation on midplane cooling rates of a 0.5 in. thick AA7075 plate quenched into 70°F water, and (b) effect of surface preparation on midplane cooling rates of a 0.5 in. AA7075 plate quenched into boiling water

oxidation tendency for silver relative to aluminum, the cooling behavior of AlMgSiCu and a silver (99.5 %) probe was compared. Thermal conductivity (α) and specific heat capacity of various materials are provided in Table 5. Thermal conductivity, α , is a measure of the “rate of propagation” of temperature change in a body and is related to the specific heat capacity:

$$\alpha = \frac{\lambda}{\rho \times C_p} \quad (1)$$

where C_p is the specific heat capacity, λ is the thermal conductivity, and ρ is the density.

Figure 23 shows the cooling curves recorded during quenching of an aluminum (AlMgSiCu) and a silver

Table 5 Thermal conductivity and specific heat capacity for different materials

Material	Thermal conductivity (m^2s^{-1})	Specific heat capacity ($\text{KJ Kg}^{-1} \text{K}^{-1}$)
Aluminum 99.5	95×10^{-6}	0.896
Silver 99.5	174×10^{-6}	0.235
Nickel	14×10^{-6}	0.448
Cr Ni Steel*	4×10^{-6}	0.477
Inconel 600**	4×10^{-6}	0.465

*Austenitic stainless steel SAE 30304.** Ni-based alloy.

specimen (Ag 99.5) in a water-soluble polymer. The aqueous polymer quenchant concentration was 10% by volume, and the bath temperature was 25°C. The temperature of both materials when quenched was 520°C. Both probes were cleaned with 600 grit abrasive paper before each test.

The polymer film surrounding the probe surface ruptured simultaneously around the entire surface, also called “explosive” rewetting, for both probes, and the rewetting times ($t_F - t_S$) were extremely short. However, a stable film boiling range lasting about 4 s was observed for the silver probe which was not observed for the aluminum probe. The centerline probe temperature was about 440°C for silver and 500°C for aluminum. The reason that the rewetting occurs about 4 s later for the silver probe is the greater oxidation resistance of silver. (The ratio of heats of formation of Ag_2O_2 and Al_2O_3 is 0.05.) When the quenching temperature of the silver probe is increased to 800°C, considerable stabilization of the film boiling occurs as observed in Fig. 24a. Wetting now starts at about 260°C after 24 s compared to the start of wetting of the AlMgSiCu probe after 1 s at about 500°C. The main reason for this stabilization of the film boiling phase of the entire surface of the silver probe is the reduction of the silver oxide at the higher temperature. The high-temperature annealing of the silver

Fig. 24 Comparison of the cooling processes of a cylindrical AlMgSiCu probe (dia. 15 × 45 mm) with those of a silver probe. Probes are quenched into a 10% solution of a water-soluble polymer at 25°C (temperatures recorded at the geometric center of the probe): solution-treating temperature is 520°C for the AlMgSiCu probe and annealing temperature is 800°C for the silver probe: (a) changes in temperature and conductivity as a function of time and (b) cooling rate as a function of temperature

probe removes the oxide and leaves a bare metal surface, resulting in the stabilization of film boiling during quenching, especially in water-soluble polymers. Accordingly, the

Fig. 23 Comparison of the cooling processes of a cylindrical AlMgSiCu probe (dia. 15 × 45 mm) with a silver probe of the same dimensions. Probes are quenched into a 10% solution of a water-soluble polymer at 25°C (temperatures at the geometric center of the probe): solution-treating temperature is 520°C (AlMgSiCu probe) and annealing temperature is 520°C for the silver probe

maximum cooling rate of the silver probe is not reached until a centerline probe temperature of 200°C as shown in Fig. 24b.

If distilled water at room temperature is used as the quenchant instead of an aqueous polymer, the silver and the AlMgSiCu probes show almost identical cooling behavior with coinciding rewetting kinematics as shown in Fig. 25. This means that the quenching behavior determined in water with silver probes can be safely compared with those obtained for aluminum probes. However, when polymer solutions are used, there are clear differences, especially with respect to initial wetting.

Quench System The probes, after heating in either an electrical air furnace or in a fluidized bed at 870°F for 7075 or 920°F for 2024, were quenched into the tank illustrated in Fig. 26.^[10] The quenchant velocity flowing past the probe was controlled with a variable speed pump. The linear flow velocity was calculated using the volume flow from the pump and the cross-sectional area of the sleeve and the probe. The quenchant temperature was controlled to

Fig. 25 Comparison of cooling processes of a cylindrical AlMgSiCu probe (dia. 15 × 45 mm) with those of a silver probe. be within $\pm 2^\circ\text{F}$ and maintained at the correct temperature with resistance heaters and a cooling coil.

Furnace and Racking System The “rapid quench” furnace system utilized for the aluminum sheet distortion work discussed here is illustrated in Fig. 27. The furnace is located approximately 5 ft above the floor and utilizes the quench system illustrated in Fig. 27, which was placed directly underneath the furnace.

A stainless steel radiation shield was located between the heating elements located on the sides of the furnace and the sheet rack shown in Fig. 28 to protect the panels from direct radiation. A fan was used to provide brisk air flow for uniform heating. Sliding doors on the furnace bottom provided a seal during soaking and allowed the panels to be dropped at a controlled rate.

Three 5/16 in. holes were drilled into each aluminum panel, nominally 5 × 7 in., as shown in Fig. 28.

The sheets were annealed after shearing and machining to remove any mechanically induced residual stress. Two 1/4 in. threaded rods were placed through the top two holes, and stainless steel spacers were used to provide at least a 1/2 in. gap between each sheet. Fine gauge thermocouple wire was threaded through the bottom hole to secure the lower half of the panels to the hanger. Slack was left in the wire so that any distortion could freely occur. For this study, each rack contained four sheets, 0.032, 0.040, 0.063, and 0.125 in. as shown in Fig. 28a.

The drop velocity of the rack into the quenchant was controlled using a pneumatic dashpot. The drop velocity was determined by measuring the time required for the piston to move a fixed distance. A 20 KHz clock and counter were triggered as the piston moved between the two Hall-effect probes. The distance between the Hall-effect probes was divided by the time required for the piston to pass between the probes provided the drop velocity. Total sheet probe distortion was determined by summing the maximum distortion measured for each sheet when

Fig. 27 Schematic representation of the “rapid quench” furnace system and drop mechanism used for sheet distortion studies

lying “flat” on the bench. The total distortion was taken as the average of the total distortion of four separate runs.

Surface Rewetting Measurements

Temperature variation with time during the cooling process was measured by a thermocouple inserted to the geometric center of a cylindrical probe. Rewetting kinematics was determined by measuring the change in conductance between the probe and a counter electrode during the transition from film boiling to nucleate boiling as shown in Fig. 29.^[15,16]

If the heated probe is completely surrounded by a vapor blanket, the electrical resistance between the probe surface and the counter electrode is high because of the insulating effect of the vapor blanket. As the vapor blanket collapses, the quenching fluid wets the probe causing the electrical resistance between the probe surface and the counter electrode to decrease and the conductance to increase. Using calibration curves, the percentage of the surface (A) from the conductance (G) and the wetting kinematics (dA/dt) may be determined from the change in conductance with respect to time (dG/dt).

Rewetting Kinematics from Quenched Aluminum Bodies Cooling behavior of aluminum during quenching

is affected by the following: quenchant composition (type and concentration of a polymer quenchant), bath temperature, temperature of the aluminum being quenched, and surface condition of the aluminum. Aluminum rewetting behavior when quenched into distilled water is strongly affected by bath temperatures above 40°C. Figure 30 shows that the temperatures for the beginning of the rewetting process (T_s) and for the end of the process (T_F) and the elapsed time between t_F and t_s within which the two boiling phases, film boiling and nucleate boiling, appear simultaneously, as a function of bath temperature.^[16] Up to bath temperatures of 40°C, the probe surface wets very quickly (<1 s) and the rewetting process always began at the lower surface. At temperatures above 60°C, the rewetting time, the time when the entire probe surface is wetted with the quenchant ($t_F - t_s$), increases sharply with increasing bath temperature, and the temperature distribution in the probe becomes extremely uneven. This means that with increasing bath temperature, the precipitation kinetics become increasingly nonuniform in the longitudinal direction. For example, if aluminum castings are quenched in water at $\geq 60^\circ\text{C}$ to reduce distortion and residual stresses, the opposite results will be achieved.^[17,18]

These difficulties can be avoided by using water-soluble polymers as aluminum quenchants.^[19–22] These polymers

Fig. 28 Schematic representation of (a) aluminum sheets, sheet spacing, and (b) rack assembly

Fig. 29 Schematic illustration of the measuring principle for determining the percentage of wetted samples surface of rewetted immersion-cooled specimens

Fig. 30 Dependence of temperatures T_s and T_f (measured at the geometric center of the probe) and wetting time ($t_f - t_s$) on bath temperature during immersion cooling of a cylindrical AlMgSiCu probe (dia. 15 $\times$ 45 mm) in distilled water

are usually used at bath temperatures of 20°C–35°C. The quenching characteristics of these polymers in this temperature range are practically independent of bath temperature.^[22] Aqueous polymer quenchants provide a less severe quench than cold water, and the quench severity can be varied by varying quenchant concentration.^[21–24]

Figure 31 shows the effect of polymer concentration on the wetting behavior of a cylindrical AlMgSiCu probe quenched in a commercial polymer quenchant.^[15,16]

The time until initial wetting of the probe surface increases with polymer concentration, which means that film boiling persists for longer periods of time with increasing polymer quenchant concentration. This behavior appears in Fig. 31 as a decline of the starting temperature for wetting (T_s) measured at the geometric center of the probe. The rewetting time increases only about 2 s with increasing quenchant concentration.

The cooling time from the solution-treating temperature where the mixed crystal phase begins is very important for age-hardened aluminum alloys.^[4]

Therefore, the effect of water temperature and of polymer quenchant concentration on cooling time was compared. Figure 32 shows that the cooling time varies between 2 and 16 s in both cases; however, the effect achieved by varying the polymer quenchant concentration was more favorable. (Note: The temperature was measured in the center of the probe, which reveals nothing about rewetting behavior or about the temperature distribution within the probe).^[15,16]

In addition to bath temperature and polymer concentration, agitation is also an important variable which will be reported in a subsequent report.^[24,25]

Aluminum surface condition during the quenching process also exhibits a large effect on quenching performance. Surface characteristics can be greatly altered by various factors such as variations in the duration of solution

Fig. 31 Dependence of temperatures T_s and T_f (measured at the geometric center of the probe) and wetting time ($t_f - t_s$) on polymer quenchant concentration during immersion cooling of a cylindrical AlMgSiCu probe (dia. 15 × 45 mm) in water-soluble polymer at 25°C

Fig. 32 Time required for cooling a cylindrical AlMgSiCu probe (dia. 15 × 45 mm) from solution-treating temperature (temperature at which the probe was immersed) to 180°C: (a) Cooling in distilled water at varying bath temperatures and (b) cooling in water-soluble polymer quenchant at varying quenchant concentrations and 25°C

Fig. 33 Cooling process of a cylindrical AlMgSiCu probe (dia. 15 × 45 mm) annealed in air for different periods of time: quenchant = distilled water, 25°C, (a) changes in temperatures and conductivity as a function of time, (b) cooling rate as a function of the temperature at the geometric center of the probe

treatment.^[26] Figure 33 shows the cooling and rewetting behavior of AlMgSiCu cylindrical probes that were solution treated for variable lengths of time then quenched in distilled water ($T_B = 25^\circ\text{C}$). With increasing duration of the

solution treatment time from 1 to 180 min, which results in corresponding increase in the depth of the surface oxide layer, the conductance–time curves and temperature–time curves clearly show the retardation of cooling, i.e., the prolongation of wetting time with increasing duration of heat treatment (Fig. 33a).^[16] The cooling rate decreases with increasing duration of solution heat treatment (Fig. 33b).^[15,16]

Quench Media

Air

When sheet metal components made of V95 (AA7075) or D16 (AA2024) alloys are hardened, the permissible time for which articles of different thicknesses may be passed through the air for cooling is best determined from the temperature at the start of hardening.^[27] From the data that have been obtained, this temperature can be determined by calculation with sufficient accuracy.

$$T = T_0 - 7.05T / s \quad (2)$$

where T = temperature of the D16 or V95 test pieces at any point in time while moving in air, T_0 = initial temperature ($^{\circ}\text{C}$) of the test piece that in this reported work was 500°C for D16 and 470°C for V95, T is the exposure time (s) in air, and s is the thickness of the test piece in mm. For section thicknesses between 1 and 6 mm, it was reported that the error in temperature estimation does not exceed 1%–2%.

The effect of test piece movement through air is shown in Fig. 34a for the D16 alloy and Fig. 34b for the V95 alloy test pieces. As expected, for both alloys, increasing air velocity increases heat transfer rates and faster rates would generally be recommended. However, edgewise movement would provide better cooling uniformity and would be preferred.^[27]

In a recent patent, air quenching was used to air-quenchable thin section components with complex geometries.^[28] Air-quenchable alloys include 6xxx and 7xxx alloys, and air quenchability is typically determined by the total copper content. In general, aluminum alloys containing less than 0.4% may be air quenchable. Specific air quenchable 6xxx alloys include 6061, 6063, 6022, 6008, 6451, and 6005. Examples of air quenchable 7xxx alloys include 7003 and 7005.

After solution heat treatment, the component is quenched in air, and typically the specified process allows a quench delay time for transferring the load from the furnace until immersion of 30 s or less. The air may be heated, or cooled, at ambient temperature. In some cases, specific gases or gas mixtures such as argon, nitrogen, or argon/nitrogen blends or air/gas mixtures may be used. The gas temperature is typically maintained to 25°C – 45°C but lower temperatures may be used. The air may be still or moving by using fans or an HVAC (Heating, Ventilation, and Air Conditioning) system. The authors of Ref. [28] described the use of multiple ducted 150 HP fans to provide air flow around the cooling components. Preferred cooling rates for this process typically range from 6°C/s to 25°C/s . Cooling rates outside of this range may be strong but not tough (cooling rate too fast) or tough but not strong (cooling rate too slow).

Reference [29] reports an air quenching system and experimental procedures to obtain heat transfer coefficient (HTC) data under various air quenching conditions. The convection heat transfer of cast aluminum alloy (319) during air quenching has been investigated with a simple cylindrical probe in Fig. 35 under different quenching conditions including air velocity, air temperature, air relative humidity, and part orientation (see Fig. 36). Table 6 shows that the HTC data increase significantly with increasing air velocity. This increase is essentially linear as shown in Fig. 37. The probe orientation also affects HTC considerably. The inclined quenching orientation (45°) results in a better heat transfer in comparison with vertical or horizontal

4.8	15	46–50	Vertical	63.90
4.8	25	31–33	Vertical	70.53

orientations. The air humidity and air temperature have little effects on HTC data. The relationship between HTC and air velocity developed in this study can be used in production to optimize the desired air velocity for the required cooling rate.^[29]

Water

When water is used to quench age-hardenable aluminum alloys, heat transfer from the workpiece to the quenchant is determined by three boiling phases: film boiling, nucleate boiling, and convective heat transfer. Film boiling occurs upon initial immersion. This is a slow cooling process because the hot surface is surrounded by a vapor blanket. As the part cools, the vapor blanket collapses and nucleate boiling results. The transition temperature between film boiling and nucleate boiling is called the “Leidenfrost temperature.” Heat transfer is fastest during nucleate boiling. The HTC, α , for nucleate boiling is about 100 times the value of α for film boiling.^[30,31]

When the part has cooled below the boiling point of the quenchant, slow cooling occurs by a convective heat transfer process.

Since aluminum solution heat treatment temperatures are significantly higher than the Leidenfrost temperature, film boiling is to be expected initially when quenching into water.^[32,33]

If the surface temperature at any given point on the workpiece is less than the Leidenfrost temperature, stable wetting and nucleate boiling will occur at that point.^[34–36] Figure 38a illustrates a typical wetting sequence during cooling of a cylindrical specimen quenched in distilled water at 40°C. The simultaneous

Fig. 38 (a) Wetting sequence for a cylindrical specimen quenched in distilled water at 40°C and (b) temperature TZ (measured in the center of the specimen) and wetted specimen surface as a function of time during cooling of an AlMg5 sample in distilled water at 80°C. TZ and tZ: Temperature in the center of the specimen when it is immersed into the quenchant and the time of immersion. TS and tS: Temperature in the specimen center and time when wetting starts. Tf and tf: Temperature in the specimen center and time when the wetting process is concluded

presence of different boiling phases with the HTC of one surface region is greater than 100 times the other causes extremely uneven cooling of the workpiece. Figure 38b illustrates the rewetting sequence of a cylindrical aluminum (AlMg 5, 15 mm dia. $\times$ 45 mm) quenched into distilled water at 80°C with the percentage of the wetted surface ($A = A(t)$) and with the change in temperature at the geometric center of the cylindrical workpiece ($T = T(t)$) during cooling.^[15,16]

As Fig. 38 illustrates, all three cooling mechanisms may exist on the surface simultaneously. This will strongly affect the wetting processes that occur during quenching resulting in substantial thermal gradients and increased distortion. Figure 39 illustrates that the boiling mechanism is stabilized by increasing the water temperature, and it is clearly evident at 60°C.^[18,37]

The consequences of uneven cooling include^[15,16] the following:

- Regions where the film boiling exists exhibit greater separation of the supersaturated mixed crystal structure than regions of faster cooling (low t_s). During age hardening, these regions (high t_s) experience a smaller

Fig. 39 Cooling curves as a function of water temperature for 1/2 in. 7075 aluminum plate

increase in hardness and also exhibit greater potential for IGC than neighboring regions with faster cooling.

- Volume regions where film boiling persists exhibit a much lower- or higher-temperature yield point during the cooling process than regions with shorter film boiling phases. The nonuniformity of this process results in significant plastic deformation due to increased thermal stresses and increased distortion.

Therefore, determination and characterization of the cooling processes involved in quenching is critically important, especially with water quenching. To satisfy this need, a process to quantitatively measure the rewetting process of standard quenched aluminum probes was developed^[38,39] (see “Surface Rewetting Measurements” section on rewetting measurements).

In many cases, solution heat-treated aluminum is simply air cooled. Quench-hardenable alloys such as 2024, 2219, 7075, 7050, and 6061 are often quenched in cold water. However, in some cases, cold-water quenching produces unacceptable distortion due to the high thermal gradients which are induced upon cooling. One of the earliest alternatives to cold-water quenching was “delayed quenching.” For example, Fink and Willey reported the use of a delayed quenching process where the aluminum alloy was initially quenched in boiling water followed by a cold-water quench at the appropriate time as illustrated in Fig. 39.^[40]

Alternatively, if distortion problems are encountered with cold water (50°F–90°F, 10°C–32°C) quenching, then “hot water” (140°F–160°F, 60°C–71°C) quenching is used.^[18] Cooling curve as a function of water temperature is provided in Fig. 39, and properties of 7075 aluminum plate as a function of water temperature are given in Fig. 40.^[18]

Agitation Rate Dependence The effect of agitation on cooling rates and properties on water quenching have been reported by various authors.^[41] The sensitivity of hot water (160°F, 71°C) to increasing agitation is significantly greater than colder water temperatures. Interestingly, although

Fig. 40 Delayed quenching cooling curves for 0.064 in. thick 7075 aluminum alloy quenched in boiling and cold water

quench factor (cooling rate) sensitivity to increasing agitation increases with section size, the effect is small. It should be noted that this does not mean that agitation rate is unimportant! Conversely, uniform agitation is required to facilitate uniform film formation, which results in more uniform thermal gradients and reduced distortion.

Polymer Quenchants

Polyethylene Oxide (PEO) (or Alternatively Designated as Polyethylene Glycol—PEG) Quenchants Of the various quenching media alternatives to hot water quenching to provide improved distortion control, solutions of water-soluble polymers are the most commonly used today. Polymers that have been evaluated for aluminum quenching applications include polyvinyl alcohol, polyacrylamide, polyacrylic acid, polyethylene oxides (PEOs), and polyalkylene glycols (PAGs).^[42,43] PEO polymers of relatively high molecular weight (5×10^5 – 5×10^6) are among the polymeric alternatives that have received considerable attention owing to their excellent distortion control at very low use concentrations.^[44]

In one published study, evaluating high-molecular weight PEO showed that aqueous solutions of this polymer

exhibited excellent distortion reduction for both panels and sheets constructed from Russian alloy D16 (AA2024). These data are shown in Table 7.^[42] Similar results were claimed for Russian aerospace alloys V95 (AA7075) and AK4-1 (similar to AA2014).

Schneider et al. performed a detailed analysis of the use of various quenching media including aqueous PEO solutions to reduce distortion of drop forged panels.^[45] They used a cooling curve criterion ($\Delta v/v$) to assess the propensity for distortion. Cooling curves were obtained using a blank of the D16 alloy with a symmetrically located rib of 76 mm in height. They then measured the difference in cooling rate for the tip of the rib and the center of the blank (Δv) divided by the cooling rate in the center of the test piece. The ($\Delta v/v$) ratio is a measure of cooling uniformity. By evaluating the test panel with a wide range of quenching severities, the classifications shown in Table 8 were developed. The authors did report that while distortion was observed for large complex forgings using aqueous PEO solutions, for plain sheet material, little, or no distortion would be expected.

Schneider et al. also correlated their cooling criterion ($\Delta v/v$) with internal stresses and they found that for Group C, when $\Delta v/v = 1$, the internal stresses were negligible. For Groups A and B, where $\Delta v/v = 1.01$ – 1.23 , compressive internal stresses were obtained that increased as the $\Delta v/v$ ratio increased and that continued to increase for Group A.^[45]

As noted previously, although cold-water quenching of 7xxx series aluminum alloys produces excellent mechanical properties, the relatively high cooling rates produced by cold water often lead to undesirable residual stresses, distortion and warping, and in some cases cracking.

Although hot water quenching has been used for many years to reduce quench distortion for aluminum, it is often insufficient to produce optimal minimization of distortion. In such cases, an aqueous poly(alkylene glycol)—PAG copolymer quenching medium may be used. The distortion reduction advantages of PAG quenchants relative to both

Table 7 Distortion results of D16 test specimens quenched in water and a 0.25% of a PEO solution^[42]

Test specimen ^{a,b}	Quenchant	Warping (mm) ^c

Panel (1300 × 400 × 3.5 mm)	0.25% Aqueous PEO solution ^d	2	0	4	12	36	12	0	4	13	28
Sheet (1200 × 400 × 1.0 mm)	Water (20°C)	82	8	10	15	65	3	50	90	42	13
Sheet (1200 × 400 × 1.0 mm)	0.25% Aqueous PEO solution ^d	0	0	18	3	19	26	0	0	8	0

^aNominal composition range (%) for alloy D16 (Fe 0.5 max, Si 0.5 max, Mn 0.3–0.9, Cr 0.1 max, Ti 0.15 max, Al 90.9–94.7, Cu 3.8–4.9, Mg 1.2–1.8, Zn 0.25 max, (Ti + Zr) < 0.2, and all others < 0.15). Similar to 2024 (USA).
^bThe test specimens were quenched from solutionizing temperature of $500 \pm 5^\circ\text{C}$ into the quenchant. The D16 test specimens were naturally aged.
^cWarping was determined from the deviation of the test specimen from the plane of the supporting plate at different points along the perimeter.
^dThe molecular weight of the PEO polymer was reported to be 3.3×10^6 . The aqueous solutions were prepared by mixing the PEO powder in water for 4–5 h.

Table 8 Characterization of distortion propensity using cooling rate criterion

Cooling criterion ($\Delta v/v$)	Type of distortion	Quenching media
A (1.65–1.24)	Flaking, twisting	Water at 18°C; 20% aqueous solution of PEO ¹
B (1.23–1.01)	Twisting	40% Aqueous solution of PEO ^a , water at 80°C, and water at 20°C with a thermal insulated coating (TIC)
C (1.0–0.1)	Insignificant distortion is typical	Water at 58°C, 75°C, and 80°C with TIC; water at 95°C and 100°C; liquid nitrogen

^aThe PEO used for this work was designated as Breox with no specific product identification.

cold and hot water is illustrated in Fig. 41.^[46] PAG polymer quenching media were first reported by Blackwood and Cheesman.^[47] Polymer quenchants are solutions of water, a PAG copolymer, and additional additives such as a corrosion inhibitor.^[46]

It has been shown that water does not effectively wet the surface of aluminum during quenching.^[15,16]

Three distinctly different cooling regimes, with dramatically different heat transfer characteristics, are present on the surface of aluminum simultaneously during the quenching process, which will produce potentially sufficient thermal gradients to increase distortion. This is shown in Fig. 38.^[16]

PAG copolymer quenchants form a surface film which surrounds the aluminum surface during quenching, as shown in Fig. 42,^[48] which both mediates heat transfer and enhances the uniformity of wetting, thus minimizing distortion. The improved wetting process is evident by comparing “rewetting” times of aluminum quenched in water and a PAG copolymer quenchant solution.^[8]

**Fig. 41** Comparison of distortion reduction achieved with aluminum sheet quenched in cold water, hot water, and a 20% solution of a Type I quenchant

Source: Courtesy of Tenaxol Inc., Milwaukee, WI.

Fig. 42 Illustration of the quenching mechanism of an aqueous solution of a PAG copolymer during the cooling of hot metal

Rewetting times ($t_F - t_S$) are the difference in the time when film boiling begins (t_S) and when nucleate boiling ends (t_F). This is illustrated by comparing Figs. 30 and 31.^[16]

A study conducted on A356-T6 and A357-T6 castings showed that it was possible to achieve similar, but more uniform, mechanical properties with a PAG polymer quenchant than with hot water.^[49] A comparison showing the relationship between cooling rate and thickness for A356 aluminum is shown in Fig. 43.^[49,50]

Heat transfer rates decrease as the thickness of the polymer film increases. Polymer film thickness is dependent on both agitation and quenchant concentration. The timing of the breakage of the film is dependent on the film strength of the polymer, concentration, bath temperature, and agitation. Cooling curve performance as a function of polymer concentration is illustrated in Fig. 44.^[37]

AMS Specifications The most common PAG quenchants that are used in the aerospace industry today are designated as “Type I” quenchants.^[21] Type I quenchants are defined by the physical properties that they exhibit in

Fig. 43 Cooling rate/plate thickness correlation for water and a Type I quenchant

Fig. 44 Cooling curves for 1 in. 7075 aluminum alloy plate quenched into different concentrations of a Type I polymer quenchant

aqueous solution. These physical properties are specified in AMS 3025A and are summarized in Table 9.^[51]

There has been some informal discussion in the industry regarding the meaning of the values in Table 6. Taken together, they do reasonably specify the composition of quenchant being evaluated. For example,

1. Viscosity, at constant water content, is indicative of the copolymer molecular weight (size).
2. Refractive index, while a very old characterization method, has traditionally been related to the molar refractance values (structure) of chemical compounds and their concentrations.
3. Specific gravity, while not a critical parameter, is often used in chemical engineering processes as an indicator of composition and concentration.
4. Diluted solution viscosity is a validation that the correct polymer molecular weight and concentration is being used.
5. Separation temperature, as referred to here, is indicative of the chemical composition of the PAG copolymer being used to formulate the quenchant.

Therefore, these values reflect the chemical composition of the copolymer, molecular weight, concentration, and additive content. While additional tests could be performed,

Table 9 Physical properties of type I polymer quenchants	
Property	Specification limits
Water	45–48%
Specific gravity (20°C/68°F)	1.094 ± 0.005%
Refractive index (20°C/68°F)	1.4140 ± 0.005%
Viscosity (cS @100°F)	535 ± 70
20% Dilution with water (cS @100°F)	5.5 ± 0.5
Separation temperature	165°F ± 5

they are probably not necessary. More importantly, the as-quenched physical properties and alloy cooling rates should be determined for proper quenchant certification as already required by AMS 3025A. The physical properties must at least meet the Mil Handbook 5 design minimums.^[52]

It is not sufficient to qualify a quenchant by determining the originating vendor.

One source for recommended heat-treating conditions for using Type I quenchants is AMS 2770E.^[53] Selected recommended limitations from AMS 2770E are provided in Table 10.

The maximum attainable strength properties are dependent on the cooling rate between 750°F and 550°F (400°C and 290°C). Generally, faster cooling rates provide greater strengths up to a limit. This is illustrated in Fig. 45.^[54]

However, increasing cooling rates produce increasing thermal gradients which produce increasing thermal stresses and the potential for increased distortion. Thermal gradients are reduced by reducing the cooling rate. (This is why “hot” or boiling water is used.)

There is a cooling rate “window” that must be identified to obtain both optimal physical properties and minimum residual stresses and distortion. The position and width of the window is a function of the specific hardenability of the alloy and the geometry of the part. This concept is illustrated in Fig. 46^[55] which shows as follows:

1. Curve A is the maximum cooling rate for obtaining specific structural characteristics.
2. Curve B is the cooling rate beyond which the alloy undergoes plastic deformation resulting in residual stresses.

Table 10 Type I quenchant limitations by AMS 2770E

Alloy	Form	Maximum thickness (in.)	Maximum polymer C concentration (%)
2024-T62	Sheet	0.080	16
7075-T6	Forgings	1.0	20–22
7075-T73	Forgings	2.5	10–12
7050	Forgings	3.0	20–22

Fig. 45 Cooling rate dependence on tensile strength for various alloys

Fig. 46 Diagram illustrating the hardenability window (optimum cooling law) for aluminum alloys

3. Curve 1 does not introduce residual stresses but does not produce the desired mechanical characteristics such as boiling water.
4. Curve 2 not only produces the desired mechanical properties but also produces unacceptable residual stresses such as cold water.
5. Curve 3 is an optimized cooling process where the cooling rate is controlled to optimize mechanical properties with minimum residual stresses.

Type 1 Quenchant Concentration Limits The selection of the polymer concentration for specific aluminum alloys is section size dependent. Section size/concentration curves for 6061,^[56] 2024-T3 and T4,^[57] and 7075-T6 and T73^[57] have been reported and are provided in Fig. 47.^[58]

Effect of Agitation and Section Size and Quenchant Concentration on Physical Properties Although the effects of cross-section size on the selection of polymer quenching conditions have been specified based on various industry studies,^[21] the results of a study conducted to examine the interrelationship effect of polymer concentration and agitation and section size on the as-quenched properties of aluminum alloys have not been reported. Another objective is to review the results obtained from a designed experiment conducted to simultaneously evaluate the effects of polymer quenchant concentration, agitation rate, and section size on 7075 aluminum sheet and bar stock.

Statistically designed experiments were run to examine the effects of polymer quenchant concentration, agitation rate, and cross-section size on the quench factor for one sheet thickness for 2024-T851 and a broader range of sheet thickness and bar diameters for 7075-T73.^[59] For each point of the experimental design indicated in Table 11, a reproducible cooling curve was obtained using the indicated bar and sheet probe illustrated in Figs. 20 and 21, respectively.

Fig. 47 Working curves Type I quenchant concentration selection as a function of cross section for (a) 6061, (b) 2024-T3 and T4, and (c) 7075-T6 and T-73

Effect of Quenching Parameters on HTC's Sarmiento et al. summarized the work conducted with cooling curves obtained using AA7075 cylindrical probes with diameters of 0.5, 1.0, and 1.5 in. and with the lengths >4 times the diameter equipped with a Type K thermocouple inserted to the geometric center. These probe dimensions were selected to minimize end cooling effects. They were quenched into 10%, 20%, and 30% aqueous solutions of an AMS 3025 Type 1 polymer quenchant (UCON Quenchant A) and in water, with and without agitation.^[60] The cooling curve time–temperature data were used to computationally derive HTC's at different cooling temperatures throughout the process, and the results are summarized in Table 12.

The first three columns of Table 12 show the quenchant, probe cross-section size, and agitation rate of each of the quenchant and quenching conditions evaluated. The values of the HTC as a function of temperature for different cooling temperatures are summarized in the remaining columns as indicated in Table 12. Generally, the HTC decreases with increasing quenchant concentration and decreasing agitation rate.

Polymer Quench Bath Maintenance Suggested strategies for cooling curve analysis of PAG polymer quenchant have been reviewed previously^[61,62] and an ASTM Standard Guide has issued with specific recommendations.^[63] In general, it was suggested that the following analyses be conducted: concentration by viscosity, concentration by refractive index, determination of “delta” (the difference between concentration determined by refractive index and viscosity), determination of thermal separation temperature, conductance, biological contamination, pH, and corrosion inhibitor concentration. The following comments will provide the reader some insight into the physical meaning and thus the reasons for determination of these data.

Table 12 Summary of heat transfer coefficients as a function of cooling temperature, quenchant concentration, and agitation rate

Quenchant	Sample diameter (in.)	Agitation	Heat transfer coefficient average [w/ m ² K]

1. Concentration by refractive index—The refractive index of a solution is dependent on its composition. In general, refractive index is most dependent on contamination effects. For example, buildup of hard metal ions from industrial water sources will result in faster cooling rates and sometimes cracking or increased distortion. Also, contamination by hydraulic oils, forging lubricants, and metalworking fluids may all exhibit deleterious effects on the quenching process. Variations in refractive index are one indicator of such contamination effects. Polymer degradation also may affect refractive index but to a lesser extent.
2. Concentration by viscosity—Polymer degradation will result in reduced viscosity.^[62,64] The viscosity of PAG solutions may be affected by contaminants, but to a lesser extent than if significant degradation has occurred.
3. Determination and meaning of delta—It is useful to determine the difference between the concentration obtained from refractive index and that obtained by viscosity. The difference in these two values is called delta. Typically, large unexpected changes in the value of delta over time indicate an out of control process, and further work must be done to determine the cause of the problem and to take corrective action. However, the quenchant may undergo slow contamination process, such as hard metal ion buildup, or even a slow degradation process. If so, the delta value, after being reasonably stable for some time, will gradually increase. When the delta value exceeds 6–8, often associated problems will result and corrective action must be taken or the quenchant must be replaced.
4. Thermal separation—Thermal separation will provide a measure of the cloud point of the quenchant.^[65] If significant degradation has occurred, the cloud point will increase. Usually, this is accompanied by cooling rate increases.
5. Inhibitor concentration—Polymer quenchants contain water and therefore, not surprisingly, are susceptible to corrosion. Since the corrosion inhibitor may be lost due to drag-out and other processes, it must be replenished periodically. Therefore, the corrosion inhibitor concentration must be monitored.
6. Conductance—Solution conductance is dependent on ionic content. If substantial ionic contamination has occurred, increases in solution conductance will be observed.
7. Other tests—Additional tests may be conducted to determine the causes of physical property variation. For example, size exclusion chromatography (or gel permeation chromatography) may be performed to observe the degree of polymer degradation. Alternatively, infrared spectroscopy may be performed to determine if oxidation of the polymer has occurred.
8. Biological contamination—A common source of polymer degradation is biological contamination. This can be easily determined and monitored by commercially available patch tests.

Thermal Separation The cooling mechanism of an aqueous PAG solution is dependent on an inverse solubility mechanism. This is illustrated in Fig. 45. Every PAG quenchant exhibits a characteristic temperature at which a thermal separation process occurs. The characteristic temperature is called the “cloud point” of the polymer, and it is dependent on the polymer structure and composition as shown in Fig. 49.^[65] At the cloud point, the hydrated PAG polymer becomes insoluble. The thermally separated polymer is significantly more viscous than the homogeneous solution, and the viscosity of the hydrated polymer is dependent on both the molecular weight of the polymer and the bath temperature which dictates the degree of hydration of the polymer. Increasing amounts of hydration

Fig. 49 Schematic illustration of thermal separation of a Type I PAG polymer quenchant

of the polymer reduces the viscosity of this layer. The thermal separation process is reversible with the separated layer redissolving as the solution temperature decreases below the cloud point.

It is likely that the quench bath will become contaminated by salts if the parts are preheated in a salt bath. Salt contamination may also occur from the concentration of hard metal ions if tap water is used for dilution of the quenchant. In either case, the presence of salt may cause faster cooling rates and increase the separation temperature of the PAG copolymer used to formulate the Type I quenchant.^[61] Salts may be removed by thermal separation as illustrated in the scheme provided in Fig. 49^[65] or the quenchant can be replaced if salt contamination becomes excessive.

Although thermal separation may be performed by simply heating the quenchant in the tank until thermal separation occurs, this process is not readily applicable to larger tanks. For these applications, a “one-pass through with heat recovery” process has been developed and is illustrated schematically in Fig. 50. This process may be applied on quenchant solutions as low as 1%.^[66]

Membrane Separation Reverse osmosis (RO) and ultrafiltration (UF) are two of the most common pressure-driven separation techniques that may be used to separate a polymer such as a PAG and, if the system is properly designed, additives from aqueous quenchant solution.^[67,68] The primary difference in these two techniques is the system pressures and the size of the molecules which can be effectively separated as shown in Table 13. Currently RO is the more favored method since more complete separation of the polymer and additives is possible. This will be the focus of the remainder of this section.

Table 13 Relationship between the membrane separation method, system pressures, and size of molecules separated

Membrane type	Size of solute separated	Pressure (psig)
UF	0.001–2 μm , (5000–200000 molecular weight)	10–100
RO	0.0001–0.001 μm	200–1000

The initial quenchant solution is called the “feed solution.” The quenchant feed solution is passed through a pressurized membrane as shown in Fig. 51. The fluid that passes through the membrane, which is called the “permeate,” is typically pure water in the membrane separation process being described here. The permeate passes into the core of the membrane assembly where it is either released from the system or delivered to a storage tank for further use. The concentrated solution that does not pass through the membrane is either recycled through the membrane assembly to further concentrate it or it is delivered to a storage tank for reuse.

The rate of permeate separation, Q_p , is equal to the rate of purified water passing through the membrane. This is usually expressed as volume/min at 25°C. The flow of the concentrate, Q_c , is equal to the flow of the retained polymer. The flow rate of the feed stream of the incoming quenchant, Q_f , is equal to the permeate rate plus the concentrate rate ($Q_f = Q_p + Q_c$).

In membrane separation technology, the recovery rate is used to characterize the separation system. Recovery rate (%) is defined as follows:

$$\text{Recovery (\%)} = \frac{Q_p}{Q_f} \times 100 \quad (3)$$

Fig. 50 One-pass through heat separation of a Type 1 PAG polymer quenchant

Fig. 51 Schematic illustration of a typical membrane filter assembly
Source: Courtesy of Osmonics, Inc.

The total concentration, %C, is typically reported as follows:

$$C_{ave} = \frac{C_F + C_C}{2} \quad (4)$$

$$\text{Passage } G = \frac{C_C}{C_{ave}} \quad (5)$$

$$\text{Retention} = \frac{C_F}{C_{ave}} \quad (6)$$

where C_F = Feed concentration, C_p = Permeate concentration, C_C = Concentrate concentration, C_{ave} = Average concentration.

All well-formulated polymer quenchants contain corrosion inhibitors. One problem with membrane separation is that corrosion inhibitors will be removed with the permeate stream. One way to minimize this problem is to use "salt-rejecting" membranes.

As water is separated from the quenchant during separation, the feed concentration (C_F) increases, the concentrate concentration (C_C) increases, and the permeate concentration (C_p) remains essentially unchanged and the permeate flow rate decreases asymptotically, feed flow rate decreases proportionate to the flow/pressure curve of the pump supplying the solution to the membrane, salt passage as a percentage increases, and the pressure required to perform the separation increases. These processes are illustrated in Fig. 52.^[67]

The polymer concentration may be automatically monitored by one of three methods: density, viscosity, or refractive index. Trouble-free operation requires that the system be properly engineered accounting for their inherent deficiencies. For example, the density method is susceptible to bias from contamination and air bubbles. Viscosity-concentration relationships are typically nonlinear and require appropriate detector concentration calibration. Refractive index is affected by oil and metallic salts.

In some cases, there may be sludge, oil, or oxides present in the quenchant solution that may damage the membrane assembly and therefore must be separated from the quenchant solution before the separation process.

The sludge is prefiltered from the feed stream using conventional 50–100 mesh filter cartridges. Such strainers require frequent cleaning.

The oil is separated from the feed stream by coalescing technology that permits the removal of the micron size oil droplets by coalescing them into larger particles that are then separated by density difference. This process is illustrated in Fig. 53.^[67] The primary driving force affecting oil separation by coalescence is the excess free energy at the interface of the dispersed oil droplet that is caused by unbalanced forces at the droplet surface. The relatively small interfacial tension is sufficient to permit oil coalescence in a contaminated quenchant solution. Thus, the dispersed oil is then collected in a settling tank where it is separated from the quenchant solution based on specific gravity.

Fig. 52 Representative curves for salt passage, permeate flow, and average concentration (C_{ave}) as a function of time

Fig. 53 Illustration of the sequence of operation of liquid/liquid surface coalescing

Blistering due to Lubricant/Quenchant Polymer Contamination Instances have been reported where residual polymer quenchant, die lubricants, and other hydrocarbon materials are present on the surface of the aluminum during tempering. This may lead to the formation of blisters and voids on the aluminum surface after quenching. This effect may be observed metallographically by the presence of “water marks” as illustrated for AA7075 in Fig. 54.^[5] Cleaning of the parts with a caustic etch and nitric acid accentuated the appearance of the blisters and produced a “smutty” residue in the area of the blisters. Sectioning showed that the blisters and voids were present to a depth of 0.050 in. with no indications of stringers, laps, etc.

Schuler reported that such blisters were due to high temperature oxidation of the residual hydrocarbon material during solution heat treating which produced hydrogen or water vapor which may migrate into the grain boundaries resulting in the formation of blisters or voids. Similarly, residual poly(alkylene glycol) polymer after quenching due to incomplete rinsing may produce the same effect during tempering.

High temperature oxidation may be controlled or eliminated by more effective precleaning or rinsing. A volatile fluoride atmosphere, such as that produced by ammonium perfluoroborate (0.004 oz./ft³ of furnace volume), may also be used to control the effect of water vapor.^[69,70]

Galvanic Corrosion Galvanic corrosion is caused by the contact of dissimilar metals with an electrochemical

Fig. 54 Cross section of surface blistering (as polished, 50 ×)

potential sufficient to allow current flow between the metals. For galvanic corrosion to occur, an electrolyte (salt solution) must be present as shown in Fig. 55. The galvanic series of metals is shown in Table 14.^[71] Metals close to each other will not undergo galvanic corrosion.

Aluminum galvanic corrosion may occur if the parts are in contact with a steel quench tank and exposed to a salt solution. Similar problems may occur if aluminum is joined to copper, such as through the use of copper wire to fasten aluminum parts or panels to a rack and immersed into a quenchant with salt contamination.

Although galvanic corrosion is not commonly encountered, it may occur if the above situations are allowed to occur.

Carbonated Water

As indicated previously, cold water is the most commonly used quenching medium for many quench-hardenable aluminum alloys (2xxx, 6xxx, and 7xxx). However, the relatively fast cooling rates upon initial immersion and through the critical region (750°F–550°F) shown in Fig. 56 produce high thermal gradients resulting in correspondingly high residual stresses and distortion or cracking.^[72,73] Thermal stresses due to high thermal gradients upon initial immersion may be reduced by raising the water temperature as illustrated in Fig. 57^[73] by comparing Δt^{cw} (cold-water cooling time) with Δt^{ww} (warmwater cooling time). Although the overall thermal gradient was decreased by increasing temperature, the cooling rate through the critical region was also reduced, which may result in an undesirable reduction of properties. In addition, hot water quenching is well known to produce nonuniform cooling resulting in even greater distortion than expected.^[74] ALCOA has addressed this problem with the use of carbonated water. Carbonated water is prepared by dissolving carbon dioxide (CO₂) at 0.001–0.2 standard cubic feet of gas per gallon of water, depending on the water temperature.^[73,75,76] Although other gases that exhibit sufficient solubility in water may be used, such as ammonia and nitrogen, CO₂ is preferred because it is odorless, relatively inexpensive, and highly soluble in water. A typical immersion and spray quench system for use with carbonated water quench systems is provided in Figs. 58 and 59, respectively.^[73]

It is thought that the mechanism of quenching in carbonated water involves the formation of an insulating vapor barrier around the hot aluminum surface upon initial immersion. The vapor barrier is formed by coalescence of water and CO₂ bubbles (varying from 100 to 350 μ in size). Upon further cooling, the CO₂ and water vapor bubbles break away from the surface and are reabsorbed into the water as they float to the surface. Typically, very little fluid motion at the water surface is observed with continued cooling. Vaporization of CO₂ ceases, and the cooling capacity of the quench medium approximates that of cold water (if cold water is used).

Fig. 55 Illustration of galvanic corrosion and the galvanic series

If cold-water quenching is needed, the carbonated water may be pumped to a storage tank or discarded (since CO₂ is environmentally benign) and cold water added to the tank. Alternatively, a pressurized air sparge may be used to remove the CO₂, thus quickly restoring the quenchant to that of a cold-water quench. Variations of this technology may be employed to achieve continuously variable cooling rates.

A related process has been patented by Japanese workers where the film boiling region of the overall cooling process is delayed using a time-quenching process to a temperature where the material strength exceeds the thermal stress of the cooling metal. At this point, the cooling rate is increased. This is accomplished by cooling the metal at a temperature, equal to or greater than, the critical cooling temperature.^[77] In some cases, either sodium chloride or sodium carbonate is used to control the stability of the film boiling region and cooling rates.

Ultrasonic Agitation

Yekinni et al. studied the effect of agitation on hardness of as-quenched cast AA6050 aluminum alloy.^[78] They reported that quench tank agitation may be provided by various methods such as recirculation pumps, open and submerged spray, air or nitrogen sparge, propeller agitation, and with or without a draft tube. Ultrasonic quenching was noted without citation and was not the specific

focus of the work reported. Furthermore, reports on the effect of quench tank agitation on properties for aluminum alloys are not common, although problems such as uniform flow, racking stable vapor blanket formation around hot parts are well known.^[79,80] Ultrasonic agitation is well known, if not commonly practiced, for the heat treatment of steel.^[81] Although electrical and magnetic fields have also been reported to minimize the potential vapor phase formation and reduction of cracking during steel quenching, similar studies have not been reported, for aluminum quenching.

Ultrasonic frequency (energy) is the form of vibrational waves and refers to *frequencies* greater than audible sound, which typically ranges from a few hundred Hz to a few thousand Hz (20–20,000 Hz). This range is typically designated as low frequency or power ultrasound. A hertz (1 Hz) is equal to one vibration per second. Ultrasonic *frequencies* (ultrasound) are typically 20–400 kHz and is usually transferred at a high power level (a few tens of Watts),^[82] and therefore, ultrasound in this range is capable of modifying the medium where it is propagated. Power ultrasound is typically sufficient to create acoustic cavitation, a necessary condition to optimize ultrasonic agitation. (Note: The frequency of a typical adult male is 85–180 Hz and for a typical adult female is 165–255 Hz.)

Ultrasonic vibrations are generated using a transducer. The vibrations are in the form of a wave where the peak of the wave is where the pressure is highest and the trough

(valley) of the wave is where the pressure is lowest. Air pockets are created and collapse (cavitation) in the trough of the wave. Ultrasonic cavitation and subsequent implosion generates agitation (sonication) on a microscale. The greater the frequency generated by the transducer, the smaller the bubbles that are created in solution and if sufficiently small, they will uniformly cover an entire surface, even those with complicated geometries. This process will provide uniform agitation and in the case of quenching, increased bubble motion with an increased number of bubbles will facilitate increased surface heat transfer.^[83] A sufficiently strong ultrasonic field will disintegrate a vapor film, thus assuring more uniform

convective heat transfer with much lower propensity for cracking and distortion.^[84]

The implosion of the cavities formed during acoustic cavitation is a relatively violent process. Experimental results have shown that the impact of a collapsing transient cavitation bubble could last 10^{-7} s reaching a local pressure of up to 193 MPa. The bubble size is approximately 10^{-4} m depending on the frequency and bubble implosion times occur within microseconds, which has been shown to result in a particle displacement velocity of approximately 100 m/s. In this way, acoustic cavitation may enhance heat transfer rates and promote fluid turbulence. Convection HTC increases of up to 25 times have been reported.^[82]

More recent work by Prezlj et al have shown that for common quenching conditions in water and aqueous polymer solutions, the expected bubble frequency range should be between 500 and 18,000 Hz, and that the frequency range depends on the size of the bubble and immersion depth as shown in Fig. 60.^[83]

One of the major sources of quench distortion is nonuniform heat removal from the surface of a part during quenching. Nonuniform heat removal is caused by nonuniform wetting of the surface by the vapor blanket surrounding the hot metal part being quenched which leads to increase thermal gradients and formation of undesirable stresses.

Fig. 60 Expected frequency range depends on the bubble size and immersion depth

Vapor blanket formation and rupture can be facilitated by the use of vibrational waves produced by the mechanism described above. Although *ultrasonic quenching* has been successfully utilized to reduce quench-induced distortion and cracking of steel components,^[85–88] until recently, it has not been reported for use with aluminum components.^[89,90]

To examine the effect of ultrasonic agitation on aluminum alloy quenching, Redmann et al. utilized an experimental arrangement that was successfully used in an earlier ultrasonic steel quenching study.^[91] For this work, Redmann et al. prepared an AlSi1MgMn aluminum alloy probe whose chemistry and thermal–physical properties of the probe are summarized in Table 15. A schematic illustration of the cylindrical probe with dimensions and thermocouple placement is provided in Fig. 61.^[89] As indicated in Fig. 61, the probe utilized six 0.5 mm Type K thermocouples placed at the center and at five positions 0.65 mm from the surface. The time–temperature data for the cooling curves was obtained at a data acquisition rate of 50 Hz.

Ultrasonic vibrations were provided by a sonotrode (transducer). Three different sonotrodes were ϕ 18, 34, and 50 mm and the corresponding ultrasonic energy amplitudes were 31, 19, and 19.6, respectively,^[90] with the corresponding

^aThe composition of the aluminum alloy AlSi1MgMn (AA6082) used for this work was as follows: 0.73 Si, 0.22 Fe, 0.05 Cu, 0.48 Mn, 0.61 Mg, 0.003 Cr, and 0.009 Zn (% by wt).

^bThese data were obtained from Sysweld 2010® version 12.0.

^cThe CP value was measured by differential scanning calorimetry.

^dThe thermal diffusivity (X) was calculated from the thermal conductivity (λ) divided by density (ρ) and specific heat capacity (CP) at constant pressure.

Fig. 61 Schematic illustration of cylindrical AlSi1MgMn aluminum alloy probe used by Redman et al. in their US quenching study^[89]

positions from the probe surface of 10, 30, or 50 mm. The ultrasound energy was applied in-line with the centeraxis of the sonotrode and the thermocouple placement at one-half the height of the probe. Two of the five surface thermocouples were in-line with the middle axis of the sonotrodes and one thermocouple directly faced the sonotrode (0°). The opposite side (180°) with three intermediate positions at 45°, 90°, and 135° is shown in Fig. 61. Note that ultrasonic wave propagation in this type of configuration can be envisioned to behave as an impinging beam.

It should be noted that the diameter of a sonotrode is related to the liquid volume and processing intensity. With smaller diameters, ultrasonic energy delivered is more focused with a greater amplitude (higher energy). Larger sonotrode surfaces provide ultrasonic energy over a larger surface area but at a lower amplitude.

The aluminum probe was heated to 540°C and removed from the surface and quenched in unagitated tap water with and without ultrasonic assistance. The temperature of the water bath was varied from 60°C to 85°C. When ultrasonic energy was applied, the ultrasound was turned on before the beginning of the quenching process. The experimental apparatus is depicted in Fig. 62.^[90] Note that when the transducer is immersed into a fluid as shown here, this is designated as a *direct ultrasonic application* of the transducer.

Figure 63 illustrates the cooling curves obtained with a ($\phi 29.5 \times 120 \text{ mm}^2$) AlSi1MgMn (AA6082) aluminum alloy probe with thermocouples located near the surface after quenching in water at various temperatures with no agitation. Note that the duration of vapor blanket cooling (film boiling) increases with increasing water temperature, particularly at temperatures greater than 60°C. In order to determine the effectiveness of ultrasonic quenching, 85°C water with the longest and most stable vapor film formation region was selected for the Redmann et al. study discussed here.^[89,90]

To determine the effect on the stability of the vapor blanket cooling region, three different sonotrode diameters were evaluated and the results are shown in Fig. 64.^[89]

Fig. 62 Comparison of conventional still quenching and ultrasonic (US) quenching. The upper series of photographs show conventional, unagitated (no US agitation) of tap water at 85°C. The lower series of photographs show US quenching of tap water at 85°C at the same time intervals. Both series of photographs show the presence of a 50 mm diameter sonotrode entering horizontally with a 10 mm spacing between the end of the sonotrode and the surface of the aluminum alloy probe

Source: Courtesy of Prof. Olaf Kessler, University of Rostock, Germany.

These data show that the stability of the vapor film decreases with increasing sonotrode diameter (increasing ultrasonic wave strength).

In a different set of experiments, the effect of the placement of the sonotrode tip placement from the probe surface was varied. For this study, the sonotrode diameter was $\phi 50 \text{ mm}$. The results shown in Fig. 65 indicate that the effectiveness of the ability of US wave energy to rupture the relatively stable vapor film of water at 85°C increased with decreasing spacing between the end of the sonotrode and the aluminum probe surface.^[89]

The effect of the position of the sonotrode tip relative to the probe surface on the relative ability to affect

Fig. 63 Cooling curves obtained with thermocouples located near the surface of the ($\phi 29.5 \times 120 \text{ mm}^2$) AlSi1MgMn (AA6082) aluminum alloy probe quenched in water at various temperatures with no agitation

Fig. 64 Cooling curves of the ($\phi 29.5 \times 120 \text{ mm}^2$) AlSi1MgMn (AA6082) aluminum alloy probe quenched in 85°C water with and without US agitation. Three different sonotrode diameters were evaluated: $\phi 50$, $\phi 34$, and $\phi 18 \text{ mm}$. The distance between the end of the sonotrode and the probe surface was 10 mm. The data shown are for the thermocouple at 0° (the surface directly facing the sonotrode)

Fig. 65 Cooling curves of the ($\phi 29.5 \times 120 \text{ mm}^2$) AlSi1MgMn (AA6082) aluminum alloy probe quenched in 85°C water with and without US agitation. The sonotrode diameter was $\phi 50 \text{ mm}$; however, the distance between the end of the sonotrode and the probe surface was varied as shown. The data shown are for the thermocouple at 0° (the surface directly facing the sonotrode)

vapor film rupture is illustrated in Fig. 66, where the near-surface cooling curves obtained at sonotrode positions of 0°, 90°, and 180° are shown for the aluminum alloy probe quenched in 85°C water.^[90] Although cooling curves were obtained at 90° and 135°, they are not shown in this figure.

Cooling curves measured at 45° and 135° are not shown in this figure. These data show that the cooling was fastest at the position of the sonotrode closest to the probe surface (0°) and the cooling at the 180° position was very similar to that shown for the centerline cooling curve. The cooling at 90° was intermediate between that shown for 0° and 180°.

While the data shown so far do confirm that ultrasonic quenching will destabilize, or eliminate, vapor blanket cooling and thus enhance quenching uniformity, Fig. 67

Fig. 66 Cooling curves of the ($\phi 29.5 \times 120 \text{ mm}^2$) AlSi1MgMn (AA6082) aluminum alloy probe quenched in 85°C water with and without US agitation. The sonotrode diameter was $\phi 50 \text{ mm}$. The distance between the end of the sonotrode and the probe surface was 10 mm. The data shown are for the near-surface thermocouples at 0°, 90°, and 180° and for the thermocouple at the geometric center of the probe

Fig. 67 Heat transfer coefficients of the ($\phi 29.5 \times 120 \text{ mm}^2$) AlSi1MgMn (AA6082) aluminum alloy probe quenched in 85°C water with US agitation. The sonotrode diameter was $\phi 50 \text{ mm}$. The distance between the end of the sonotrode and the probe surface was 10 mm. The data shown are based upon the near-surface thermocouple data obtained for the aluminum probe at 0° and 180°. The “adapted” heat transfer data shown were corrected for radial heat transfer affecting both positions: 0° and 180°

shows that at least for immersion quenching using transducers that the vapor film rupture is dependent on the position of the surface being quenched relative to the tip of the transducer. For the geometry shown, the closest surface to the transducer tip exhibited the greatest HTC's and the opposite side exhibited much lower heat transfer rates. However, initial simulation of these results did not correlate with the measured results. In fact, it was found that the simulated results at 0° were too low and the results on the opposite, 180° , side were too high. In order to obtain reasonably correct values, the use of various scaling factors was required. The results of the corrected (adapted) heat transfer simulations are shown in Fig. 67, which were suitable for subsequent heat treatment process simulation.^[89]

In most industrial ultrasonic applications that have been reported for steel quenching, large tanks are typically used such as that depicted for the system reported by Harvey shown in Fig. 68.^[87,88] This system utilizes a circular metal tank where the quenchant is water. The ultrasound energy is applied using three magnetostriction transducers attached at uniform spacings to the outer surface around the tank. In this way, the ultrasonic energy is focused to the center of the tank. Note that when the transducer is external to the tank, this is designated as an *indirect ultrasonic application* of the transducer.

Alternatively, piezoelectric transducers may be used as well. However, Bulat reported that magnetostrictive transducers were preferable for use as ultrasonic wave generators because of the power that they can develop and the frequencies at which they operate most efficiently range from 60 kc/s (kHz) down to 15 kc/s (kHz). Bulat reported that the best results were obtained at the range of 15–22 kHz.^[92]

The oscillations of the transducers are accomplished using an electronic oscillator and amplifier. If longer parts are quenched, additional transducers may be required to extend deeper into the tank and provide greater depth of agitation. The degree of efficiency of vapor film removal

Fig. 68 Harvey ultrasonic quenching system with 20 Hz transducers arranged at the periphery of the cylindrical quench tank. The transducers are welded at a stress antinode

is increased when the natural period of vibration of the container walls is in a state of resonance with respect to the frequency of the ultrasonic waves causing the vibration. For additional information regarding construction and use of this system.^[88] Further information regarding the construction of ultrasonically agitated tanks suitable for quenching has been provided by Brown^[93] and Massa.^[94]

Uphill Quenching

Definition of the Process Uphill quenching is also known as “deep freezing,” “cold stabilization,” or “tricycle stress relieving.” This process is conducted after the normal quenching process and prior to aging by immersing quenched aluminum parts into dry ice or liquid nitrogen followed by immersion in boiling water or blasting with high-pressure steam.^[95,96] The uphill quench process, when performed optimally, is conducted in four steps:^[97]

1. The quenched part is cooled to a “subzero” temperature, usually using liquid nitrogen.
2. The parts are held at the subzero temperature until they have achieved thermal equilibrium.
3. The parts are immediately transferred to the elevated temperature medium, preferably high-pressure steam.
4. The part is then aged in accordance with the alloy and desired temper.

The objective of uphill quenching is to offset residual stresses formed by rapid cooling by rapid heating thus producing a substantial decrease in residual stresses of the overall process. To be effective, the temperature gradients (ΔT) formed from the uphill quench must be greater than those formed by normal cryogenic cooling.^[98] Furthermore, the subsequent reheating after cryogenic cooling must not be sufficient to affect the tensile properties.^[96]

When hot aluminum is cooled after solutionizing, the heat transfer does not occur uniformly over the surface of the workpiece, which produces significant thermal stresses, which then lead to distortion and, in some cases, cracking. If the hot aluminum is quenched cryogenically by immersion into liquid nitrogen or a dry-ice bath, a continuous film is formed around the workpiece providing an improvement in the uniformity of cooling but a significant thermal gradient is formed between the surface and the core of the metal. However, cryogenic cooling does not indicate a rapid reheating of the workpiece after quenching. Therefore, the terms *cryogenic cooling* and *uphill quenching* refer to very different processes and should not be confused with each other.

Uphill Quenching Conditions and Tensile/Yield Strength Results Uphill quenching is most often used for precipitation-hardenable alloys including aluminum–copper,

aluminum–magnesium, and aluminum–zinc–magnesium alloys used for wrought or cast products. To evaluate the effect of varying uphill quenching conditions, test blocks ($304.8 \times 152.4 \times 50.8 \text{ mm}^3$) were cut from hot-rolled plate of one of two alloys: 2014 with a composition of 4.4% Cu, 0.8% Si, 0.8% Mn, 0.4% Mg, and the balance Al and 7075 which had a composition of 5.6% Zn, 2.5% Mg, 1.6% Cu, 0.3% Cr, and the balance Al. The 2014 test blocks were solutionized for 3 h at 504°C and the test blocks of 7075 were solutionized for 3 h at 466°C. After solutionizing, all test blocks were quenched in cold water. One test block (a control block) of each alloy was then aged after precipitation hardening: 2014 was aged for 10 h at 171°C immediately after quenching and the 7075 was aged for 36 h at 121°C 4 days after quenching. The remaining blocks were uphill quenched within 30 min to 1.5 h after cold-water quenching.

The uphill quenching processes were conducted by immersing the blocks in either dry ice/trichloroethylene (−78°C) or by further cooling by transferring to liquid N₂ (−195°C) and holding at temperature for 5 min after reaching equilibrium. After chilling the test blocks to either −78°C or −195°C, they were immersed into boiling water for 3–4 min or transferred to a steam cabinet where they were heated for 30 min with high-pressure steam (approximately 180 psig) jets positioned to assure uniform reheating.^[95,96,99] In both reheating processes, boiling water or high-pressure steam, the final temperature was 99°C. The reheating process is a critical part of the uphill quenching procedure since the reheating rate must be sufficiently rapid to cause plastic deformation and be sufficient to exceed the elastic limit within the metal.^[100]

After reheating, the test blocks were aged. AA2014 was aged for 10 h at 171°C and AA7075 was aged for

36 h at 121°C after which time the residual stresses and tensile properties were determined. The residual stresses obtained as a result of these treatments are summarized in Table 16, and the mechanical properties are summarized in Table 17.^[100]

The residual stress range shown in Table 16 indicates the difference in the maximum compressive stress at the surface and the maximum tensile stress in the center of the test block. These data show that cooling in liquid nitrogen after cold-water quenching and reheating with high-pressure steam produced the greatest amount of reduction in residual stresses.

The mechanical properties that were obtained from these different uphill quenching conditions are shown in Table 17.^[100] These results show that even cooling to the

Table 17 Mechanical properties of uphill quenched aluminum test specimens

Test number ^a	Alloy designation ^b	Tensile strength (MPa)	Yield strength (MPa)	Elongation (%)

7	7075	Dry ice	Steam	−78 to 99	109	50
8	7075	Liquid N ₂	Steam	−195 to 99	38.6	84

Test blocks ($304.8 \times 152.4 \times 50.8 \text{ mm}^3$) were cut from hot-rolled plate. Alloy 2014 was solutionized for 3 h at 504°C; alloy 7075 was solutionized for 3 h at 466°C. All test blocks were quenched in cold water. The control blocks were then aged after precipitation hardening: Alloy 2014 was aged for 10 h at 171°C soon after quenching; alloy 7075 was aged for 36 h at 121°C 4 days after quenching; Composition of alloy 2014—4.4% Cu, 0.8% Si, 0.8% Mn, 0.4% Mg, and balance Al; composition of alloy 7075—5.6% Zn, 2.5% Mg, 1.6% Cu, 0.3% Cr, and balance Al; Chilling was done by immersing the blocks in either dry ice/trichloroethylene (−77.8°C) or by further cooling by transferring to liquid N₂ (−195.5°C) and holding at temperature for 5 min after reaching equilibrium; After cooling in dry ice or liquid N₂, block was individually transferred to a chamber where it was immediately heated by a blast of high-pressure steam (126 kgf/m²) from jets for 30 s which raised the temperature to 99°C. Other chilled blocks were immersed into boiling water for 3–4 min.

lowest temperature and rapid reheating with high-pressure steam did not produce any significant effects on either tensile or yield strength. However, it was observed that test specimen 5, AA2014, which was cooled in liquid nitrogen and reheated with high-pressure steam, exhibited slightly lower elongation than that obtained with the other test specimens however, this small difference was not expected to significantly affect the ductility.^[100]

Effect of Uphill Quenching Process Variables Four process variables will be discussed that were studied previously by Hill et al.: (i) the temperature to which the part is cooled; (ii) the reheating method; (iii) yield strength, and (iv) residual stress state of the aluminum alloy at the time the part is uphill quenched (which varies with the total time following the initial quenching process).^[99]

Effect of Cooling Temperature The data in Table 16 show that the greatest reduction in residual stress was obtained with the lowest cooling temperature, in this case, liquid nitrogen (-195°C). Generally, residual stress reduction increases as the maximum temperature difference increases as shown in Fig. 69.^[99] The maximum temperature differential must be sufficient to provide the necessary stress reduction to offset the residual stresses caused by the conventional thermal processing. To provide the maximum temperature differential for stress reduction, the reheating of the material must be initiated from as low a temperature as possible.

Wiley reported that to obtain any significant advantage from uphill quenching, the maximum temperature difference should be at least 78°C . In some cases, it may be advantageous to cool to even lower temperatures than that provided by liquid nitrogen, such as those achievable

with liquid helium (-269°C). However, when cooling in liquid gases such as nitrogen or helium, it may be advisable to first cool to an intermediate temperature of -70°C to -130°C in order to conserve gas.

Reheating Methods The first objective of uphill quench is to cool the material to as low a temperature as possible. In order to maximize the thermal gradient in the process, the second step is to reheat the material as fast as possible to a temperature just below the artificial aging temperature. This is illustrated in Table 18, where high-pressure steam provided a significant advantage over low-pressure steam and both modes of reheating provided considerably greater residual stress reduction relative to boiling water. It is important to note that the reheating must be as uniform as possible. Therefore, the steam is directed uniformly over all surfaces of the material being reheated.

Table 18 Effect of reheating method^a

Reheating method	Maximum temperature difference ($^{\circ}\text{C}$) ^b	Residual stress reduction (%) ^c
High-velocity steam	371	82
Low-velocity steam	253	44
Boiling water (no agitation)	110	19

^aThese data relate to quenching of 7075 test specimens ($50.8 \times 152.4 \times 308.4 \text{ mm}^3$) cooled to -195°C within 1.5 h after solutionizing and cold-water quenching. The test specimens were quenched in liquid nitrogen reheated in the medium shown in the table and then aged to a T6 temper.

^bBetween the surface and geometric center (midplane).

^cRelative to control test specimens not uphill quenched.

Fig. 69 Correlation of the residual stress reduction with the maximum temperature difference between the surface and the core of the test specimen during uphill quenching. These data relate to the quenching of 2014 test specimens ($50.8 \times 152.4 \times 308.4 \text{ mm}^3$) cooled to -195°C within 1.5 h after solutionizing and cold-water quenching. The test specimens were reheated using high-pressure steam and then aged to a T6 temper: (1) maximum temperature difference between the surface and the center (midplane) and (2) residual stress reduction relative to material not uphill quenched

Pellman et al. conducted uphill quenching processes using a perfluorocarbon in the vapor phase, preferably, perfluoromethyldecalin (bp = 142°C).^[101] Advantageous properties of these fluids for use with uphill quenching include the following: constant boiling point below the aging temperature of the alloy, high heat transfer rates, and sufficient thermal stability to provide a uniform reheating process. These perfluorocarbons provide a maximum thermal gradient significantly greater than that achievable with steam without increasing the temperature of the alloy above its aging temperature. For example, the temperature differential provided by perfluoromethyldecalin of an alloy cooled in liquid nitrogen is 257°C versus 206°C, the maximum thermal gradient reported in the literature for high-pressure steam.^[101] A summary of residual stress reduction for 7075 using different cooling and reheating regimes is summarized in Table 19.

In an apparently similar work, Wang et al. described uphill quenching of 7050 aluminum forgings where the forgings were quenched in cold (8°C) water after solutionizing and then immediately cooled to -196°C in liquid nitrogen then reheated in a very hot (120°C to ~175°C) proprietary liquid bath and then tempered to a T74 condition. The results of this work also confirmed that the degree of stress relief was directly proportional to the magnitude of the maximum temperature difference as reported originally by Willey^[100] and Hill et al.^[99]

One common application for uphill quenching is to minimize the distortion of aluminum mirrors used in space applications. Ohl et al. studied the effect of various reheating media on residual stress and distortion produced during the heat treatment and water quenching and quenching with a Type 1 aqueous polymer quenchant^[21,102] of a 6061 aluminum alloy.^[103,104] The results of Ohl's study showed that uphill quenching of AA6061 that was quenched in either room temperature water or in a Type I quenchant resulted in approximately 15% residual stress

reduction when first cooled in liquid nitrogen then reheated in boiling water.

In addition to the known disadvantage of using boiling water relative to high-pressure steam that was shown above, Croucher also showed that at least in some cases, uphill quenching could not be successfully performed on Type I polymer quenched material because of the lower residual stresses that are produced relative to cold-water quenching.^[95] Therefore, although uphill quenching may be effective for some parts, such as those quenched in cold water, the uphill quenching process may not be effective with parts having low as-quenched residual stresses such as aluminum alloy parts quenched in hot water or aqueous polymer quenchants.^[95,97]

Effect of Yield Strength and Stress State and Prior to Uphill Quenching The objective of uphill quench is to counteract the unfavorable stresses in the part after quenching. The lower the surface compressive stresses, the greater the potential favorable effect of uphill quenching. Therefore, uphill quenching should be conducted as soon after quenching as possible before natural aging increases the yield strength of the part. Uphill quenching of a tempered part, for example, a 7075 in the T6 temper condition, would not be effective for this reason.

Disadvantages One of the primary disadvantages of uphill quenching is that it is a relatively expensive process that is often considered too difficult, especially since it requires residual stresses to be measured on each part, to be a reliable stress-relieving process, especially when compared to mechanical deformation processes that can be performed at room temperature. However, processes like tensile deformation have been very successfully applied for relief of quenching stresses; it is typically limited to sheet and plate with a uniform cross section in the stretching direction. While compression-tension loading may also be

Table 19 Comparative residual stress reduction of uphill quenched 7075 using different cooling and reheating regimes^a

Uphill quenching method		Temperature differential (°C)	Reduction in residual stress (%)

used, this method is limited by configuration, shape, and size.^[105]

Cryo Quenching

Details of the uphill quenching process were provided previously where the use and importance of the well-defined rapid reheating step immediately following cryogenic cooling most often conducted in liquid nitrogen. It is important to note that if there is no rapid reheating following cryogenic cooling, then the process is simply cryo quenching, not an uphill quenching process as defined previously. One successful example of cryo quenching of a thin sheets of a Russian Alloy D16AM (similar to AA2024) was reported by Il'yushko and Bedarev.^[98]

Il'yushko and A.S. Bedarev reported that for sheet thicknesses up to 5 mm, the strength and elongation of the D16AM test pieces quenched in water and liquid nitrogen were essentially equivalent. However, thickness >5 mm resulted in lower strength when quenched in liquid nitrogen because of a lower relative cooling rate compared to water.^[98]

To evaluate the relative distortion obtained with cryo quenching, C-ring test specimens shown schematically in Fig. 70a were prepared, solutionized at 500°C, and then quenched into water at 20°C, water at 90°C, and liquid nitrogen, and for comparison a test specimen was quenched into air as well. The results, shown in Fig. 70b, indicate that the average deflection of the test specimen quenched into liquid nitrogen was approximately 1.5 mm compared to the approximately 50 mm deflection when quenched into water. Although air did produce the lowest deflection, it did not provide the necessary strength properties. Therefore, it was concluded that thin-walled (≤ 5 mm) D16AM aluminum components could be successfully cryo quenched in liquid nitrogen to obtain minimal distortion while maintaining acceptable strength and corrosion resistance.^[98]

Fig. 70 Effect of different quenchants on D16AM aluminum (AA2024) C-ring distortion. (a) Figure on the left is a schematic of the C-ring distortion test specimen. (b) Figure on the right illustrates the total ring opening at point "A" in test specimen where the quenchants were quenched from a solutionizing temperature of 500°C into (i) water at 20°C, (ii) water at 90°C, (iii) liquid nitrogen (−196°C), and (iv) air. The areas indicated by "1" are minimum distortion and "2" are maximum distortion

Fluidized Bed Quenching

There have been a number of reports on the use of batch and continuous fluidized bed systems for quenching aluminum alloys such as complex AA319 and AA356 castings.^[106,107] Fluidized bed quenching systems are typically capable of producing HTC's between those attainable by forced air convection and water.^[108] Furthermore, as opposed to aqueous polymer quenchants where a hydrated polymer film surrounds the part upon immersion, fluidized bed particles are in direct contact with the surface through the entire quenching process. Therefore, since there is no unstable water vapor barrier formation, the thermal gradients formed within a part during fluidized bed quenching are much lower than those produced by water and aqueous polymer quenchants. It has been reported that residual stresses formed in AA356 powder metal castings during fluidized bed quenching are approximately 70% lower than those formed during water quenching.^[109]

A fluidized bed quenching system consists of gas diffusion assembly, fluidized bed solid support, and fluidizing gas. The fluidized bed is generated by blowing a gas, e.g., nitrogen, argon, carbon dioxide, Helium, or hydrogen through the solid support. Examples of common solid supports include aluminum oxide, silica, molecular sieves,^[110] or staurolite sand ($\text{FeAl}_3\text{Si}_2\text{O}_{12}\text{OH}$).^[111] Heat transfer within the fluidized bed has three primary components:

1. The particle convective component that is dependent on heat transfer between the bulk of the fluidized bed and the heat transfer surface of the particle.
2. The interphase gas convective component where heat is transferred between the particle surface and the interphase gas.
3. The radial component of heat transfer.

This process involves bubbles of the fluidizing gas rising through the bed resulting in a mixing process by the

movement of the solid particles. The particles disrupt the gas film at the cooling metal surface. The required gas flow rate required to fluidize the bed is typically at least three to five times the minimum fluid rate.^[110]

Typically, aluminum castings are quenched in 60°C–80°C water. Although the cooling rates produced are suitable for obtaining the design minimum properties, the relatively unstable nature of the water vapor surrounding the parts produces residual stresses sufficiently high to result in significant distortion and possibly cracking. These problems have been reported to be overcome by using a fluidized bed utilizing air, helium, and nitrogen gas as the fluidizing (blowing) gas. Fluidized bed quenching provides the additional flexibility to vary the cooling rate by adjusting processing parameters such as bed particle diameter, fluidizing gas, and fluidizing bed solid support.^[111] The HTC obtained is intermediate between forced air convective cooling and water.^[108]

As reported by Chaudhury and Apelian, the cooling rate of the water-quenched castings was greater than those quenching in the fluidized bed quenching system as shown in Fig. 71. The maximum cooling rate for the water-quenched alloy was -80°C/s (-144°F/s) compared to -11°C/s (-19.8°F/s) for the fluidized bed quenched bar. The change in the cooling rate was much greater for the water-quenched bar varying from 0°C/s to -80°C/s (0°F/s to -144°F/s) compared to the change in cooling rate obtained for the fluidized bed quenched bar varying from 0°C/s to -11°C/s (0°F/s to -19.8°F/s). For these reasons, much lower residual stresses and reduced distortion and cracking propensity would be expected for quenching in a fluidized bed than when quenching in water.

Ionic Liquids

Among the most common causes of quench distortion and cracking is the unstable formation of a film boiling (vapor blanket) phase at the hot metal interface during quenching in vaporizable liquids such as water, which leads to nonuniform heat transfer and high thermal gradients and

undesirable residual stresses. Currently, one of the most common quenchants that reduce undesirable residual stresses and produce lower distortion is aqueous solutions of PAG copolymers as defined in AMS 3025.^[51] Alternative media that do not exhibit unstable film boiling have been described previously and include fluidized bed quenching. In this section, another alternative nonvaporizable liquid system that has recently been investigated is a class of fluids designated as *ionic liquids*.^[112,113]

Ionic liquids are actually salts that are liquid at, or near to, room temperature. Structurally, ionic liquids consist only of ions (cations and anions). Hayes et al. more specifically defined ionic liquids as a subset of molten salts with melting points (T_m) below 373 K while the term *molten salt* is used for structures with a $T_m > 373$ K.^[113]

Typically, the cations and anions are large and unsymmetrical, and are selected specifically to destabilize the potential formation a solid-phase crystal. Although there are no specific rules to form an ionic liquid, typically this may be achieved within a relatively large window of ion structures by balancing ion–ion interactions. For example, the alkyl chain length (n) of the cation must be sufficient to reduce Coulombic forces and disrupt lattice packing, but not so long ($\approx n < 12$) that it will increase the melting point of the salt. (Cohesive interactions increase with length of nonpolar groups such as linear alkanes.)^[113] Figure 72 illustrates a number of selected examples of cations that have been used to form ionic liquids.^[114]

Current evidence suggests that the ions in ionic liquids self-assemble into amphiphilic nanostructures. The existence of this defined solvent structure is implicated in almost all aspects of their chemistry. Therefore, ionic liquids should be considered nanoheterogeneous, coherent, and essentially regular fluids.^[113]

Typical properties of an ionic liquid are summarized in Table 20.^[115] Generally, ionic liquids exhibit low vapor pressures and moderate specific conductivities which are generally in the range as those exhibited by aqueous electrolytes. Because ionic liquids do not boil, but thermally degrade at high temperatures, they are of interest

Fig. 71 Comparison of cooling time and rate (dT/dt) curves for a tensile bar of AA354 aluminum casting alloy quenched in a fluidized bed and water at 25°C

Fig. 72 Illustration of representative cations (usually organic) and anions in ionic liquids. The cation–anion pair is usually selected so that the resulting salts cannot pack completely. This will minimize the potential for crystallization so that the ionic liquid will remain liquid over a wide range of temperatures

Table 20 Typical properties of ionic liquids^[116]

Salt	Cation and or anion quite large
Freezing point	Preferably below 100°C
Liquidus range	Often >200°C
Thermal stability	Usually high
Viscosity	Normally <100 cP
Dielectric constant	Implied <30
Polarity	Moderate
Specific conductivity	Usually <10 mS/cm, “good”
Molar conductivity	< 10 S cm ² /mol
Electrochemical window	>2V, even 4.5 V, except for Brønsted acidic systems
Solvent and/or catalyst	Excellent for many organic reactions
Vapor pressure	Usually negligible

as potential quenchants since lower distortion than that typically exhibited by vaporizable fluids such as water.

Two ionic liquids were selected by Beck et al. to assess their quenching behavior.^[116,117] One was 1-ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide denoted as [EMIm][NTf2], whose structure is shown in Fig. 73, was chosen because of its high thermal stability and 1-ethyl-3-methylimidazolium ethyl sulfate denoted as [EMIm][EtSO4], whose structure is shown in Fig. 74, was selected because of its good availability and generally extensive characterization.^[116] The purity of the ionic

Fig. 73 Structure of 1-ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide ([EMIm][NTf2])

Fig. 74 Structure of 1-ethyl-3-methylimidazolium ethyl sulfate ([EMIm][EtSO₄])

liquids was greater than 98% as reported by the suppliers. A comparison of the physical properties of these two ionic liquids is provided in Table 21.^[118,119]

It is important to note that although it is assumed that ionic liquids do not boil, but decompose at elevated temperatures and atmospheric pressures as shown in Table 21, some may undergo boiling at sufficiently high temperatures at reduced pressure. As has been reported by Earle et al., [EMIm][NTf2] has been established to exhibit boiling without decomposition using a short-path distillation apparatus at 300°C and 0.1 mbar (1 mbar = 100 Pa).^[120] However, since most quenching processes are performed at atmospheric pressure, it can be reasonably assumed that ionic liquids such as [EMIm][NTf2] are not volatile and would not be expected to exhibit film boiling or significant decomposition under normal quenching conditions.

Two observations from Table 21 that may be made are that the viscosities of ionic liquids are relatively high compared to water or aqueous polymer quenchants, and the HTC's at 30°C are similar to petroleum quench oils, which are typically not used in aluminum quenching because their cooling rates are insufficient to produce the desired design mechanical properties. One method used with molten ionic salt baths to address this shortcoming is to add water.^[125] The effect of water addition on the quenching performance of ionic liquids has been evaluated and will be discussed subsequently.^[116,117,126] Alternatively, viscosity reduction may also be accomplished by increasing the quench bath temperature as shown in Table 22, which

compares the viscosity temperature behavior of [EMIm][EtSO4] and [EMIm][NTf2].^[119]

Perhaps the most common method to assess quenching performance is to determine cooling time–temperature cooling curves. Cooling curves were determined for [EMIm][NTf2] and [EMIm][EtSO4] with and without the addition of tap water with cylindrical (Φ 29.5 $\times$ 120 mm²) EN AW-6082 (AlSi1MgMn) probes equipped with Type

K thermocouples located at the geometric center and 0.65 mm from the surface at one-half length. The probes were solutionized at 540°C and then quenched. The cylindrical 0.9 L cylindrical quenching bath was equipped with a flat window for viewing the quenching process and a magnetic stirrer at the bottom for agitation. The transfer time from the furnace to the quench bath was less than 10 s, and the data acquisition rate was 50 Hz.^[117]

The interfacial phase behavior of pure [EMIm][NTf2] and with the addition of water at different times during the quenching process at 30°C is shown in Fig. 75.^[116] The top series of pictures show the cooling process of pure [EMIm][NTf2]. No film boiling or nucleate boiling processes are evident. Instead the schlieren cooling behavior due to density variations caused by the rise of the hot fluid from the aluminum interface to the surface is observed during a convective cooling process. This is expected since ionic liquids, in general, do not boil at atmospheric pressures.

Jacquemin et al.^[127] have determined the weight and mole fraction of a series of ionic liquids. The values for Emim⁺NTf2[−] and Emim⁺EtSO4[−] are shown in Table 23.^[127]

The middle series of pictures in Fig. 75 show the cooling process observed for [EMIm][NTf2] containing 3.5 mass (ma.) % tap water. Although bubble formation and no film boiling are initially observed, bubble formation (nucleate boiling) proceeded rapidly after the first 5 s of cooling and is no longer observed after 10 s.

The bottom series of pictures in Fig. 75 show the cooling process observed for [EMIm][NTf2] containing 10 ma.% tap water. At this higher content, bubble formation continues for up to 10 s after which time it is hardly observable.

Although not shown here, Beck reported that at a higher bath temperature of 85°C there continues to be no film

Fig. 75 Photographic series of the quenching process of an aluminum probe quenched into in pure [EMIm][NTf2] and water mixtures at an initial bath temperature of 30°C: (a) No water added, (b) 3.5 ma.-% water, and (c) 10 ma.-% water
Source: Olaf Kessler, University of Rostock, Germany.

boiling or nucleate boiling in pure [EMIm][NTf2]. Convective cooling was facilitated by a schlieren cooling process. When 3.5 ma.-% water was added, bubble formation occurred for more than 10s which decreased slowly after 20s.^[116]

Table 23 Molar masses (MIL) and water content in mass fractions (w_w) and mole fractions (x_w) of the dried and water-saturated Emim⁺NTf2⁻ and Emim⁺EtSO4⁻^[128]

Ionic liquid	Molecular weight (g/mol)	$w_w \times 10^3$		$x_w \times 10^3$	
		Dried	Saturated	Dried	Saturated
Emim ⁺ NTf2 ⁻	391.31	0.05	19.8	1.10	305
Emim ⁺ EtSO4 ⁻	236.29	0.10	Miscible	1.30	Miscible

In a related study, Beck showed that the pure [EMIm][EtSO4] ionic liquid cooled exclusively by convection. When 5 ma.-% tap water was added, the resulting [EMIm][EtSO4] solution did exhibit nucleate boiling (no film boiling) which dissipated after 5s and could no longer be observed after 10s. When 10 ma.-% of tap water was added, the interfacial bubbles were observed for 10s of cooling, which slowly dissipated as cooling continued. This study showed that the interfacial cooling behavior for [EMIm][EtSO4] ionic liquid was very similar to that observed for [EMIm][NTf2], with or without the addition of tap water.^[116]

Finally, Beck et al. used high-speed video recording where the interfacial quenching process for both [EMIm][NTf2] and [EMIm][EtSO4] ionic liquids and tap water could be observed on a millisecond scale that ionic liquids with a limited water content do not generate film boiling at the beginning of a quenching process.^[128] However, when water was added to the ionic liquid, film boiling was observed. At higher water contents, short-term film boiling on the order of 0.1 s was observed. In addition, an explosive rewetting process was observed as well.

The cooling curves of cylindrical aluminum probes obtained by quenching in tap water and [EMIm][NTf2] at an initial bath temperature of 85°C are shown in Fig. 76.^[117] Tap water exhibits the classic Leidenfrost cooling behavior with a relatively low HTC due to film boiling for the initial 15 s of the water cooling process until the surface

Fig. 76 Comparison of cooling curve behavior of water, pure [EMIm][NTf2], and [EMIm][NTf2] containing 2 ma.-% tap water at a bath temperature of 85°C with agitation. The cooling curves shown in this example are those obtained by the near-surface thermocouple in the aluminum probe. The image on the left is the cooling time–temperature profiles and the image on the right is the heat transfer coefficient–surface temperature profile

temperature is approximately 450°C at which point there is a transition to the much faster cooling nucleate boiling process. However, the ionic liquid [EMIm][NTf₂] does exhibit any evidence of film boiling or nucleate boiling, and only very low convective cooling was observed as expected from the images shown in Fig. 75. When 2 ma.% of tap water is added to the pure [EMIm][NTf₂], the cooling power increased significantly and the maximum HTC approximately to 3600 W/(m²K).

The dependence of maximum HTC of ionic liquid on bath temperature and water content for both ionic liquids studied by Beck et al., [EMIm][NTf₂] and [EMIm][EtSO₄], is summarized in Table 24.^[114,117] Interestingly, increasing the bath temperature at a comparable water content exhibited only a minimal effect on the maximum heat transfer or [EMIm][NTf₂]. However, the maximum heat transfer was increased significantly by increasing the water content. This was true for both ionic liquids

evaluated [EMIm][NTf₂] and [EMIm][EtSO₄]. It is important to note, however, that the maximum HTC (cooling power) of [EMIm][EtSO₄] was substantially greater than that obtained for [EMIm][NTf₂].

The effectiveness of quenching performance of [EMIm][EtSO₄] ionic liquid, in view of its greater quench severity (versus [EMIm][NTf₂]), on the hardness of three aluminum alloys in the T6 temper condition was compared, and the results are summarized in Table 25.^[117] The three aluminum alloys were AA6182, 2219, and 7349, and the average cooling rates to 200°C for each of these alloy test specimens when quenched into tap water and [EMIm][EtSO₄] show that the highest value was obtained for the AA2219 8 mm thin plate. The cylindrical test specimen of AA6082 was quenched from 540°C versus 470°C for AA7349, which would produce lower cooling rate as shown in Table 25.

Hardness tests results are shown in Table 25. The T6 hardnesses of AA6082 and AA2219 that were quenched in [EMIm][EtSO₄] are comparable to those that were water quenched. Beck et al. suggested that this was because the ionic liquid causes overcritical cooling rates for these two alloys, which was supported by the average measured cooling rate down to a sample temperature of 200°C, which is within the range of critical cooling rates for these two alloys. Quenching of AA7349 in [EMIm][EtSO₄] resulted in a lower T6 hardness than that obtained by water quenching. However, even water quenching with an average measured cooling rate of 71 K/s down to a sample temperature of 200°C cannot meet the critical cooling rate of AA7349 of approximately 300 K/s.^[114] Quenching in [EMIm][EtSO₄] can generate 90% of maximum hardness required.

Ionic liquids as quenchants for aluminum were interesting because they did not exhibit boiling points. Therefore, they would be expected to result in lower distortion because of the nonuniform cooling and resulting thermal gradients afforded by hot, or cold, water, the most common quenchant used for aluminum components. Thus far, it has been

Table 24 Dependence of maximum heat transfer coefficient of ionic liquid on bath temperature and water content

shown that at least one ionic liquid is capable of producing design minimum mechanical properties comparable to water. At this point, the results of the relatively limited distortion experiments that have been reported thus far will be summarized.

A schematic illustration of the AA7349 test piece used for distortion measurements is shown in Fig. 77.^[117,126] The length of the test specimens was 120 mm. A Type K thermocouple was inserted to the geometric center at a depth of 36 mm to monitor the solution annealing temperature. The test specimens were heated in an air circulation furnace up to 470°C at which point it was quenched in the Y-direction into 15 L of either tap water or [EMIm][EtSO₄] at 25°C. Distortion was measured on the 60 × 120 mm² face using a 3D coordinate system measuring device before and after heat treatment. The measuring density was 12 points × 24 points.

The average flatness of the test specimens before heat treatment was approximately 80 μm as shown in Fig. 78. After quenching in water, the average flatness increased to 160 μm. When the test piece was quenched into [EMIm][EtSO₄] at 25°C, no significant change in flatness relative to the initial condition was observed. Interestingly, before heat treatment there was a slight bending along the Z-direction; but after quenching in water, a combination

Fig. 77 Schematic illustration of the “T-shaped” AA7349 test piece used distortion analysis. Distortion was determined by measuring the flatness of the bottom 60 mm face shown above

Fig 78 Summary of the average “flatness” showing the average and extremes obtained for the 60 mm face of the test piece shown in Fig. 77

of bending along the Z-direction and Y-direction was observed.^[117,126]

In conclusion, although only limited exploratory work with ionic liquids thus far, in view of their interesting potential as quenchants for aluminum alloys and the distortion reduction potential that they afford, it is expected that this work will be expanded further into both steel and aluminum quenching applications.^[131] It must be noted that in view of the limited production volumes, the prices of the ionic fluids are prohibitive. However, it is expected that prices will decrease dramatically as their potential for industrial applications, such as for metal quenchants, production volumes will correspondingly increase and prices should decrease.

Additional Quenching Media

A number of other quench media have been reported, which include the following: cryogenic liquids such as aqueous concentrates of sulfite–yeast media^[132] and quenching into a “mud” composed of water, clay, an additive of magnetite (one of the oxides of iron—Fe₃O₄—which is ferromagnetic), ferrosilicon (an alloy of iron and silicon with an average silicon content between 15 and 90 wt.% containing a high proportion of iron silicides), or barite (a mineral consisting of barium sulfate—BaSO₄), and other additives to provide corrosion protection, anticoagulation, and antifoaming.^[133] However, to date, cold water, hot water, and aqueous polymer solutions are the most frequently used throughout the world in the aerospace aluminum processing industry.

Effect of Coatings on the Quenching Process The effect of various surface treatments on the yield strength of AA7075 after quenching into boiling water and then subjecting to a T6 temper is shown in Table 26.^[134] Although the experimental conditions for the formation of the black oxide were not provided, one method to accomplish surface blackening is performed by anodizing, which involves first cleaning the aluminum surface, then placing

Table 26 Effect of surface treatment of 7075 quenched at 100°C on the yield strength of 7075-T6^{a,b}

Surface treatment	Yield strength— σ_y (MPa)
Clear (caustic) etch	213.86
Sanded	223.09
As-rolled	285.53
Black oxide (see text for description)	415.67
Powdered oxide ^c	468.70

^aDetailed characterization of these coatings was not provided in the original reference.

^bQuenching medium was boiling water.

^cAlthough details were not provided in the original reference, this was apparently a thermally sprayed aluminum oxide coating.

the component into an electrolytic cell containing a dilute acid such as sulfuric acid. The component is connected to the positive side (anode) of an electrolytic cell and the tank is the cathode or negative ground of the cell. This electrolytic process produces a hydrated aluminum oxide coating that is integral to the aluminum alloy substrate. The electrochemical reaction is carefully controlled with respect to time, temperature, and current density to control the thickness of the black oxide finish. Thickness of 0.1–1.0 mm. thick is typical although the coating thickness here was not reported for the data shown in Table 26.^[134]

The effect of surface treatment on the yield strength after quenching in boiling water and then aging data summarized in Table 26 show that boiling water quenching of as-rolled or sanded aluminum produces significantly poorer yield strength than that obtained with a cold-water quench. However, the application of either a black oxide or a sprayed powdered oxide finish to the aluminum surface produces a substantial improvement in yield strength than that obtained for the aluminum without the oxide coatings. It was reported that the powdered oxide coating was nearly as effective with a boiling water quench as obtained with a cold-water quench: σ_Y (MPa) = 476.7 (sanded), 478.2 (as-rolled), and 481.2 (black oxide).^[134] The cooling curves at 21°C for these three surface conditions are shown in Fig. 79.

The HTC data corresponding to three of these cooling processes are important since quenching involves heat transfer from the cooling metal surface to the cooler quenchant and are shown in Fig. 80.^[134] The HTC data show that the maximum HTC of the black oxide-coated aluminum was marginally higher than the as-rolled aluminum and both were significantly greater than that exhibited by the aluminum with a sanded surface. Furthermore, the film boiling to nucleate boiling transition occurred much earlier

Fig. 79 Effect of surface preparation on midplane cooling of a 0.5-in. thick 7075 alloy plate quenched in water at 21°C and superimposed with the C-curve for 7075-T6

Fig. 80 Heat transfer coefficients of a 0.5-in. 7075 alloy plate quenched in water at 21°C

for black oxide-coated aluminum than either of the other two aluminum surfaces or the aluminum with the sanded surface exhibited the most delayed film boiling to nucleate boiling transition.

The HTC data shown in Fig. 81 show that the magnitude of the HTC follows the order of the following:

powdered oxide > clear etched > sanded > black oxide
> as-rolled

These data show that if reproducible quenching performance is desired, then the *exact* condition of the surface to be quenched must be specified.^[134] The effect of surface treatment on the yield strength after quenching in boiling water and then aging to the T6 temper is quite dramatic as shown in Table 26. First of all, by comparing the results of cold water (21°C) with boiling water (100°C) quenching of as-rolled or sanded aluminum produces significantly poorer yield strength than obtained with a cold-water quench. However, it is also evident that the application

Fig. 81 Heat transfer coefficients of a 0.5-in. 7075 alloy plate quenched in boiling water

of either a black oxide or a powdered oxide finish to the aluminum surface produces substantially greater yield strength than the aluminum without the oxide coatings, and the powdered oxide coating was nearly as effective with a boiling water quench as any of the surface treatments with a cold-water quench.

Ulysse and Schultz studied the effect of various coatings by quenching instrumented cylindrical probes machined from 7075-T6511 round bars 38.10 mm dia. and 171.40 mm long. The probe tip was rounded for smooth entry into the 60°C water quenchant. The surface of all of the probes used in this study was machined and polished. Each probe was equipped with two Type K thermocouples located at mid-length (depth of 76.20 mm): one at the geometric center and the other 16 mm from the surface. A new probe was used for each test.^[135] A schematic of the probes used for this work is shown in Fig. 82.

In addition to an uncoated probe used for reference, three probe coatings were used for this study:^[135]

1. Coating 1—An aluminum oxide (Al_2O_3) solution made by using 10% of very fine ($< 1\ \mu\text{m}$) Al_2O_3 powder in water and 1% sodium silicate. *Sodium silicate* is the common name for compounds with the formula $(\text{Na}_2\text{SiO}_2)_n\text{O}$. One member of this series is *sodium metasilicate*, Na_2SiO_3 . Note: Aluminum oxide is used to improve surface wettability.
2. Coating 2—An aluminum silicate hydroxide (aluminum silicate dehydrate or Kaolinite) solution prepared from 10% Kaolinite powder (with median particle sizes of $< 1\ \mu\text{m}$) in water and 1% sodium silicate.

Fig. 82 Schematic illustration of the instrumented probe machined from 7075-T6511 round bars used in the Ulysse and Schultz coating study^[135]

Kaolinite is a clay mineral with the composition $\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$.

3. Coating 3—A non-foaming anionic phosphate commercial wetting agent, $[\text{Na}_2(\text{RO})_2\text{P}_2\text{O}_6]$. The “R” group is typically a long-chain fatty hydrocarbon but not specifically identified by the authors.

The coatings were applied by first washing with a surfactant, rinsing and then heating to 65°C at which point the coatings were applied by dipping the probes into the desired coating solutions and then allowed to dry. The probes were solutionized at 470°C for 30 min and then quenched into 60°C water, and the cooling time–temperature data were collected at a frequency of 10 Hz. The HTC were then calculated by finite element analysis method. The resulting HTC–surface temperature profiles obtained are shown in Fig. 83.

Figure 5 shows the classic boiling heat transfer behavior where film boiling, nucleate boiling, and convective cooling was obtained for the untreated probe. A maximum heat transfer coefficient of 11,100 $\text{W}/(\text{m}^2\cdot^\circ\text{C})$ is observed for the nucleate boiling stage. Coating 1 (aluminum oxide) improved the heat transfer but it was most notable above 400°C, and the observed increase was likely due to better wettability than that exhibited by the untreated probe. However, Coating 3 (anionic phosphate surfactant) resulted in a rapid increase in heat transfer to 6000 $\text{W}/(\text{m}^2\cdot^\circ\text{C})$, and it continued to rapidly increase to approximately 21,000 $\text{W}/(\text{m}^2\cdot^\circ\text{C})$ in the nucleate boiling range. The heat transfer coefficient curve for aluminum silicate (Kaolinite) Coating 2 also had excellent wetting compared to the uncoated probe (as observed by decreased film boiling). The surface structures responsible for these behaviors and therefore the mechanisms were not reported in the study.

Fig. 83 Coating 1—An aluminum oxide (Al_2O_3) solution made by using 10% of very fine ($< 1\ \mu\text{m}$) Al_2O_3 powder with the remaining volume consisting of water and 1% sodium silicate; Coating 2—10% of very fine Kaolinite powder with the remaining volume consisting of water and 1% sodium silicate; Coating 3—A phosphate non-foaming anionic $[\text{Na}_2(\text{RO})_2\text{P}_2\text{O}_6]$ commercial wetting agent

The relative cooling curve behavior obtained for these treatments was determined by comparing the times to cool from 470°C to 200°C which are summarized in Table 27.^[135] As observed with the calculated HTC's in Fig. 83, Coatings 2 and 3 exhibited the best surface cooling enhancement.

Ulysse followed this work with a study to evaluate the potential use of Kaoline coatings on AA7050 industrial forgings where the longest section was approximately 626 mm, the widest section was approximately 411 mm, and a representative depth was approximately 156 mm.^[136] The forgings were equipped with 16 Type K thermocouples inserted at various locations in the forgings. Each forging, coated and uncoated, was solutionized at 478°C for about 1 h at which time it was slowly lowered directly into the quenching tank which was approximately 3.65 m long and 1.2 m deep containing 60°C water. Residual stresses were then measured by a hole-drilling method.

From the cooling time–temperature data, it was observed that the Kaoline-treated forgings exhibited substantially faster cooling times from 478°C to 200°C as was observed in the earlier Ulysse and Schultz study.^[135] The Kaolin solution promoted surface wettability and nucleate boiling resulting in increased surface heat transfer. It is important to consider that while improved heat transfer may provide improved mechanical properties, it may also be correspondingly deleterious to residual stresses due to corresponding increases in thermal gradients during quenching which was confirmed by the hole-drilling residual stress measurements.^[136]

The effect of surface coatings on residual stress and distortion of a four-port variable-pitch airscrew propeller hub closed die forging manufactured from AA2014 with a width of 260 mm and a mass of approximately 25 kg was studied by Tanner and Robinson.^[137] Prior to heat treatment, the forging was bored out to improve cooling rates reducing the mass to approximately 15 kg. It was reported that cooling rates greater than 100°C/s are required between 400°C and 290°C to achieve the maximum tensile strength. However, these cooling rates will not be obtained in thick section sizes due to much slower surface heat transfer resulting in nonuniform mechanical properties. Traditionally, these parts are quenched into boiling water to reduce residual stresses. In Tanner and Robinson's work, the objective was to improve the cooling rate during a boiling water quench by surface modification.

Table 27 Cooling time from 470°C to 200°C comparisons for the different coatings

Coating	Cooling time at center (s)	Cooling time at surface (s)
Uncoated	8.6	7.0
Coating 1	4.7	3.1
Coating 2	Not available	2.7
Coating 3	3.5	2.1

In order to provide a clean surface prior to quenching, hot caustic etching is performed to remove residual forging lubricants after forming. This process leaves a residual black copper oxide powder residue on the surface of the part which may be subsequently removed by immediate immersion into nitric acid prior to heat treatment. (This process is designated as “desmutting.” Removal of the black oxide is known to increase cooling rates.)

Cooling during quenching was monitored using thermocouples inserted into the center of the thickest section of the forging. Heat treatment was performed according to MIL-H-6088G for heat-treating 2014-T6 die forgings by quenching from 496°C to 507°C into 60°C to 82°C water followed by aging for 10 h at 166°C–177°C.^[138] AA2014-T4 requires a similar quench followed by a minimum natural aging period of 96 h at room temperature. Table 28 summarizes the different heat treatments that were evaluated in this work.^[137]

Forging 2014-1 was heat treated to a T6 condition for use as a control. The remaining forgings were quenched into boiling water and artificially aged for different periods of time and at different temperatures. Forgings 2014-5 and 6 were not desmuted prior to heat treating. Forging 2014-3 was cut into two equal halves after solution heat treatment and quenching. These halves were labeled “A” and “B” with section “B” receiving a double aging treatment.

To prevent plasticity, the forgings were aged for 12 h at 170°C before residual stresses were determined by hole drilling.^[139] The results of this study are shown in Fig. 84.^[137]

As a result of this study, Tanner and Robinson concluded the following:

1. Although quenching the AA2014 forgings into 60°C water produced mechanical properties that exceeded specifications, comparatively large residual stresses were obtained.
2. Quenching the AA2014 forgings into boiling water yields reduced residual stresses; however, the mechanical properties were unacceptably low.
3. When the black copper oxide coating produced by hot caustic etching is not removed prior to solution

Table 28 Heat treatments used for AA2014 forgings

Forging number 2014	Heat treatment (h/°C)	Quench ^a	Aging (h/°C)
1	4/500	Q60	12/170
2	4/500	BWQ	12/170
3A	4/500	BWQ	96/140
3B	4/500	BWQ	96/140 + 12/160
5	4/500	BWQ ^b	12/170
6	4/500	BWQ ^b	12/170 + 8/205

^aQ60 = 60°C water quench; BWQ = boiling water quench.

^bDesmuted before boiling water quench.

Fig. 84 Residual stress and deflection as a function of quenchant type and aging treatment for forging numbers 1, 2, 5, and 6 heat treated according to Table 28

heat treatment and boiling water quenching, low residual stresses with good mechanical properties are obtained.

- The black oxide-coated AA2014 forgings cool significantly faster than uncoated forgings because the HTC is increased at higher temperatures due to unstable film boiling and acceleration of the transition from film boiling to nucleate boiling due to the presence of the black oxide coating.
- An artificial aging treatment of 12 h at 170°C produces the best mechanical properties for the different quenching methods tested. Additional aging at higher temperatures did not produce further improvement in mechanical properties or residual stress reduction.

In conclusion, surface coatings may be used to enhance surface HTCs and cooling rates while producing acceptable mechanical properties and reduced residual stress and distortion.^[81]

Intergranular Corrosion

Aluminum is solution treated at temperatures generally in the range of 400°C–540°C (750°F–1000°F). During solution treatment, some alloying elements are redissolved to produce a solute-rich solid solution. The objective of this process is to maximize the concentration of hardening elements including copper, zinc, magnesium, and/or silicon in the solid solution. The concentration and rate of dissolution of these elements increases with temperature. Therefore, solutionizing temperatures are usually near the liquidus temperature of the alloy.^[1,97]

If an aluminum alloy is slowly cooled from an elevated temperature, alloying elements precipitated and diffuse from solid solution to concentrate at the grain boundaries, small voids, on undissolved particles, at dislocations, and other imperfections in the aluminum lattice as shown in Fig. 1.^[1] For optimal properties, it is desirable to retard this diffusion process and maintain the alloying elements in the solid solution. This is done by quenching from the solution temperature. For quench-hardenable wrought alloys such as 2xxx, 6xxx, and 7xxx and casting alloys such as 356, this is accomplished by the quenching process. The objective is to quench sufficiently fast to avoid undesirable concentration of the alloying elements in the defect and grain boundary structure while at the same time, not quenching faster than necessary to minimize residual stresses which may lead to excessive distortion or cracking. After quenching, aluminum alloys are aged, and during this process, a fine dispersion of elements and compounds that are precipitated significantly increases material strength. The diffusion process and precipitation kinetics varies with the alloy chemistry.

The cooling process of age-hardenable aluminum alloys not only affects properties such as strength and ductility, but it also affects thermal stresses. Thermal stresses are typically minimized by reducing the cooling rate from the solutionizing temperature. However, if the cooling rate is too slow, undesirable grain boundary precipitation will result. However, if the cooling rate is too fast, there is an increased propensity for distortion. Therefore, one of the primary challenges in quench process design is to select quenching conditions that optimize strength while minimizing distortion and at the same time, assuring that other undesirable properties are not obtained, such as IGC, which is also cooling rate dependent.

Bates and Totten have addressed the selection of quenchant and quenching conditions that will optimize the material strength and minimize the potential for distortion.^[22] However, although it is well known that properties such as corrosion resistance are also cooling rate dependent, the problem of quenching system evaluation with respect to strength, distortion, and corrosion are rarely evaluated together. The objective of this section is to provide an overview of IGC of aluminum alloys and to illustrate the effect of cooling rate on both strength and IGC.^[140]

Pitting and IGC

Pitting is the most common corrosion process encountered with aluminum alloys and a major cause is variations in the grain structure between adjacent areas on the metal surfaces in contact with a corrosive environment. Pitting results in the formation of very small holes (pits) in the surface and are covered by white or gray powder-like deposits appearing as blotches on the surface.^[141]

IGC, also referred to as intercrystalline corrosion (ICC) occurs most commonly in the following aluminum alloys:

Al-Cu-Mg (2xxx), Al-Mg (5xxx) which is similar to the Al-Cu-Mg alloys, Al-Mg-Si (6xxx), and Al-Zn-Mg-Cu (7xxx).^[142,143] (The 2xxx, 6xxx, and 7xxx series are heat treatable.) IGC refers to a selective dissolution of the surface grain boundary zone and typically the grains below the surface zone are not attached, as shown in Fig. 85. As discussed above, upon cooling from the solutionizing temperature, alloying elements may concentrate at the grain boundaries to form intermetallic compounds that differ from the adjacent matrix electrochemically from the metal adjacent to the grain boundaries.^[144,145]

The critical temperature range and time (s) for the transition of pitting to IGC is shown by the so-called TTP (time-temperature-property) or C-curve illustrated in Fig. 2.^[2] The C-curve for 2024-T4 shows the change in

corrosion behavior by correlating the critical temperature range where precipitation was fastest. Increased IGC for 2024-T4 will be favored if cooling rates are excessively slow during quenching. Similar behavior can be shown for other aluminum alloys. Therefore, it is important that cooling rates during quenching be sufficiently fast to avoid this undesirable behavior.

As the IGC process continues, exfoliation will result, which refers to the lifting of the surface grains which is caused by expansion due to increasing volume of the corrosion products accumulating in the subsurface grain boundaries.^[146] Exfoliation has been reported to result in severely reduced structural strength, plasticity, and fatigue. Exfoliation in aircraft aluminum alloy structural materials is most often observed with extrusions, where the grain thicknesses are often less than the rolled forms.^[141]

Electrochemical Behavior of IGC Processes

IGC is caused by the formation of a microgalvanic cell between the intermetallic compounds formed in the grain boundary during cooling and the adjacent metal. These intermetallic compounds may be either anodic or cathodic, with respect to the adjacent metal, depending on their composition. Figure 86 illustrates these two situations.^[147] In one case, noble (inactive) alloying elements may precipitate in the grain boundaries leaving a “depleted zone” adjacent to the grain boundary which is electrochemically active. Conversely, electrochemically active alloying elements may precipitate at the grain boundary and then the metal adjacent to the grain boundary will be noble. Note that corrosion behavior has also been shown to be due to the heat treatment process, which will not be discussed here. The reader is referred to Ref. [148] for more detailed discussion.

To illustrate this process, consider IGC occurring in 2xxx or 7xxx alloys that would be caused by the loss of copper or sufficient magnesium in areas near the grain boundaries to create an anodic electrochemical potential. The electrochemical potential (electromotive force, EMF)^a for various aluminum alloys provided in Table 29 shows that the presence of copper in solid solution with aluminum makes it more cathodic^b.^[149] An aluminum alloy containing 4% copper in solid solution will exhibit an EMF of -0.69 V. However, copper concentrations in the grain boundaries may reduce the EMF to -0.84 V, making it more anodic. Grain boundary corrosion may also occur when the grain boundary precipitates are more anodic than the adjacent solid solution. For example, Mg₂, Al₃,

Fig. 85 The corrosion testing was according to the BS ISO 11846:1995 method B. The sample is a model AlMgSi aluminum alloy (6000 series) that was extruded using a research extrusion press with a reduction ratio of 34:1. The extruded sample dimensions were 78×2.7 mm: (a) Cross section of the sample after corrosion test illustrating the intermetallic deposition in the grain boundaries in the surface region and (b) cross-sectioned sample showing the microstructure of the test specimen

^aMeasured in an aqueous solution of 53 g NaCl + 3 g water per liter at 25°C.

^bThe order of the EMF values in the above table indicates the ability of a compound reduce any compound metal below it. The values shown in the table entries are reduction potentials. The α (Ag-Mg) (Mg_5Al_8) compound at the top of the list has the most negative number which indicates that it is the strongest reducing agent in the series shown. The strongest oxidizing agent is silicon with the least negative (most positive) EMF potential shown in Table 29.

MgZn_2 , and $\text{Al}_x\text{-Zn}_x\text{Mg}$ are more cathodic than CuAl_2 and $\text{Al}_x\text{Cu}_x\text{Mg}^c$.^[150]

IGC Control

The degree of IGC may be controlled by the selection of the temper and maximizing the cooling rate permissible that will provide minimum distortion. For example, the T4 and T6 temper conditions are typically selected when optimum resistance to IGC is required.^[151] Schuler reported that the critical cooling rates (cooling rates between 750°F and 550°F) for the 7xxx series to be <400°F/s and 1000°F/s for the 2xxx series to achieve optimal resistance to IGC. The data in Table 30 show the effect of cooling rate on IGC for 50 mm AA7075 round bar.^[152] The depth of attack was consistently greater toward the center of the round bar as the cooling rate decreased.

Other factors affecting IGC include transfer rate from the furnace to the quench, air entrainment in the quenchant, and the ratio of section mass/surface area. However, these factors, in the final analysis, affect cooling rates and therefore IGC.

At this point, it is important to note that often in the industry, cooling behavior of various quench media is

^cWhen two dissimilar metal compounds with different electron affinities (EMF values) are connected, there is a potential for electrons to pass from the material with the smaller affinity for electrons (anode—the more negative pole) to the material with the greater affinity for electrons (cathode—the more positive pole). A potential difference between the materials will increase until an equilibrium is achieved. This “equilibrium potential” is defined as that potential which balances the difference between the propensity of the two metals to gain or lose electrons.

Table 30 Effect of cooling rate on maximum intergranular penetration of 7075 as a function of cooling rate^[152]

Sample	Cooling rate (50 mm dia. bar) (°C/s)	Location (a)	Depth of attack (mm)

		Center	1.09

^aSurface—Within 3.2 mm of cylinder surface.

^bCenter—Within 3.2 mm of cylinder centerline.

determined using an INCONEL 600 probe according to ISO 9950 or ASTM D6200. However, the thermal conductivity of INCONEL 600 is much less than that of aluminum, as shown in Table 31.^[16] Clearly, the low thermal conductivity of INCONEL 600 versus aluminum renders this probe to be relatively insensitive to the cooling properties experienced by an aluminum alloy during quenching.

Silver probes are also used to evaluate quench severity exhibited by different quenchants. Because of the similarity of the thermal characteristics of silver and aluminum and because of the significantly lower oxidation tendency for silver relative to aluminum, the cooling behavior of AlMgSiCu and a silver (99.5%) probe was compared.^[16]

Thermal conductivity (λ) and the specific heat capacity of various materials are provided in Table 31. Thermal conductivity is a measure of the “rate of propagation” of temperature change in a body and is related to the specific heat capacity by Eq. 1.

Tensi et al. have compared cooling curves recorded during quenching of an aluminum (AlMgSiCu) and a silver specimen (Ag 99.5) in a Type I water-soluble polymer quenchant solution. The Type I aqueous polymer quenchant concentration was 10% by volume, and the bath temperature was 25°C. The temperature of both probe materials

when quenched was 520°C. Both probes were cleaned with 600 grit abrasive paper before each test. The cooling curves obtained are shown in Fig. 24.

The polymer film surrounding the probe surface ruptured simultaneously around the entire surface, also called “explosive” rewetting, for both probes and the rewetting times ($t_F - t_S$) were extremely short. However, a stable film boiling range lasting about 4 s was observed for the silver probe which was not observed for the aluminum probe. The centerline probe temperature was about 440°C for silver and 500°C for aluminum. The reason that the rewetting of the silver occurs about 4 s later for the silver probe is the greater oxidation resistance of silver. (The ratio of heats of formation of Ag_2O_2 and Al_3O is 0.05.) When the quenching temperature of the silver probe is increased to 800°C, considerable stabilization of the film boiling occurs as observed in Fig. 24a. Wetting now starts at about 260°C after 24 s compared to the start of wetting of the AlMgSiCu probe after 1 s at about 500°C.

The main reason for this stabilization of the film boiling phase of the entire surface of the silver probe is the reduction of the silver oxide at the higher temperature. The high-temperature annealing of the silver probe removes the oxide and leaves a bare metal surface, resulting in the stabilization of film boiling during quenching, especially in water-soluble polymers. Accordingly, the maximum cooling rate of the silver probe is not reached until a centerline probe temperature of 200°C as shown in Fig. 24b.

If distilled water at room temperature is used as the quenchant instead of an aqueous polymer, the silver and the AlMgSiCu probes show almost identical cooling behavior with coinciding rewetting kinematics as shown in Fig. 26. This means that the quenching behavior determined in water with silver probes can be safely compared with those obtained for aluminum probes. However, when polymer solutions are used, there are clear differences, especially with respect to initial wetting.

It is important that whatever probe material is used should reasonably approximate the expected quenching behavior of the aluminum alloy of interest, especially if cooling rate dependence of the quenching media and process is being used to determine the potential for IGC. For these reasons, it is recommended that heat treaters request cooling curve data obtained using either an aluminum or silver probe. (The advantage of silver relative to aluminum is its inertness and therefore it may be reused, whereas aluminum alloy probes typically cannot.)

Residual Stress Reduction

Type I polymer quenchants have been reported to offer significantly greater residual stress reduction than hot water in a number of studies. The results of one of the earliest reported studies that was conducted using the Sach’s Bore Out Method on aluminum A356 castings are shown in Fig. 87.^[46,152]

Table 31 Thermal conductivity and specific heat capacity for different materials

Material	Thermal conductivity (m ² s ⁻¹)	Specific heat (kJ kg ⁻¹ K ⁻¹)
Aluminum 99.5	95 × 10 ⁻⁶	0.896
Silver 99.5	174 × 10 ⁻⁶	0.235
Nickel	14 × 10 ⁻⁶	0.448
CrNi Steel ^a	4 × 10 ⁻⁶	0.477
INCONEL 600 ^b	4 × 10 ⁻⁶	0.465

^aAustenitic stainless steel SAE 30304.

^bNickel-based alloy.

Fig. 87 Residual stress comparison of hot water and a Type I quenchant as a function of concentration for A356 aluminum castings

Torgerson and Kropp conducted extensive residual stress and other mechanical property comparisons between hot water and a Type I quenchant at various concentrations on 7050-T736 forgings and plate.^[153] It was

found that Type I quenchants provided minimum distortion while still meeting the design minimums for forgings up to 5 in. thick.

2.5.1 Campbell's Analysis

When aluminum part, such as a casting, is quenched into room temperature water, the ΔT (change in temperature) between the initial and final temperature is nearly 500°C. Since the core of the casting cools more slowly than the surface, there will be a tensile strain (ϵ), as-quenched, which is estimated from^[154] the following equation:

$$\epsilon = \alpha \cdot \Delta T \quad (7)$$

where α is the coefficient of thermal expansion (approximately $20 \times 10^{-6} \text{K}^{-1}$). The approximate value of quench strain under these conditions is as follows:

$$20 \times 10^{-6} \cdot 500 = 1.0\%$$

The strains are at least 10 times the yield strain as illustrated in Fig. 88.^[154] This is greater than the plastic limit, which may lead to cracking upon quenching.

Figure 89 provides the centerline measured quench rates for a 20 mm bar.^[154] The modulus is determined from its volume/surface area (area/circumference ratio) and is determined to be 5 mm. From this estimation and Fig. 89, it is possible to determine the cooling rate where distortion and cracking problems may occur.

Using the thermal properties from Table 32, which relate to aluminum at approximately 250°C and steel at 500°C,

Fig. 88 Sequence of steps to illustrate the origin of residual stress in quenching and aging treatments

Fig. 89 Cooling rate for a 5mm modulus aluminum plate subjected to various quench severities

Table 32 Comparison of thermal properties of aluminum and steel

Metal	Thermal conductivity (W/m/K)	Density (pkg/m ³)	Specific heat (Cp) (J/kg/k)	Thermal diffusivity (d) (m ² /k)
Aluminum	200	2700	1000	10 ⁴
Steel	50	7800	500	10 ³

the thermal diffusivity (D) of aluminum is calculated from^[155] the following equation:

$$d = K / (\rho \cdot C) \quad (8)$$

The diffusivity for different thicknesses (x), where heat can diffuse, may be estimated from the following equation:

$$x = (dt)^{-1/2} \quad (9)$$

If $x = 10\text{ mm}$, $t = 1\text{ s}$, the cooling rate upon cooling from 500°C to 250°C is as follows:

$$\text{Cooling rate (CR)} = \frac{\Delta T}{d} = \frac{250}{1} = 250\text{ K/s}$$

Using this process, the relationship between average diffusion distance at different cooling rates may be determined as shown in Fig. 90.

If the following relationship is used,^[154]

$$\tau = \frac{\Delta T}{\text{CR}} \quad (10)$$

where ΔT is $500 - 250 = 250$ for aluminum and a critical parameter may be calculated:

$$(x^2 \cdot \text{CR})_{\text{CRIT}} = D \cdot T_{\text{CRIT}} \quad (11)$$

Fig. 90 Rate of quench versus diffusion distance for heat during the critical time of the quench showing the extent of safe and dangerous regimes for aluminum castings and test bars. Area 1 was the regime for test bars quenched in water. Area 2 was quenched in 35% of a polymer quench

where the critical value of $D\Delta T$ is 2.5×10^{-2} for aluminum alloys and 2.5×10^{-3} for steel. Therefore, if the value for X or Q is sufficient to meet the critical parameter, then there will be a high probability of quench stresses in excess of the yield stress in the casting.

DISTORTION CONTROL

One of the most difficult problems in the aluminum heat-treating industry is distortion control.^[95] Type I polymer quenchants will significantly reduce distortion relative to a water quench as shown in Fig. 41.^[46] Selected examples of parts that have been successfully quenched in a Type I quenchant are shown in Figs. 91,^[156] 92,^[156] and 93.^[157] Suttie reported that a Type I PAG quenchant provided significant distortion reduction for 7075-T6 forgings relative to cold water while producing substantially higher tensile strengths than boiling water.^[24] Similar results were reported by Collins and Maduell on the same alloy.^[158]

Racking

One of the major causes of distortion is nonuniform heat removal from the parts being quenched. To achieve optimal distortion reduction, the placement of the parts, commonly known as “racking,” in the quench is critical. The most important factors to be considered in this regard are^[159–162] as follows:

1. Part spacing.
2. Part configuration.

Fig. 91 Lycoming engine head (390 alloy) (a) quenched upright in 25% Type I and (b) quenched in 25% Type I on its side to facilitate more uniform fluid flow to minimize distortion (This engine cracked in boiling water.)

3. Agitation.
4. Immersion rate.
5. Thickness variation within the part.
6. Quench medium.

Part Spacing

Perhaps the most important consideration is part spacing. It is essential that sufficient space be provided around the part to optimize quenchant–surface area contact. This will enhance heat extraction from the hot surface while minimizing the formation of hot spots or localized temperature increases within the quenchant due to poor fluid flow (agitation), which is a major cause of distortion.^[160]

To achieve optimal flow, parts must be properly “racked” with the use of “fixtures”.^[157] Fixtures may be a basket or a rack with places to hang or place small parts so that they will not move when immersed into the quenchant. Even larger parts, although relatively heavy, must

Fig. 92 Dip-brazed 6061 panel section
Source: Courtesy of Tenaxol Inc., Milwaukee, WI.

Fig. 93 7075-T6 Die forging quenched in 20% Type I quenchant
Source: Courtesy of Tenaxol Inc., Milwaukee, WI.

be racked properly to assure optimal and uniform heat removal during the quench. Such parts should not be indiscriminately dumped into a basket and quenched. Instead, the parts must be placed in the tank so that adequate fluid flow around all of the surfaces is assured.

The amount of space between the parts must be increased with increasing mass. For water quenching, the distance between the part surfaces must increase with increasing water temperature. Water temperatures greater than 160°F should not be used for larger cross sections.^[161]

As an aluminum component is heated to the solutionizing temperature, it will increase in size due to thermal expansion thereby increasing in size with increasing temperature.

This distortion is often encountered when parts are racked too close together.^[163]

As the temperature of the load is increased, parts that are racked too closely will exert pressure on each other as they attempt to expand. Since the yield strength of the aluminum alloy is relatively low at elevated temperature, stress will be relieved by moving or bending. It is not uncommon that when the parts are quenched, the distortion due to furnace temperature nonuniformity will be quenched into the part. Therefore, it is fundamentally erroneous to conclude that upon removal of the part from the quenching bath that all of the distortion observed is only due to the quenchant itself.^[163]

Note that the coefficient of linear expansion is approximately twice that of steel which indicates that a substantially greater change in length (or volume) would be expected for

aluminum alloys than steel as shown in Table 33.^[164] For a more accurate assessment of relative diction of different aluminum alloys, it is important to understand that actual linear expansion values vary with the composition of the aluminum alloy.^[165] Therefore, the probability of quench distortion for aluminum would be expected to be greater for aluminum components than steel.^[166] Typical expected linear expansion of aluminum when heated from ambient temperature to 890°F is illustrated in Table 34.^[163] For this reason, the potential problem of distortion must be considered when the difference in linear expansion between the part and the supporting baskets and fixtures must be considered. Typically, distortion is increased when a thin gauge aluminum component is wired to a steel rack before quenching.

Part Configuration

Croucher’s rule of thumb is to place parts in a basket so that they will offer least resistance to fluid flow.^[162]

Table 33 Linear thermal expansion coefficients of aluminum and aluminum alloys

Metal	Coefficient of linear thermal expansion	
	μin/in·°F	μm/m·°C
Aluminum (99.996%)	13.1	23.6
Aluminum alloys	10.6–13.3	19–24
Steel	6.1–6.9	10–12.5

Table 34 Typical approximate expansion of long aluminum alloy components during furnace heating—ambient temperature—70°F–890°F (Δ 820°F)

Part length (ft)	Linear expansion (in.)
8	0.96
12	1.42
16	1.89

Agitation

Figure 94 shows that the directional placement of a complex part in the quenchant is often critical if distortion and cracking is to be prevented. Simple thought analysis is often sufficient so that optimal fluid flow around the part is assured. For example, situations where the part would be placed to block fluid flow may result in excess vibration of the hot part leading to increased distortion.^[161] An illustration of such a part is provided in Fig. 93. (Note: Similar distortion problems may be observed upon heating where the load on the hot homogenized aluminum may be sufficient to plastically deform it^[162]).

Yang et al. performed computational flow modeling to obtain insight into the use of draft tube agitation and flow baffles on the properties of AA357 thin-wall castings with a complicated geometry after water quenching.^[167] The quenching tank utilizes two impellers, two draft tubes, two overflow baffles, and two directional flow baffles, as shown in Fig. 95 and 96. The rectangular quenching tank is 2.5 × 2.5 × 3 m3 with a vertical plane of symmetry. The rectangular quenching zone is 1 × 1 × 1 m3. Two vertical marine propellers rotating in the same direction are used. The three-blade impeller diameter is 450 mm with a pitch of 65 mm.

The results of this study showed^[167] the following:

1. Computational flow modeling of the flow distribution of the water in the quench tank showed that the agitation speed and the position of directional flow baffle have important impacts on the flow distribution and flow rate. Increasing the agitation speed results in a large flow rate in quenching zone. However, this is accompanied by a corresponding increase in nonuniformity of the flow velocity.
2. The flow velocity curves are heavily dependent on the position of the directional flow baffle.
3. Immersion (dropping) rate—Delays between solutionizing and precipitation hardening of high-strength

Fig. 94 AA6061 assembly showing effects of different racking methods on distortion

Fig. 95 Experimental water quenching tank for computational modeling: (a) Front view and (b) top view

Fig. 96 Schematic illustration of draft tube and flow baffle with dimensions (mm)

aluminum alloys can lead to natural aging which then affects artificial aging response.^[168] Factors that may cause this undesirable natural aging effect include the following: load placement in the furnace which can be a problem since the solutionizing temperature may be close to the eutectic melting point causing grain boundary melting,^[169] quench agitation must be sufficiently severe to obtain maximum mechanical strength and toughness, and the transfer time between the furnace and the quench may be the most critical.

Distortion is generally reduced by increasing immersion rates. If aerospace parts are being quenched, then specific limitations on the delay (transfer) time from the furnace to the quench are specified. More specifically, the quench transfer time refers to the elapsed time from when the furnace door starts to open until the load is fully immersed. For wrought aluminum parts, Table 35 provides recommended immersion times for various sheet thicknesses.^[166]

Table 35 Recommended quench delay times for aluminum sheet of various thicknesses^[53,138]

Minimum thickness		Quench delay time (s)
mm	in.	
Up to 0.41, inclusive	Up to 0.016, inclusive	5
>0.41–0.79, inclusive	>0.016–0.031, inclusive	7
>0.79–2.29, inclusive	>0.031–0.090	10
>2.29	>0.090	15

Typically, immersion rates between 0.5 and 8 ft/s are used. In some cases, if it is not possible to rack the part in a way that promotes fluid flow around the surface, then slower immersion rates are recommended.

In order to meet the transfer time criterion, drop-bottom furnaces are often used for solutionizing aluminum parts before quenching. These furnaces are capable of obtaining temperature uniformity of $\pm 3^\circ\text{C}$ ($\pm 5^\circ\text{F}$). To facilitate the fastest possible transfer time, the drop-bottom furnaces are equipped with hydraulically actuated doors that open sufficiently fast to easily meet a required 15 s quench delay time.^[170] The quench tank, or in some cases, a quench car may be controlled manually or automatically. One example is illustrated in Fig. 97 where a mobile quench tank equipped with four propeller agitators along one side of the tank to provide uniform flow through the load is shown. The flow pattern produced around a basket of racked parts is also shown in the schematic illustration in the inset of Fig. 97.

In this mobile quench system, baffles were positioned at the bottom of the agitators to direct the flow of the water quenchant under a divider baffle and then into the quench zone where the flow is then diverted upward through the load by two baffles at the bottom of the tank. Water flowing back to the agitators is partially diverted downward by the divider baffle where it interacts with flow from the agitators before being directed back up through the load. Optimal quenchant flow velocities for this system were determined to be 24–37 cm/s (0.8–1.2 ft/s).^[170]

Fig. 97 Illustration of a mobile quench tank with four agitators along one side. The flow pattern produced with this agitation system is shown in the schematic in the inset

Royer has also reported that the quench transfer rates required by the AMS-H-6088 standard for AA7075^[138] for larger section sizes can be achieved without the use of a drop-bottom furnace.^[168] In this study, a 9.75 in. (248 mm) diameter scalped AA7075 aluminum ingot was heated to a forging temperature range of 720°F–775°F (380°C to 413°C) and held for 10–15 min/ in. of cross section. Royer reported that based on measured temperatures, the minimum time for any part of the forging to reach 775°F was greater than 125 s. Since typically the maximum quench delay time for any quench was 40 s, the heat treatment process would meet AMS-H-6088 quench requirement transfer limitation. In such as case, the use of a drop-bottom furnace would not be required.

Shi et.al. studied the effects of both water temperature and quench delay time (transfer time) on the the mechanical properties of the 4 mm thickness 7A04 aluminum alloy plates. The results of this study showed that when the water quenchant temperature and the transfer time before quenching are greater than above 40°C and 20 s, respectively, the 7A04 alloy strength will decrease remarkably. Before the delay time after quenching is 8 h, the strengths will drop gradually while the elongation will rise continuously.^[171]

The EFC behavior of 7050-T6 aluminum alloy after being subjected to various quench transfer time after solution heat treatment was investigated by Song et al.^[172] The results showed that EFC resistance decreased with increasing quench transfer time. This is illustrated in Fig. 98.

Thickness Variations

Since large cross sections cool more slowly than thinner cross sections, complex shapes may be inherently prone to distortion. When this occurs, racking configuration may be used to help offset cross-section size variations.

Although water cooling of quenchable aluminum alloys is typically preferred as a means to assure maximum attainable mechanical properties, this may not be realistic due when there is the possibility of large thermal gradients and resulting residual stresses. This often is a problem associated with parts of widely varying cross-section sizes and complexity. In such applications, forced air cooling may be recommended to avoid high residual stress. The slower accompanying cooling rates may be sufficient to avoid large temperature differences between the inside and the outside of the part. Table 36 summarizes the general effect of racking on the cooling rate during air quenching of A319 cast aluminum engine blocks.^[173] While perfectly uniform cooling was not observed on all surfaces in every quenching orientation, the effect of racking (positioning) is evident, which illustrates the general importance of racking, even for slow quenching process such as forced air quenching.

Immersion (Dropping) Rate

Immersion rate is defined as the rate that the part is immersed into the quenchant.^[160] Distortion is generally reduced by increasing immersion rates. Typically, immersion rates between 0.5 and 8 ft/s are used. However, in some cases, it is not possible to rack the part in a way that promotes fluid flow around the surface. In these cases, slower immersion rates are recommended.

Thickness Variations

Since large cross sections cool more slowly than thinner cross sections, complex shapes may be inherently prone to distortion. When this occurs, racking configuration may be used to help offset cross-section size variations.

Fig. 98 Yield strength and strength loss after EFC tests of 7050-T6 alloys treated with different transfer time

Table 36 Relationship between racking and cooling rate^a

Air quench flow rate (ft ³ /min) ^b	Racking (parts per basket)		Cooling rate (°C/min) ^c
	Type of parts ^c	Position ^d	
150,000	I-4 blocks	11 Vertical	58–74
150,000	V-6 block	9 Opposite car	76–93
150,000	V-8 block	5 Vertical	39–52

^aThis study refers to air quenching of cast A319 aluminum engine blocks in a continuous furnace shown schematically in Fig. 99. The solutionizing temperature was 480°C–490°C.

^bConvective cooling is performed by using six tangential high-pressure blowers creating a “wing tunnel” while rotating simultaneously a large blower, located at the base of the part forces a constant stream of air over the surfaces of the forging and out at the top of the tunnel.

^cThese are A319 cast aluminum engine blocks; I-4 is an in-line cylinder block and V-6 and V-8 are conventional engine blocks of the V configuration.

^dThese positions are illustrated in Fig. 100.

^eCooling rates represent a range of values across the surface of the engine block during the quenching cooling cycle.

Fig. 99 Conveyor furnace used for experimental air quenching study

Fig. 100 Use of V-8 engine block to illustrate quenching configurations reported in Table 36

Quench Media Selection

Although certain quench media may provide lower propensity for distortion, proper racking procedure cannot be ignored. Generally, the same racking considerations are recommended for aqueous polymer quenchants as for water.

CONCLUSIONS

A review of the quenching process for aluminum alloys has been provided. This review included an overview of

the solutionizing process and a brief discussion of the role of the quenchant. The use of Jominy testing of aluminum alloys has been discussed as well as fundamental aspects of quenchant testing by cooling curve analysis. The two most common quenchants for aluminum alloys are water (hot and cold) and aqueous polymer solutions, and both types of quenchants were discussed in detail. Alternative quenching media including air, uphill quenching, cryo quenching, fluidized bed, ionic liquids, and other lesser known quenchants have been discussed as well. The importance of cooling rates on IGC and the necessity of selecting quenchants that provide optimal resistance to

IGC while at the same time achieving the required design minimum mechanical properties was demonstrated. Finally, the role of quenchant selection on residual stress and distortion control was discussed. Together, the content of this article will provide an excellent insight into the vital role of the quenching process on the thermal processing of aluminum.

Quenching of Aluminum Solid Cylinder: Numerical Study

Shahriar Jahanian

Department of Mechanical Engineering Technology, Penn State University—Altoona
Campus, Altoona, Pennsylvania, United States

Abstract

A numerical method is presented for evaluating the residual stress distribution in a long aluminum solid cylinder subjected to rapid cooling. An analytical model is developed for the temperature distribution. For the boundary conditions, experimental data for the outer surface of the cylinder are used, and a reasonable agreement between the predicted temperature distribution at the center of the cylinder and the experimental data is observed. For the numerical analysis, a quasi-static, uncoupled thermoelastoplastic analysis, based on a hyperbolic sine law, is presented. The numerical results are presented for the temperature distribution as well as the thermoelastoplastic stress distribution in a solid cylinder with temperature-dependent properties. The residual stress distribution is compared with the results of other investigators who used the Finite Element Method, and a reasonable agreement between our results and previous results is observed. The conclusion is reached that the temperature dependency of the yield stresses and the problem of post-yielding are two important factors to be considered when developing a model for predicting the residual stresses in quenched bodies.

Keywords: Finite element method (FEM); Quenching; Residual stress; Temperature distribution.

In general, quenching involves rapid cooling of metallic alloys from a high temperature to room temperature. Such cooling, if rapid enough, results in hardening and an increased strength of the material. In quenching aluminum alloys, the objective is to cool them as rapidly as possible, especially through the range of approximate 290°C to 400°C. Quenching aluminum at low speeds may result in some precipitation that impairs the strength and corrosion resistance of the alloys. On the other hand, uncontrolled rapid cooling of the same piece may result in cracking. With proper control of the quenching process, one may avoid the aforementioned problems.

A survey of literature on the problem of thermoelastoplastic stress formulation shows an increasing interest among researchers in this branch of science. The earliest analysis of this type of problem dates back to the late 1920s when Sachs^[1] presented his classical work in this branch of science. Weiner and Huddleston^[2] and Landu and Weiner^[3] were among the first investigators who looked into the more complex type of transient thermoelastoplastic problems. Subsequently, several other researchers investigated the problem.^[4–11] However, those researchers' assumption that the properties of a material are independent of temperature is at best an idealization.

Dastidar and Ghosh^[12] were among the first to incorporate the temperature dependency of the properties of the material in their mathematical model. They solved the transient thermal problem in a hollow sphere by

assuming a Ramberg–Osgood^[28] type of material. For modeling plastic deformation, different approaches have been adopted. Shevchenko and Merzlyakov^[13] adopted a hyperbolic sine law.^[14] Kim^[15] proposed a temperature-dependent strain hardening law for his analysis. Rammerstofer et al.^[16] considered the pseudoplasticity effect in their analysis.

The Finite Element Codes, such as ADINA and Bersafe, were adopted by Mitter et al.^[17] and Fletcher and Lewis,^[18] respectively. Li and Chen^[19] adopted the Bodner and Partom^[20] constitutive equation for viscoplastic strain analysis. An extension of Mendelson's^[21] method of successive elastic solution was adopted by Ishikawa and coworkers,^[22–25] Boyer and Boivin,^[26] and Jeanmart and Bouvaist.^[27] The aforementioned investigators tackled the thermoelastoplastic problems in different geometrically shaped bodies for the Ramberg–Osgood^[28] type of material. Later, Jahanian and Sabbaghian^[29,30] and Jahanian^[31,32] used the extension of Mendelson's^[21] method to solve the problem of cylindrically shaped objects with linear strain hardening.

The residual stresses developed in mechanical components at the end of quenching may be detrimental or beneficial to the fatigue life of the material. Considering the high expense of examining the quenching process experimentally, the development of a theoretical technique for predicting the residual stresses developed during this process is desirable. In this article, the problem of

transient thermal stress in an infinitely long aluminum cylinder subjected to rapid cooling is solved by using a hyperbolic sine law for inelastic material deformation.^[14] The residual stresses developed in the cylinder at the end of the quenching process are evaluated and compared with the work of Zabaras et al.^[33] A reasonable agreement is observed.

THEORETICAL ANALYSIS

Consider an aluminum cylinder that is initially at temperature ($T = T_1$). The cylinder is suddenly placed in a quenchant. The initial shrinkage of the outer surface of the cylinder relative to its center may result in tensile axial stresses at the outer surface and compressive axial stresses at the center. At the later stage of cooling, when the temperature of the outer surface reaches room temperature, the center temperature begins to drop. At this stage, the rate of cooling of the center is higher than that at the outer region. This tends to unload the stresses that are generated at the early stage of cooling. If there is no plastic flow, the cylinder remains stressfree at the end of cooling. However, at higher temperatures, the yield stress is relatively low and other properties, such as modulus of elasticity and coefficient of thermal expansion, are temperature dependent. The temperature dependency of these parameters enhances the plastic flow. Under this circumstance, the unloading of the stresses results in the reversal of the stresses developed during the early stage of cooling. Some of these stresses may remain in the material as residual stresses. To evaluate the residual stresses, the following theoretical procedure is adopted.

Transient Temperature Distribution

Consider a long solid cylinder of radius a that is initially at temperature $T = T_1$; a condition of generalized plain strain exists ($\epsilon_z = f(t)$ only in the cylinder).

The cylinder is suddenly immersed in a bath of water at Temperature $T = T_0$, where T_0 is room temperature and ($T_0 < T_1$). The transient temperature distribution in the cylinder can be found by solving the general heat conduction equation given by Carslaw and Jaeger^[34]

$$\nabla \cdot [k(\nabla T)] = \gamma C \frac{\partial T}{\partial t} \quad (1)$$

The following boundary conditions hold true for such a problem:

$$\begin{aligned} T(r, 0) &= T_1 & \text{at } r = a \text{ and } t = 0.0 \\ T(R, t) &= g(t) & \text{at } r = a \text{ and } 8 > t > 0.0 \\ T(R, t) &= mt & \text{at } r = a \text{ and } 32 > t > 8 \end{aligned} \quad (2)$$

where $g(t)$ is defined in Appendix B. Let us define the following dimensionless properties:

$$\begin{aligned} \phi_0 &= 1 - \frac{K_1}{2} & \tau &= \frac{h}{a^2} t & \theta &= \frac{T}{T_0} & \mu &= \frac{mCa^2\gamma}{KT_0} \\ \lambda_n &= \frac{\alpha_n}{a} & h &= \frac{K}{C\gamma} & \rho &= \frac{r}{a} \end{aligned} \quad (3)$$

where K is the thermal conductivity, C is the specific heat, and γ is the mass density. They are defined by two parameters—the first one, designated by subscript zero, is the dimension and the second designates temperature dependence—as follows:

$$K = K_0 K^*(\theta) \quad C = C_0 C^*(\theta) \quad \gamma = \gamma_0 \gamma^*(\theta) \quad (4)$$

where

$$K^*(\theta) = 1 - K_1 \theta \quad (5)$$

where K_1 is a constant. For example, when $K_1 = 0.0$, thermal conductivity is not a function of temperature. In Eq. 3 h is the thermal diffusivity, which is taken as constant.^[34]

Introducing Eqs. 5, 4, 3, and 2 into Eq. 1 and performing further simplification, one may obtain

$$\phi = \begin{cases} \frac{2}{\beta_n} \sum_{n=1}^{\infty} e^{-\beta_n \tau \frac{\beta_n J_0(\beta_n \rho)}{J_1(\beta_n)}} \int_0^1 [e^{\beta_n^2 \lambda} g(\lambda)] d\lambda & 0 < t < 8 \\ \mu \left(\tau - \frac{1 - \rho^2}{4} \right) + 2\mu \sum_{n=1}^{\infty} e^{-\beta_n \tau \frac{J_0(\rho \beta_n)}{\beta_n^2 J_1(\beta_n)}} & 8 \leq t \leq 32 \end{cases} \quad (6)$$

and, finally,

$$\theta(\rho, \tau) = \frac{1}{K_1} \left[1 - (1 - 2K_1 \phi)^{1/2} \right] \quad (7)$$

Fundamental Equations for Stress and Strains

Total strains developed during the cooling of the cylinder are the sum of the three terms—the elastic, the thermal, and the plastic components, and are expressed as

$$\epsilon_{ij} = \epsilon_{ij}^e + \delta_{ij} \int \alpha dT + \epsilon_{ij}^p \quad (8)$$

The dimensionless parameters are defined as

$$\sigma_r^* = \frac{(1 - \nu)\sigma_r}{E_0 \alpha_0 T_0} \quad \epsilon_r^* = \frac{(1 - \nu)\epsilon_r}{\alpha_0 T_0} \quad (9)$$

The coefficient of thermal expansion α and the elastic modulus E are assumed to be temperature dependent and have been defined in terms of two parameters (Zabaras et al.^[33] and Jahanian^[31,32]) as

$$\alpha = \alpha_0 \alpha^*(\theta) \quad E = E_0 E^*(\theta) \quad (10)$$

where

$$\begin{aligned}\alpha^*(\theta) &= 1 + \alpha_1\theta - \alpha_2\theta^2 \\ E^*(\theta) &= 1 - E_2\theta - E_1\theta^2\end{aligned}\quad (11)$$

Upon introducing the above equations to the familiar stress strain relation, and by substituting the results into the equilibrium and strain compatibility equations, one may obtain

$$\begin{aligned}E^* \epsilon_\theta^* &= \frac{1-2\nu}{2(1-\nu)} \int \epsilon_\theta^* \frac{\partial E^*}{\partial \rho} d\rho + \frac{1}{2\rho^2(1-\nu)} \int \rho \epsilon_\theta^* \frac{\partial E^*}{\partial \rho} d\rho \\ &\quad + (1+\nu) \frac{1}{\rho^2} \int E^* \rho \left(\int \alpha^* d\theta \right) d\rho \\ &\quad + \frac{1-2\nu}{2(1-\nu)} \int E^* (\epsilon_r^{*p} - \epsilon_\theta^{*p}) \frac{d\rho}{\rho} \\ &\quad + \frac{1-2\nu}{2\rho^2(1-\nu)} \int \rho E^* (\epsilon_r^{*p} - \epsilon_\theta^{*p}) d\rho \\ &\quad - \frac{\nu}{\rho^2(1-\nu)} \int \rho E^* \epsilon_z^* d\rho + C_1 + \frac{C_2}{\rho^2}\end{aligned}\quad (12)$$

and

$$\begin{aligned}E^* \epsilon_r^* &= \frac{1-2\nu}{1-\nu} \int \epsilon_\theta^* \frac{\partial E^*}{\partial \rho} d\rho - E^* \epsilon_\theta^* + (1+\nu) E^* \int \alpha^* d\theta \\ &\quad + \frac{1-2\nu}{1-\nu} E^* \epsilon_r^{*p} + \frac{1-2\nu}{1-\nu} \int \frac{E^*}{\rho} (\epsilon_r^{*p} - \epsilon_\theta^{*p}) \\ &\quad d\rho - \frac{\nu}{1-\nu} E^* \epsilon_z^* + 2C_1\end{aligned}\quad (13)$$

The detailed derivation of Eqs. 12 and 13 is given in Appendix A. The boundary conditions are

$$\sigma_r^*(\rho=0) \text{ is bounded and } \sigma_r^*(\rho=1)=0 \quad (14a)$$

and the constraint of no axial forces,

$$2\pi \int_0^1 \sigma_z^* d\rho = 0 \quad (14b)$$

By introducing the above boundary conditions to Eq. A.18 and the third equation of Eq. A.2, constants C_1 , C_2 , and ϵ_2 can easily be obtained.

Plastic Strain Increment

The plastic strains that are parts of Eqs. 12 and 13 may be evaluated using the equation

$$\epsilon_{ij(t=k)}^{*p} = \epsilon_{ij(t=k-1)}^{*p} (r, t) + \dot{\epsilon}_{ij}^{*(p)} (r, t) \Delta \tau \quad (15)$$

The first term on the right side is the total plastic strain at the previous time increment, and the second term is the strain rate evaluated from Eq. 16.

A hyperbolic sine law^[14,33] was adopted for the plastic strain increment as

$$\dot{\epsilon}_{ii}^{(n)} = \frac{3}{2} A e^{-C/\theta} [\sinh(B\sigma)]^n / \sigma \quad (\text{no sum over } i) \quad (16a)$$

$$\sigma = \sqrt{\frac{3}{2} (S_{rr}^2 + S_{\theta\theta}^2 + S_{zz}^2)} \quad (16b)$$

where

$$B = B_1 \frac{E_0 \alpha_0 T_0}{(1-\nu)} \quad C = C_{11} / (T_0 + 273) \quad (16c)$$

The numerical values of the aforementioned parameters are given in Eq. 19. Constants A , B , and C are material parameters that are assumed to be independent of temperature in this investigation, and S_{ij} is the deviatoric stresses.

NUMERICAL PROCEDURE

For the numerical analysis of the derived equations in the previous section, the following procedure was adopted. The cross section of the cylinder was partitioned into 100 unequal elements in the radial direction. Initially, for the time increments, 50 unequal divisions were selected. The radial divisions at areas closer to the outer surfaces were smaller than the divisions at the areas closer to the center of the cylinder. The time increments at the early stage of cooling were smaller than those at the later stage of cooling. This is due to the fact that at those areas or during those time intervals the material experiences a more rapid temperature gradient.

At time t , a first approximation for strains was obtained by employing Eqs. 12 and 13 and by assuming the hoop strains appearing in the right side of the equations to be zero. Subsequently, the value of ϵ_θ^* on the right side of Eqs. 12 and 13 was the first initialized value of ϵ_θ^* at time t . The new value was used to obtain a better value for ϵ_θ^* . This procedure was repeated until a desired accuracy of convergence was obtained.

After the desired convergency was obtained, stresses were evaluated using Eq. (A.2). Then the yielding was checked. In this problem, yield stresses were assumed to be a function of temperature, and the data for yield stresses were obtained from^[36,37] for Al-4.6% Mg. At each time step, σ was compared with the yield stress. If σ was less than yield stress, plastic strains were assumed to be zero; otherwise, they were evaluated.

To obtain the plastic strains, Eq. 16 was employed. Using the deviatoric stresses at step $(i-1)$, σ , which appears in Eq. 16a, was evaluated. Using Eqs. 16a, 15, 12, and 13 one may easily obtain the strains. Having new values for strains, one can easily obtain the stresses by using Eq. A.2. Later a new value for strain rate can be obtained by making use of Eq. 16a. The new value is called the corrected value of the plastic strain rate $(\dot{\epsilon}_{ij}^{(p)c})$. Using Eq. 17, now one may find the corrected plastic strain $(\epsilon_{ij}^{(p)c})$.

$$\epsilon_{ij}^{(p)c} = \epsilon_{ij}^{(p)} (r, t) + \frac{\Delta \tau}{2} [\dot{\epsilon}_{ij}^{(p)c} + \dot{\epsilon}_{ij}^{(p)}] \quad (17)$$

Having the plastic strains, one can define an effective strain as

$$\begin{aligned}\epsilon_e &= \sqrt{\frac{2}{3} \epsilon_{ij} \epsilon_{ij}} \\ \epsilon_e^c &= \sqrt{\frac{2}{3} \epsilon_{ij}^c \epsilon_{ij}^c}\end{aligned}\quad (18)$$

The maximum relative difference between effective strain and the corrected effective strain was found. If it fell within a prescribed error tolerance, it was accepted; otherwise, the procedure was repeated until a desired convergency was reached.

In this analysis, $\Delta\tau$ must be so small that overshooting of stresses does not occur. To prevent the overshooting, the following procedure was adopted. During the loading and unloading of the cylinder (unloading refers to situations where elastic stresses are released), whether the stresses are compressive or tensile, one can easily show that the following conditions always hold true.

1. $|\Delta \epsilon_{ij}^p| < |\Delta \epsilon_{ij}^{\text{total}}|$.
2. $\Delta \epsilon_{ij}^{e+p+th}$ and $\Delta \epsilon_{ij}^p$ should be of the same sign.
3. S_{ij} and $\Delta \epsilon_{ij}^p$ should be of the same sign.

Accordingly, at each time step, the above conditions were checked before accepting the strain increment. If the aforementioned conditions were not satisfied, the time increment was locally divided into ten smaller increments. The same procedure was followed until the desired conditions were satisfied.

The procedure just described may imply that once plasticity has occurred at a particular radius, an additional plastic strain increment will continue to be produced in each succeeding time interval. However, it should be pointed out that there is a distinct possibility of not reaching the yield point during some time intervals, even though yielding may have occurred in previous intervals. This is due to the fact that yield stress and modulus of elasticity are functions of temperature. Accordingly, there might be instances where the rate of cooling is such that it will increase the yield stress to the extent that yielding will not take place. Hence, it is necessary to check for yielding at each time interval.

RESULTS OF NUMERICAL CALCULATIONS

For the purpose of discussion and comparison with experimental results, the following data for 5182 commercial Aluminum alloy from Zabaras et al.^[33] were used:

$$\begin{aligned}v &= 0.3 & A &= 0.579 \times 10^{10} \text{ S}^{-1} & B_1 &= 0.062 \times 10^{-6} \text{ m}^2/\text{N} \\ n &= 1.35 & C_{11} &= 20948.76 \text{ K} & a &= 0.03495 \text{ m} \\ \alpha_1 &= 9.55 \times 10^{-1} & \alpha_2 &= 4.4 \times 10^{-1} & K_1 &= 0.1307 \\ \alpha_0 &= 11.687 \times 10^{-6} (\text{°F})^{-1} & E_1 &= 1.465 \times 10^{-1} \\ E_2 &= 2.5 \times 10^{-1} & E_0 &= 7.3 \times 10^{10} \text{ N/m}^2\end{aligned}\quad (19)$$

Poisson's ratio, $\nu = 0.3$, is assumed to be unaffected by temperature (Zabaras et al.^[33]).

DISCUSSION OF RESULTS

Figure 1 shows the temperature distribution at the center of the cylinder. The results are in agreement with the experimental results. The residual stress distributions are depicted in Figs. 2, 3, and 4.

As one can see, the radial residual stresses are tensile throughout, while the tangential and axial stresses are tensile at the center of the cylinder and compressive in the vicinity of the outer surfaces.

Fig. 1 Comparison of the experimental and numerical temperature distributions at the center of the cylinder

Fig. 2 Residual radial stress distribution

Fig. 3 Residual tangential stress distribution

Fig. 4 Residual axial stress distribution

A careful scrutinization of the results indicates that the predicted residual stresses using the present method differs from that predicted by the Zabaras et al. model.^[33]

In the work of Zabaras et al.,^[33] once the plastic stage has started at a particular radius, an additional plastic strain increment is assumed to be continued in each succeeding time increment. This assumption is correct for materials at very high temperatures, but it is not accurate at lower temperatures.

In the present problem, the initial temperature was close to the melting point. Thus, at the early stage of cooling, plastic deformation occurs because the yield stress at that temperature is low. However, at the later stage of cooling, as the temperature drops, the yield stress increases. This new yield stress may be higher than the total equivalent stresses developed at the lower temperature. Accordingly, there might be a situation when yielding does not occur, even though yielding may have occurred during previous stages. In this paper, the aforementioned phenomenon is called “post-yielding.”

The reason for the deviation between the results predicted by the present model and the model used by Zabaras et al.,^[33] particularly at the area close to the outer boundaries where the temperature gradient is high and the yield stresses increase very abruptly, is the fact that Zabaras et al.^[33] did not consider the problem of “post-yielding” in their analysis.

CONCLUSIONS

A new method has been developed for predicting residual stresses in a quenched aluminum bar. The following conclusions have been derived.

1. The radial stresses are tensile throughout, and the tangential and axial stresses are compressive at the center and tensile in the vicinity of the outer surfaces.
2. The temperature distribution predicted by the present method is very close to actual experimental results.
3. Temperature dependency of yield stress and problems of post-yielding are two important factors that should be considered in the numerical calculations.

APPENDIX A

One can easily show that the following relations hold true:^[21]

$$\begin{aligned}
 \sigma_r &= -\frac{E}{(1-2\nu)} \int \alpha dT + \frac{E}{(1+\nu)(1-2\nu)} \left[(1-\nu) \epsilon_r + \nu(\epsilon_\theta + \epsilon_z) \right] - \frac{E}{1+\nu} \epsilon_r^p \\
 \sigma_\theta &= -\frac{E}{(1-2\nu)} \int \alpha dT + \frac{E}{(1+\nu)(1-2\nu)} \left[(1-\nu) \epsilon_\theta + \nu(\epsilon_r + \epsilon_z) \right] - \frac{E}{1+\nu} \epsilon_\theta^p \\
 \sigma_z &= -\frac{E}{(1-2\nu)} \int \alpha dT + \frac{E}{(1+\nu)(1-2\nu)} \left[(1-\nu) \epsilon_z + \nu(\epsilon_\theta + \epsilon_r) \right] - \frac{E}{1+\nu} \epsilon_z^p
 \end{aligned} \tag{A.1}$$

By introducing Eqs. 9, 10, and 11 into Eqs. A.1 and upon further simplification, one may obtain the equations

$$\begin{aligned}\sigma_r^* &= -\frac{E^*}{(1-2\nu)} \int \alpha^* d\theta + \frac{E^*}{(1+\nu)(1-2\nu)} \left[(1-\nu) \epsilon_r^* + \nu(\epsilon_\theta^* + \epsilon_z^*) \right] - \frac{E^*}{1+\nu} \epsilon_r^{*p} \\ \sigma_\theta^* &= -\frac{E^*}{(1-2\nu)} \int \alpha^* d\theta + \frac{E^*}{(1-\nu)(1-2\nu)} \left[(1-\nu) \epsilon_\theta^* + \nu(\epsilon_r^* + \epsilon_z^*) \right] - \frac{E^*}{1+\nu} \epsilon_\theta^{*p} \\ \sigma_z^* &= -\frac{E^*}{(1-2\nu)} \int \alpha^* d\theta + \frac{E^*}{(1+\nu)(1-2\nu)} \left[(1-\nu) \epsilon_z^* + \nu(\epsilon_\theta^* + \epsilon_r^*) \right] - \frac{E^*}{1+\nu} \epsilon_z^{*p}\end{aligned}\quad (\text{A.2})$$

Upon introducing Eq. 9 to the compatibility and equilibrium equations one may arrive at the relations

$$\begin{aligned}\frac{\partial \sigma_r^*}{\partial \rho} + \frac{\sigma_r^* - \sigma_\theta^*}{\rho} &= 0 \\ \frac{\partial \epsilon_r^*}{\partial \rho} &= \frac{\epsilon_r^* - \epsilon_\theta^*}{\rho}\end{aligned}\quad (\text{A.3})$$

Substituting the first and second equation of Eqs. A.2 into the first equation of Eqs. A.3 and using the second equation of Eqs. A.3, one may obtain the relations

$$\begin{aligned}& \frac{1}{(1-2\nu)(1+\nu)} \frac{\partial(E^* \epsilon_\theta^*)}{\partial \rho} + \frac{(1-\nu)}{(1-2\nu)(1+\nu)} \frac{\partial}{\partial \rho} \left(\rho E^* \frac{\partial \epsilon_\theta^*}{\partial \rho} \right) \\ & + \frac{E^*}{1+\nu} \frac{\partial \epsilon_\theta^*}{\partial \rho} \\ & = \left(\frac{1-\nu}{1+2\nu} \right) \frac{\partial \left[E^* \left(\int \alpha^* d\theta \right) \right]}{\partial \rho} + \frac{E^*}{1+\nu} \frac{(\epsilon_r^{*p} - \epsilon_\theta^{*p})}{\rho} \\ & + \frac{1}{1+\nu} \frac{\partial(E^* \epsilon_r^{*p})}{\partial \rho} - \frac{\nu}{(1-2\nu)(1+\nu)} \frac{\partial}{\partial \rho} (E^* \epsilon_z^*)\end{aligned}\quad (\text{A.4})$$

The following relations hold true:

$$\frac{\partial}{\partial \rho} (E^* \epsilon_\theta^*) = \epsilon_\theta^* \frac{\partial(E^*)}{\partial \rho} + E^* \frac{\partial(\epsilon_\theta^*)}{\partial \rho} \quad (\text{A.5})$$

$$E^* \frac{\partial(\epsilon_\theta^*)}{\partial \rho} = \frac{\partial}{\partial \rho} (E^* \epsilon_\theta^*) - \epsilon_\theta^* \frac{\partial(E^*)}{\partial \rho} \quad (\text{A.6})$$

Therefore,

$$\frac{\partial}{\partial \rho} \left(E^* \rho \frac{\partial \epsilon_\theta^*}{\partial \rho} \right) = \frac{\partial}{\partial \rho} \left[\rho \frac{\partial(E^* \epsilon_\theta^*)}{\partial \rho} \right] - \frac{\partial}{\partial \rho} \left[\rho \epsilon_\theta^* \frac{\partial(E^*)}{\partial \rho} \right] \quad (\text{A.7})$$

Substituting Eqs. A.7 and A.6 into Eq. A.4, the left-hand side (L.H.S.) of Eq. A.4 becomes

$$\begin{aligned}\text{L.H.S.} &= \frac{1-\nu}{(1-2\nu)(1+\nu)} \left[3 \frac{\partial}{\partial \rho} (E^* \epsilon_\theta^*) + \rho \frac{\partial^2}{\partial \rho^2} (E^* \epsilon_\theta^*) \right] \\ & - \frac{2-3\nu}{(1-2\nu)(1+\nu)} \epsilon_\theta^* \frac{\partial E^*}{\partial \rho} - \frac{1-\nu}{(1-2\nu)(1+\nu)} \rho \frac{\partial}{\partial \rho} \\ & \times \left(\epsilon_\theta^* \frac{\partial E^*}{\partial \rho} \right)\end{aligned}\quad (\text{A.8})$$

One can easily show

$$\frac{1}{\rho} \frac{\partial}{\partial \rho} (\rho^2 E^* \epsilon_\theta^*) = (2E^* \epsilon_\theta^*) + \rho \frac{\partial}{\partial \rho} (E^* \epsilon_\theta^*) \quad (\text{A.9})$$

Substituting Eq. A.10 into Eq. A.8, yields

$$\frac{\partial}{\partial \rho} \left[\frac{1}{\rho} \frac{\partial}{\partial \rho} (\rho^2 E^* \epsilon_\theta^*) \right] = 3 \frac{\partial}{\partial \rho} (E^* \epsilon_\theta^*) + \rho \frac{\partial^2}{\partial \rho^2} (E^* \epsilon_\theta^*) \quad (\text{A.10})$$

Therefore,

$$\begin{aligned}\text{L.H.S.} &= \frac{1-\nu}{(1-2\nu)(1+\nu)} \frac{\partial}{\partial \rho} \left[\frac{1}{\rho} \frac{\partial}{\partial \rho} (\rho^2 E^* \epsilon_\theta^*) \right] \\ & - \frac{2-3\nu}{(1-2\nu)(1+\nu)} \epsilon_\theta^* \frac{\partial E^*}{\partial \rho} \\ & - \frac{1-\nu}{(1-2\nu)(1+\nu)} \rho \frac{\partial}{\partial \rho} \left(\epsilon_\theta^* \frac{\partial E^*}{\partial \rho} \right)\end{aligned}\quad (\text{A.11})$$

Finally Eq. A.4 reduces to

$$\begin{aligned}& \frac{\partial}{\partial \rho} \left[\frac{1}{\rho} \frac{\partial}{\partial \rho} (\rho^2 E^* \epsilon_\theta^*) \right] - \frac{2-3\nu}{(1-\nu)} \epsilon_\theta^* \frac{\partial E^*}{\partial \rho} - \rho \frac{\partial}{\partial \rho} \left(\epsilon_\theta^* \frac{\partial E^*}{\partial \rho} \right) \\ & = (1+\nu) \frac{\partial \left[E^* \left(\int \alpha^* d\theta \right) \right]}{\partial \rho} + \frac{E^* (1-2\nu) (\epsilon_r^{*p} - \epsilon_\theta^{*p})}{1-\nu} \frac{1}{\rho} \\ & + \frac{1-2\nu}{1-\nu} \frac{\partial(E^* \epsilon_r^{*p})}{\partial \rho} - \frac{\nu}{(1-\nu)} \frac{\partial}{\partial \rho} (E^* \epsilon_z^*)\end{aligned}\quad (\text{A.12})$$

Integrating Eq. A.12 yields

$$\begin{aligned}
& \frac{1}{\rho} \frac{\partial}{\partial \rho} \left(\rho^2 E^* \epsilon_{\theta}^* \right) - \frac{2-3\nu}{(1-\nu)} \int \epsilon_{\theta}^* \frac{\partial E^*}{\partial \rho} d\rho - \int \left[\rho \frac{\partial}{\partial \rho} \left(\epsilon_{\theta}^* \frac{\partial E^*}{\partial \rho} \right) \right] d\rho \\
& = (1+\nu) E^* \left(\int \alpha^* d\theta \right) + \frac{(1-2\nu)}{1-\nu} \int \left[E^* \frac{(\epsilon_r^{*p} - \epsilon_{\theta}^{*p})}{\rho} \right] d\rho \\
& + \frac{1-2\nu}{1-\nu} (E^* \epsilon_r^{*p}) - \frac{\nu}{(1-\nu)} \frac{\partial}{\partial \rho} (E^* \epsilon_z^*) + 2C_1
\end{aligned} \quad (A.13)$$

The following relation holds true:

$$\int \rho \frac{\partial}{\partial \rho} \left(\epsilon_{\theta}^* \frac{\partial E^*}{\partial \rho} \right) d\rho = \rho \epsilon_{\theta}^* \frac{\partial E^*}{\partial \rho} - \int \epsilon_{\theta}^* \frac{\partial E^*}{\partial \rho} d\rho \quad (A.14)$$

Introducing Eq. A.14 into Eq. A.13 and integrating the results and further simplification yield

$$\begin{aligned}
& \rho^2 E^* \epsilon_{\theta}^* - \frac{2-3\nu}{(1-\nu)} \int \rho \left(\epsilon_{\theta}^* \frac{\partial E^*}{\partial \rho} \right) d\rho - \int \rho^2 \epsilon_{\theta}^* \frac{\partial E^*}{\partial \rho} d\rho \\
& = (1+\nu) \int \left[\rho E^* \left(\int \alpha^* d\theta \right) \right] d\rho + \frac{(1-2\nu)}{1-\nu} \\
& \times \int \left\{ \rho \int \left[E^* (\epsilon_r^{*p} - \epsilon_{\theta}^{*p}) \right] \frac{d\rho}{\rho} \right\} d\rho \\
& + \frac{1-2\nu}{1-\nu} \int \rho E^* \epsilon_r^{*p} d\rho - \frac{\nu}{(1-\nu)} \int \left[\rho E^* \epsilon_z^* \right] d\rho + C_1 \rho^2 + C_2
\end{aligned} \quad (A.15)$$

One can easily show that

$$\int \rho \left(\int \epsilon_{\theta}^* \frac{\partial E^*}{\partial \rho} d\rho \right) d\rho = \frac{\rho^2}{2} \int \epsilon_{\theta}^* \frac{\partial E^*}{\partial \rho} d\rho - \frac{1}{2} \int \rho^2 \epsilon_{\theta}^* \frac{\partial E^*}{\partial \rho} d\rho \quad (A.16)$$

and

$$\begin{aligned}
& \int \left\{ \rho \int \left[E^* (\epsilon_r^{*p} - \epsilon_{\theta}^{*p}) \right] \frac{d\rho}{\rho} \right\} d\rho = \frac{\rho^2}{2} \int E^* (\epsilon_r^{*p} - \epsilon_{\theta}^{*p}) d\rho \\
& - \frac{1}{2} \int \left[\rho E^* (\epsilon_r^{*p} - \epsilon_{\theta}^{*p}) \right] d\rho
\end{aligned} \quad (A.17)$$

Upon introducing Eqs. A.16 and A.17 to Eq. A.15 and with further simplification and manipulation, one may arrive at Eq. 12.

The following relation could be derived from the second equation of Eqs. A.3; upon mathematical simplification,

$$E^* \epsilon_r^* = E^* \epsilon_{\theta}^* + E^* \rho \frac{\partial \epsilon_{\theta}^*}{\partial \rho} = E^* \epsilon_{\theta}^* + \rho \left[\frac{\partial}{\partial \rho} (\rho \epsilon_{\theta}^*) - \epsilon_{\theta}^* \frac{\partial E^*}{\partial \rho} \right]$$

Introducing Eq. 12 to the above equation, one may arrive at Eq. 13. Upon substituting Eqs. 12 and 13 in the first equation of Eqs. A.2 one may obtain the relation

$$\begin{aligned}
\sigma_r^* &= \frac{1}{2(1-\nu)(1+\nu)} \int \epsilon_{\theta}^* \frac{\partial E^*}{\partial \rho} d\rho - \frac{1}{2(1-\nu)(1+\nu)} \frac{1}{\rho^2} \\
& \int \rho^2 \epsilon_{\theta}^* \frac{\partial E^*}{\partial \rho} d\rho \\
& - \frac{1}{\rho^2} \int \left[\rho E^* \left(\int \alpha^* d\theta \right) \right] d\rho + \frac{1}{2(1-\nu)(1+\nu)} \\
& \int E^* (\epsilon_r^{*p} - \epsilon_{\theta}^{*p}) \frac{d\rho}{\rho} \\
& - \frac{1-2\nu}{2(1-\nu)(1+\nu)} \frac{1}{\rho^2} \int \left[\rho E^* (\epsilon_r^{*p} + \epsilon_{\theta}^{*p}) \right] d\rho \\
& + \frac{\nu}{(1-\nu)(1+\nu)} \frac{1}{\rho^2} \int \rho E^* \epsilon_z^* d\rho + \frac{C_1}{(1-2\nu)(1+\nu)} - \frac{1}{\rho^2} \frac{C_2}{1+\nu}
\end{aligned} \quad (A.18)$$

APPENDIX B

As the experimental data depict (see Fig. 5), from $t = 8$ to $t = 20$ and from $t = 20$ to $t = 35$ the curve is linear. Accordingly, the following relations hold true:

$$T(R, t) = m_1 t \quad \text{at } r = a \text{ and } 8 > t > 20$$

$$T(R, t) = m_2 t \quad \text{at } r = a \text{ and } 20 > t > 32$$

or in general

$$T(R, t) = mt \quad \text{at } r = a \text{ and } 8 > t > 32$$

From $t = 0$ to $t = 8$, the curve assumes an S-shaped trend. Accordingly, it could be defined by a four-parameter logistic function as

$$T(R, t) = g(t) = \frac{a-d}{1+(t/c)^b} + d$$

The constants m , a , b , c , and d and the time intervals defined in the above equations can easily be obtained from the experimental data (Fig. B.1).

Abstract

Using the novel technique of electron backscattered diffraction (EBSD) in the scanning electron microscope, this article presents a comprehensive study on reaction kinetics during molten aluminum refining, applied to the removal of antimony using calcium additions and magnesium removal using silica additions. The determination of reaction products using the EBSD technique permitted to define stoichiometry of reactions taking place, as well as the clarification of the reaction mechanisms occurring during refining. Therefore, the kinetic parameters of interest such as rate constant values and activation energy of each process are obtained.

Keywords: Aluminum refining; Aluminum scrap purification; Calcium refining; EBSD; Magnesium refining.

INTRODUCTION

The use of aluminum scrap to produce different alloys has increased considerably at the start of the current century because of the low amount of energy required for its melting, in comparison to the energy required to produce aluminum from bauxite. However, contamination problems can arise if the different kinds of scrap with several chemical compositions are not separated using appropriate methods. In this way, contamination with elements such as Fe, Sb, Mg, Na, K, Pb, and Sn is quite common, so melt treatment practices have been recommended. Of these contaminants, antimony is considered to be among the most harmful because of its high potential toxicity, which is of special concern for products intended for the handling of food and drink. In addition, modification with sodium and/or strontium is not effective because of the formation of intermetallic compounds that remove these elements from solution, preventing any effect of this modification on the eutectic silicon phase.

On the other hand, magnesium is also considered a harmful impurity for most of the commercial 3XX series aluminum alloys that are prepared using scrap from beverage cans, or debris from extrusion or other wrought aluminum alloys. Refining of calcium and magnesium from molten aluminum has been performed since the late 1970s, but the mechanisms of reaction are far from being fully

understood. Therefore, the main objective of this article is to present the latest results of investigations aimed at understanding the true nature of reactions taking place during refining using the analytical technique of electron backscattered diffraction (EBSD) in the scanning electron microscope (SEM). This technique allowed determining the stoichiometry of reaction by analyzing the Kikuchi patterns of reaction products formed during refining of molten aluminum, therefore elucidating the mechanisms of reaction, which helped to enhance the reaction rate by several ways, as it will be discussed later.

THE NECESSITY OF MOLTEN ALUMINUM REFINING

General Considerations

The negative effects of antimony on the rate of modification of the silicon eutectic with sodium and/or strontium in casting Al-Si alloys have been broadly studied by Wang and Gruzleski,^[1,2] Garant et al.,^[3] and Tuttle et al.^[4] The general problem in mixing antimony with sodium and/or strontium is the formation of high-melting temperature compounds that are difficult to remove. Moreover, it is possible to generate phases with harmful morphologies that affect the mechanical properties of this type of alloy.

These compounds eliminate sodium and/or strontium from the solution, preventing the effect of sodium/strontium modification on the silicon eutectic phase. On the other hand, antimony has been shown to possess a great chemical affinity for calcium, forming stable compounds that can be removed through dross. However, to study the mechanism of reaction, it is first necessary to define the stoichiometry of the reaction. Different techniques have been proposed to hinder the effects of antimony, including dilution with pure aluminum, separation of polluted scrap, addition of an excess of the modifier agent, or removal by means of chemical agents, as described by Castrejón.^[5] However, no effective method has yet been developed at the cast shop facility level. Antimony, among other elements, possesses great affinity for calcium, as demonstrated long ago by Hardy,^[6] who established that Ca_3Sb_2 or AlSb phases could form when these elements are present in molten aluminum. Nevertheless, the mechanism of reaction outside of molten aluminum scrap has not been determined.

Another important application of aluminum scrap from cans is the production of automotive alloys such as AA380, AA319, and AA356, which are based on the Al-Si-Cu system of alloys. However, these alloys specify no more than 0.10 wt.% Mg to avoid the harmful effects of Mg on mechanical properties, as shown by Caseres.^[7] Various techniques have been developed to remove Mg from molten aluminum, such as methods based on gaseous mixtures of Ar/Cl_2 or Ar/SF_6 . Other techniques are based on the optimization of solid reactive groups like Na_2SiF_6 , AlF_3 , KAlF_4 , or SiO_2 . Previous studies performed by Martínez^[8] on the removal of Mg from Al-Si-Cu alloys established that it is possible to remove Mg from 700°C to 800°C by injecting submerged SiO_2 powder. This author claims that Mg removal takes place through the formation of a complex MgAl_2O_4 compound. On the other hand, Escobedo et al.^[9] studied the removal of Mg from molten aluminum by injecting submerged powders of SiO_2 particles with an irregular morphology, determining the reaction rate and the values of some kinetic parameters of technological interest. For some initial conditions, it was possible to remove almost 100% of the Mg in time periods on the order of 70 min. The reaction was found to stop once the formation of a complex layer of reaction products covered the SiO_2 particles. These authors suggested that the predominant reaction is transitory, indicating that contact time between the molten phase and the solid particles is quite rapid, occurring in fractions of a second. Therefore, the main disadvantage of this process is the entrapment of solid particles in the solidified alloy, called inclusions, as well as the excessive formation of slag rich in MgAl_2O_4 and agglomerates of Al_2O_3 - SiO_2 particles.

To better understand the reactions involved in the injection of submerged powders of SiO_2 for Mg removal from molten aluminum, it is necessary to mention the elaboration of mullite refractories and metal-matrix composites.

Al-Mg fibers surrounded by Al_2O_3 - SiO_2 are taken as the products of the reaction of MgO and MgAl_2O_4 . Ghosh et al.^[10] studied the production of MgAl_2O_4 by direct reaction between MgO and Al_2O_3 at 1400°C, represented by the following equation:

Zhong et al.^[11] performed an extensive bibliographical investigation on interfacial reactions occurring during the production of aluminum- Al_2O_3 fibers lined with SiO_2 composites, with several initial Mg concentrations. They analyzed the experiments performed by other authors, who found that MgAl_2O_4 formed at the Al_2O_3 fiber interface contained an Al alloy with 4 wt.% Mg at 800°C. Fishkis^[12] also confirmed the formation of MgAl_2O_4 at the interface of Al_2O_3 fibers lined with SiO_2 , embedded in an aluminum alloy containing 3 wt.% Mg. However, in similar experiments performed by Pai and Ray,^[13] they found MgO as the main reaction product, although the alloys tested contained more than 4 wt.% Mg. The proposed reaction is as follows:

Pfeifer et al.^[14] found similar results to those reported by Pai et al. They accept the formation of MgO via the reaction given by Eq. 2, indicating that MgO could also be formed by direct reaction between dissolved Mg and O_2 from the atmosphere, according to

Note the high Gibbs free energy of this reaction. However, O_2 is not soluble in molten aluminum, limiting the extent of such a reaction, as was established by Campbell.^[15] Lloyd et al.^[16] found that for Mg concentrations less than 3 wt.%, the following reaction takes place:

The reaction between the SiO_2 of the lining material and Mg is given as follows:

Hallstedt et al.^[17] established the rate of diffusion of the Al^{+3} and Mg^{+2} cations through MgO and MgAl_2O_4 , determining that diffusion through MgAl_2O_4 is up to ten orders of magnitude faster than through MgO . Moreover, they found that the interfacial reactions between dissolved Mg

and SiO_2 stopped as the concentration of Mg increased, becoming negligible at Mg concentrations above 7 wt.%. Molins et al.^[18] characterized the interface between Al_2O_3 fibers lined with SiO_2 and an alloy containing 3 wt.% Mg. They found not only MgO , but also MgAl_2O_4 , formed through the following chemical reaction:

After aging the alloy at 500°C for 6 h, dissolved Mg reacted with the SiO_2 of the Al_2O_3 fiber lining. Using transmission electron microscopy, these authors identified Al_2O_3 , MgO , and MgAl_2O_4 phases. Their results indicate that the chemical reactions in the solid state are slow enough to permit identification of the several oxides being formed. The results about the effect of initial Mg concentration on the nature of reaction products during the production of Al- Al_2O_3 composites have been corroborated by McLeod and Gabryel,^[19] establishing that for a Mg concentration less than 3 wt.%, the main reaction product will be MgAl_2O_4 . They constructed an equilibrium diagram representing different situations similar to the one shown in Fig. 1, and the utility of this diagram will be discussed later.

Thermodynamic Consideration for the Al-CuO-Mg System

To determine kinetics of reaction, it is needed first to assign the possible equilibria that can be reached in a specified system of reaction. The usefulness of doing this is presented for an important system such as the Al-CuO-Mg system, which has been studied for the preparation of Al-Cu alloys by the aluminothermic reduction of CuO particles.^[20] The thermodynamics of the Al-CuO-Mg system could be examined with the help of the HSC Chemistry v.6 software.^[21] Two ideal solutions are considered: the Al-Cu-Mg melt and the resulting Al-Cu-Mg solid solution. The solid reactants Al, CuO , and Mg were introduced as pure solid species (8, 0.4, and 0.08 kg, respectively). The reaction products that were expected to appear are the following: Al_2O_3 , AlN, MgAl_2O_4 , MgO , and CuO ; the intermetallic

compound Al_2Cu that was experimentally observed in the solidified samples and dross [XRD (X-ray diffraction) and SEM-EDS (energy dispersive spectroscopy) analysis] was not included since no thermodynamic data were available in the database of the software. The gaseous atmosphere (1 bar) was mainly composed of argon; some nitrogen gas from the atmosphere, i.e., 0.02 kg (0.50 in wt.%) was input to the system to allow for the formation of AlN; the atmosphere was free of oxygen and therefore the oxidation of the melt was limited to that caused by the oxygen of the cupric oxide (CuO). The equilibrium of the system was computed for the temperature range of 473–1073 K. Temperatures below the melting point of aluminum were of interest for monitoring the phases that precipitate upon cooling of the melt samples taken at higher temperatures.

The results obtained are presented in Fig. 2 for an activity of Al, Cu, and Mg in the melt, approximated by their concentration (mass fraction), that is 0.94, 0.05, and 0.01, respectively. According to the results presented in this figure, the following observations can be made:

- The reaction products of the Al-CuO-Mg system between 473 and 585 K are Al, Cu, MgO , and MgAl_2O_4 (and AlN due to the reaction between the allowed amount of atmospheric nitrogen and the solid aluminum); these are the stable phases given by the thermodynamics of the system, although it is evident from the point of view of kinetics that the reaction extent is to be limited by other factors such as the formation of impervious product layers such as Al_2O_3 over CuO particles, and that the hypothetical equilibrium will never be attained. Nevertheless, the information is of help when interpreting the transformations suffered by a melt sample that is allowed to cool down from temperatures above the melting point of aluminum.
- Between about 585 and 725 K, the reaction products are the solids Al-Cu, MgAl_2O_4 , and AlN, which coexist with the liquid phase Al-Cu-Mg.
- In the range of temperature between 725 and 870 K, the solid solution Al-Cu predominates and coexists with Al_2O_3 and AlN, and with the remaining liquid solution Al-Cu-Mg.

Fig. 1 Thermodynamic stability diagram of the oxides in molten Al-Mg alloys^[19]

Fig. 2 Equilibrium diagram of the Al-CuO-Mg system under argon atmosphere (1 bar) in the range of temperatures from 400 to 1100 K

- Above about 870 K, the solid Al_2O_3 phase produced by the reduction of CuO of Al is the only solid phase that coexists with the liquid composed by Al, Cu, and Mg.
- If the produced Al_2O_3 phase is not removed from the melt to form the slag/dross phase on top of the bath, upon cooling it will react with the Mg in the liquid phase to form MgAl_2O_4 , which will further transform to MgO and Al, upon complete solidification of the melt.

Formation of MgAl_2O_4 from the reaction of Mg and Al_2O_3 will occur at higher temperatures provided the activity coefficient of Mg is increased above that considered here (0.01). However, for this reaction to occur above 870 K, the activity coefficient of magnesium must be increased to about 0.2. The equilibrium analysis described above is important for stating that the main chemical reaction that must occur is given by Eq. 2, no matter that the value of its Gibbs free energy is not as negative as that of the reactions given by Eqs. 7 or 11. In this sense, it can be considered that the main role of magnesium is lowering the surface tension of the molten phase, although some increase in the reactivity of the molten bath can be gained by adding it.

Kinetic Considerations for Studying Reaction Rate and Reaction Mechanisms

The thermodynamics of molten aluminum solutions for refining purposes have been studied for many years. Most of the important systems behave as ideal solutions at temperatures above 973 K, so chemical refining methods can be used to remove elements such as Ca, K, Mg, Na, and Sr, as shown in the works of DiRusso,^[22] Gruzleski and Closset,^[23] Gariepy and Dube,^[24] and Moore.^[25] On the other hand, alloying can be performed taking advantage of the aluminothermic reduction of oxides such as CuO, MnO_2 , FeO, and SiO_2 . Nowadays, software can be used

to determine parameters such as the standard Gibbs free energy of reaction, chemical potential values, and activity coefficients, helping to understand how a system will behave in a given set of conditions such as temperature, pressure, and initial chemical composition. Special software have been developed for multicomponent systems, such as the programs used by Kattner^[26] and Gröbner et al.^[27] Therefore, the utility of thermodynamic software is its ability to determine the Gibbs free energy of reaction of, for example, the aluminothermic reactions given by Eqs. 1–6. Also, the following chemical reaction from the work of Moreno^[28] can be considered:

The formation of intermetallic phases once the reduced element dissolves first in the molten solution has been shown to lower the activity coefficient of Sb, thus increasing the negative value of the Gibbs free energy of reaction, as shown by Rajagopalan et al.^[29] It must also be considered that the use of a flux to remove the chemical compounds formed as slag can increase their activity coefficients, therefore augmenting the negative value of the Gibbs free energy.

Using mechanically added powders and agitation, studies by Langlais,^[30] Muñiz et al.,^[31] López,^[32] and Ayala^[33] have demonstrated the ability of aluminothermic reactions to produce Al-Sr and Al-Zr alloys with different chemical compositions. The molten aluminum solutions in these experiments contained above 1 wt.% Mg, as this amount was observed to increase bath reactivity. This effect has been well-documented by Langlais,^[30] as Mg lowers the superficial tension of aluminum and also possesses a greater chemical affinity for any element other than aluminum. These investigations reveal that the diffusion of magnesium from the bulk to the boundary layer is

the kinetic controlling step, so the reactions kinetics are determined by parameters including the initial Mg concentration in the melt, temperature, powder size, particle residence time, and agitation speed.

Aluminothermic reduction reactions are analyzed based on the following experimental observations described by Levenspiel^[34] and Rosenquist:^[35]

1. The kinetics of heterogeneous chemical reactions are governed by one or more of the following kinetic steps:
 - a. Transport of the reactive species from the bulk to the boundary layer
 - b. Chemical reaction at the interfaces between reactive molten metal particles
 - c. Formation of reaction products
 - d. Mass transfer through the layers of reaction products to the bulk
2. Two different types of chemical reactions can occur during metallurgical refining processes: molten metal–gas and molten metal–solid reactions. Molten metal–solid reactions can occur during mechanical powder addition and agitation, and consist of two different reactions:
 - a. Permanent contact reaction, which occurs at the interface of the reaction between the slag and the molten metal
 - b. Transitory reaction, which occurs inside the molten metal between the particles discharged by the plume carrier gas–reactive powder and the molten metal

The study of the interactions occurring between the reactive powders and the molten bath is quite complex. Nevertheless, some reaction zones have been determined, which are shown in Fig. 3. The description of these zones comes from the work of Macias and Flores.^[36]

- Jet zone, just at the exit of the injection lance
- Bubbling zone, composed of the injected powder particles and the carrier gas bubbles merging from the lance
- Broke-up zone, where the carrier gas bubbles reach the slag and pass into the atmosphere
- Slag zone
- Dispersion zone, where the carrier gas bubbles and slag particles are dispersed
- Intermediate zone, where the fluid becomes stagnant

For the chemical refining reactions that will be described in this work, the kinetic models available, which are shown in Table 1, need to be adjusted to the experimental results.

The following heterogeneous chemical reactions are likely to occur between molten metal and the injected SiO₂ particles:

Fig. 3 Zones of reaction during molten aluminum refining by powders injection through a carrier gas

Table 1 Analytical expressions of the function $f(\alpha)$ for different kinetic models of heterogeneous chemical reactions^[37]

Model	$f(\alpha)$
Nucleation by exponential law	$2\alpha^{1/2}$
Nucleation by exponential law	$3/2\alpha^{1/3}$
Nucleation by exponential law	$\ln \alpha$
Nucleation by potential law	$4\alpha^{1/4}$
Nucleation by potential law	$3\alpha^{1/3}$
Prout–Tompkins equation	$\ln(\alpha/1-\alpha)$
Linear growth	$-\ln(1-\alpha)$
Two-dimensional growth	$2(-\ln(1-\alpha))^{1/2}$
Two-dimensional growth	$3(-\ln(1-\alpha))^{1/3}$
Three-dimensional growth	$4(-\ln(1-\alpha))^{1/4}$
Nucleation–crystallization	$5(-\ln(1-\alpha))^{1/5}$
Three-dimensional growth	$3/2(-\ln(1-\alpha))^{2/3}$
Three-dimensional growth	$5/2(-\ln(1-\alpha))^{2/5}$
Two-dimensional growth	$4/3(-\ln(1-\alpha))^{3/4}$
Avrami's law	α
Three-dimensional contraction	$3/2(1-(1-\alpha)^{2/3})$
Two-dimensional contraction	$2(1-(1-\alpha)^{1/2})$
Volume contraction	$3(1-(1-\alpha)^{1/3})$
One-dimensional (1-D) diffusion	$\alpha^2/2$
Two-dimensional diffusion	$(1-\alpha)\ln(1-\alpha)^{1/3}$
Three-dimensional diffusion	$3/2(1-(1-\alpha)^{1/3})^2$
Difusión tridimensional	$3/2(1-2/3\alpha)-(1-\alpha)^{2/3}$
Jander equation	$3/2((1+\alpha)1/3-1)^2$
Second-order decomposition	$1/(1-\alpha)$
Third-order decomposition	$1/2(1-\alpha)^2$

When the reactive particles contain a significant amount of impurities, or if the reaction product is rigid enough, particles sizes do not decrease during reaction, yielding the name of this kinetic process. In this process, the chemical reaction is carried out first at the particle–molten metal interface, instantly forming a reaction product layer. Then, the reaction zone moves inside the particle, until reaching complete conversion. Because of the differences in atomic size between the participant chemical species, this reaction results in a significant amount of porosity, ensuring diffusion in both directions for the reduced and oxidized species. Therefore, the complete chemical reaction occurs in the four different stages described above. These stages occur in series, so the slowest one governs the global reaction rate. In this way, three different reaction mechanisms could take place, as depicted numerically in Table 2, which indicates the corresponding equations of conversion time versus particle radius and chemical composition at the boundary layer. In this table, x is the value of total conversion time, t is actual time, r_c is the actual radius of the particle, R is the initial radius of the particle, and X_b is the mole fraction of the diffusive species B . Generally speaking, because of the high temperature at which most pyrometallurgical refining processes of molten metals are performed, the reaction rate at the liquid–solid interface is high and does not constitute a limiting step. Thus, the velocity at which chemical species diffuse through the layers of reaction products constitutes the rate-determining step. Each of the kinetic mechanisms described in Table 2 results in specific susceptibilities to the process variables such as temperature, powder size, stirring speed, initial chemical composition of the melt, and residence time of the reactive particles inside the melt, so a statistical analysis must be performed to determine the reaction mechanisms governing the reaction rate.

Even when refining is performed in a controlled atmosphere, it is not possible to avoid the dissolution in the melt of small amounts of nitrogen or oxygen.

Therefore, some undesired chemical compounds can form mainly complex aluminates or nitrides, affecting the efficiency of the reaction.

The kinetics of heterogeneous chemical reactions has been studied for more than 100 years. However, advanced analytical tools such as EBSD in SEMs have only recently

permitted a proper assessment of the stoichiometry of the chemical reactions taking place. It is worth mentioning that before EBSD analysis existed, electron diffraction in the transmission electron microscope (TEM) was the most accurate technique to determine the crystallographic structure of unknown phases in a sample. Therefore, phase identification by EBSD is complementary to TEM analysis. Nevertheless, it is important to mention the differences between phase identification and phase verification, as several definitions could exist. The main difference between these terms is the number of candidate phases that must be analyzed to determine the right phase. In the case of phase verification, the operator knows quite well the phases that are present in the sample, usually analyzing less than five possible phases. In phase identification, the right phase is sought from a database of crystallographic compounds with no operator assistance.

EBSD patterns contain a great amount of information on the crystalline structure of the sample, which can allow for the determination of the spatial group of a certain phase, such as the symmetry elements contained in the pattern. Therefore, the EBSD diffraction pattern is a fundamental vehicle for determining the phases present in a sample and for a deep analysis of reaction kinetics as described in the works of Schwartz et al.^[38] and Randle and Engler.^[39]

EBSD in the SEM

When an electron beam hits a metallic sample in the SEM, several dispersion and interaction phenomena occur, producing various signals as shown in Fig. 4. Backscattered electrons are used to form an image, for chemical analysis, or for crystallographic analysis of the volume studied. Crystallographic analysis is performed by evaluating the diffraction pattern, which is generated when the primary electrons are diffracted by the lattice planes of the crystals. To obtain the best signal conditions for the EBSD analysis, the surface of the sample must form a small angle 2Θ with the electron beam.

Figure 5 shows schematically the classic diffraction analysis from the lattice planes, as described in the work of Randle and Engler.^[38] Moreover, it shows that the Θ angles for which diffraction occurs depend on the wavelength (λ) and the interplanar space of the dispersant phase, d .

Because electron diffraction through the Bragg Θ angle occurs in all directions, the diffracted beam is in the form of the surface of a cone, extending approximately from the normal plane to the reflecting atomic planes with a medium apical angle of $90 - \Theta$. In fact, considering that the source of electron dispersion lies between the lattice planes as shown in Fig. 5, two cones of radiation are formed from each family of planes. Substituting the typical values of λ and the interplanar space of the lattice d into the Bragg equation, a Q of 0.5° is obtained. Therefore, the apical angle of a diffraction cone is approximately 180° , indicating that the cones are almost planar. When a phosphor screen of the camera in

Table 2 Controlling stages for the decreasing nucleus model, and the equations indicating equivalent complete reaction time

Stage	t/τ ratio versus particle size and chemical composition	
Diffusion from the bulk to the boundary layer	$\frac{t}{\tau} = 1 - \left(\frac{r_c}{R}\right)^3$	
Diffusion through the layer of reaction products	$\frac{t}{\tau} = 1 - 3\left(\frac{r_c}{R}\right)^2 + 2\left(\frac{r_c}{R}\right)^3$	
Chemical reaction at the interface	$\frac{t}{\tau} = 1 - \frac{r_c}{R} = 1 - (1 - X_b)^{\frac{1}{3}}$	

Fig. 4 Summary of the different signals generated due to the interaction of electrons with matter in a SEM, as described in the work of Randle and Engler^[38]

Fig. 5 Origin of Kikuchi lines from the perspective of EBSD, as described by Randle and Engler^[38]

the EBSD analysis system is positioned such that it collects the diffraction cones, a pair of parallel conical sections are formed as a result, called Kikuchi lines. The sections are spaces at an angular $2\Theta_B$ distance, proportional to the interplanar spacing. Having obtained a good EBSD pattern from a metallic sample, the next step is to determine the punctual chemical composition of a particle of interest. This is done in the SEM using either EDS or wavelength dispersive spectroscopy analysis, and is important to enable a search of the crystallographic phase databases. Then, the pairs of Kikuchi lines are identified using the Hough transformation to obtain points in a Hough space that can be located automatically. Moreover, the width of the lines can also be calculated. The width of a pair of Kikuchi lines is inversely proportional to the interplanar spacing of the atomic planes, and together the lines form a reduced volume of the unit cell. More than one volume element can be generated if more than three

Kikuchi bands can be located. The unique property of the volume elements calculated in this way, starting from the EBSD pattern, is that when each volume element is multiplied by an enter, it reproduces the reduced volume of the lattice. Once the number of volume elements has been calculated, it is relatively simple to find the highest common multiple for the smaller volume elements. Then, it is necessary to search the available crystallographic charts. One of the most important crystallographic databases is that of the International Crystallographic Diffraction Data,^[40] containing more than 100,000 different inorganic compounds. Before describing the experimental evidence studied in this work, it is worth mentioning that the work in itself deals with the reaction kinetics of molten aluminum refining using EBSD to identify and therefore propose the numerical reaction rates governing Mg and Sb removal by SiO_2 and Ca, respectively. Extensive work has been conducted to measure the reaction rates of thousands of chemical reactions, so the fundamentals of such reactions are well established and are reported in several classical books such as those by Levenspiel,^[34] Rosenquist,^[35] Szekely et al.,^[41] and Poirier and Geiger.^[42] Particular efforts have been made to identify phases present in alloys of the important aluminum systems, such as the works conducted by Kaliq^[43,44] and the present authors.^[20] On the other hand, different analytical techniques continuously emerge, permitting a study of the phenomena occurring in deep molten metals. EBSD in the SEM has been useful not only for measuring reaction rates and determining the values of kinetic parameters but also for elucidating the mechanism of reaction.

REACTION KINETICS OF IMPORTANT ALUMINUM SYSTEMS: EXPERIMENTAL PART

This part of the article will present the methodology used to assess the stoichiometry of the reaction occurring

during the refining of Mg or Sb from molten aluminum by mechanically added powders and agitation of SiO_2 and Ca, respectively, using EBSD in the SEM as analytical techniques. Moreover, it is considered the reduction reaction of CuO particles to prepare Al-Cu alloys. To obtain samples for microscopic analysis, several experiments were conducted using an electrical resistance furnace with automatic temperature control as a melting unit, which contained a silicon carbide crucible and had a 4-kg molten aluminum capacity. A controlled velocity stirring device was coupled to the furnace to maintain SiO_2 , Ca, or CuO particles inside the melt. An average of 2.5 kg of molten alloy was used with the following initial chemical composition in weight percent: 9.50 Si, 0.18 Fe, 3.50 Cu, 0.03 Mn, 1.18 Mg, 0.30 Zn, and 0.08 Ti. Once the alloy melted and the temperature of interest was reached, i.e., 750°C , the stoichiometric amount of SiO_2 , Ca, or CuO was added to the center of the vortex formed by the impeller of the agitation system. In the case of Sb removal by Ca, the initial chemical composition of the alloy was adjusted to 0.5 wt.% Sb. The morphology of the added particles was irregular spherical, with a variable diameter between 0.15 and 0.22 mm. Agitation velocity was fixed at 120 r.p.m., which was kept constant during each experiment. The quantities of reactants were calculated according to the stoichiometry of reactions given by Eqs. 6 and 7 and the amount of molten alloy. Reaction temperatures of 700°C , 725°C , 750°C , and 775°C were studied, with stirring maintained for 60 min. Samples from the melt were taken every minute during the first 10 min and every 5 min thereafter. The solidified samples were chemically analyzed using plasma emission spectroscopy to determine the Mg, Sb, or Cu concentrations as a function of sampling time at constant temperature. Part of each sample was metallographically prepared for observation in the SEM using a complementary combination of micro point structural analysis techniques such as EDS and EBSD. EBSD analysis requires a sample surface in very good condition to obtain Kikuchi lines with a suitable resolution. To obtain suitable samples, a vibratory polishing machine was used at 7200 Hz without vertical movement. Then, the samples were polished for 2 h with nylon clothing discs impregnated with a solution of diamond paste in distilled water, with $1\text{ }\mu\text{m}$ diamond particle sizes. Then, a third polishing step was applied for 2 h using diamond paste with a $0.25\text{ }\mu\text{m}$ particle size. Final polishing was performed using macrocloth discs mounted over a static plate using colloidal silica as an abrasive at pH 9.8. This technique was very useful for the identification of reaction products formed by the chemical reactions taking place and their main structural characteristics. In addition, the width of the layers of reaction products was measured, and those values were used in the following analysis of the reaction kinetics. In these cases, confidence levels of EBSD analysis of 0.7 were chosen to ensure excellent identification.

The Antimony Removal from Molten Aluminum by Ca Addition

First, after the addition of calcium to the antimony-containing aluminum alloy, a removal reaction occurs over time, as seen in Fig. 6. As much as 85.2% of antimony was removed after 40 min of reaction. The morphology and size of antimony and calcium-rich particles are shown in the SEM micrograph of Fig. 7, together with the corresponding EDS patterns.

However, when EBSD was used, the Ca_2Sb and AlSb phases were identified, as shown in Fig. 8. These results indicate that the antimony removal reaction is as follows:

The SEM micrograph shown in Fig. 9 demonstrates that the Ca_2Sb phase is of pre-dendritic nature, i.e., the particles are formed while the molten alloy is still at high temperature. Upon solidification, these particles grow over the aluminum grain boundaries, acquiring a needle-like morphology, reaching a maximum length of $50\text{ }\mu\text{m}$. Although very small particles on the order of $5\text{ }\mu\text{m}$ were also observed, because their density (3.72 g/mL) is higher than that of aluminum, the particles will tend to settle down in the molten metal. On the other hand, a close relationship has been observed between particles of Ca_2Sb and those containing Al, Ca, and Si, although it was not possible to determine the crystallographic characteristics of those particles by EBSD. Apart from the lack of availability of cards containing the crystallographic characteristics of ternary Al-Ca-Sb phases, no Al-Ca-Sb or Al-Si-Sb equilibrium diagrams are available.

The Removal of Magnesium from Molten Aluminum by the Addition of SiO_2

Figure 10 shows a partially reacted SiO_2 particle that has been immersed in molten aluminum for 1 min at 750°C . The central part of this micrograph shows the

Fig. 6 Rate of antimony removal from molten aluminum after calcium addition, at 750°C

Fig. 8 EBSD patterns and their corresponding indexing for the (a) Ca_2Sb and (b) AlSb phases

corresponding EDS pattern. The EBSD patterns shown in the upper part of this micrograph are characteristic of the SiO_2 and MgAl_2O_4 phases.

A line scan analysis was performed in the SEM to obtain information about the distribution of elements at the interface solid (SiO_2)-melt phase, as well as over the layers of reaction products. At least 10 particles per sample were measured for this analysis. Figure 11 shows typical results for a particle analyzed after it was immersed for 1 min in molten aluminum at 750°C . Similar analyses were performed for particles immersed for longer periods of time.

Fig. 9 Microstructural features of AlCaSi and CaSb particles after calcium addition to AlSb alloys

Fig. 11 Elemental distribution through the particle shown in Fig. 10

These results indicate that the SiO_2 reduction reactions occur during Mg refining of molten aluminum leading to MgAl_2O_4 formation immediately once the particles come into contact with molten aluminum. Therefore, it can be concluded that the formation of MgAl_2O_4 occurs faster than the other phases because no evidence was found of the formation of MgO or Al_2O_3 , as demonstrated by the Gibbs free energy:

Figure 12 shows the variation of Mg concentration as a function of time at 750°C . This graph shows that Mg concentration diminishes continuously until reaching a constant value at constant temperature. For reaction times less than 5 min, only Al_2O_3 , MgAl_2O_4 , and Si were formed as reaction products. However, SiO_2 nuclei still persist under

these conditions. The micrograph of Fig. 13a shows the EDS and EBSD patterns of the nucleus of a SiO_2 particle that was immersed for 5 min in molten aluminum at 750°C , where Fig. 13b shows the partially reacted SiO_2 particle. Finally, Fig. 13c shows the EDS and EBSD patterns of the MgAl_2O_4 in the layer of reaction products. According to Zhong et al.,^[45] the layers of reaction products will grow until the Mg^{+2} ions in the melt are depleted. Complete conversion of the SiO_2 nucleus into reacted products occurs after 60 min, and the conversion is closely related to Mg depletion as shown in Fig. 12.

Figure 14 shows the SiO_2 -melt interface of a particle that was immersed for 10 min at 750°C , where the SiO_2 nucleus still exists. A layer of Al_2O_3 adjacent to the nucleus and an external thin layer of MgAl_2O_4 are also observed. The increase in the amount of Al_2O_3 instead of MgAl_2O_4 can be explained in terms of the depletion of Mg from the melt and over the boundary layer, as Mg depletion also affects the amount of MgO that could be formed. On the contrary, as Al concentration is always constant at the boundary layer, it is always diffusing through the pores in the layers of reaction products. According to the stability of oxides in the Al-Mg-O₂ system^[19] shown in Fig. 1, below 0.49 wt.% Mg, the Al_2O_3 phase is stable over the complete range of temperatures studied here, indicating the dissolution of MgO . This demonstrates that reactions given by Eqs. 5 and 10 occurred. Finally, particles that were immersed for more than 20 min at any temperature consisted basically of an Al_2O_3 nucleus surrounded by a thin layer of MgAl_2O_4 at the outer layer.

According to the results presented in the former analysis, the conversion rate of the SiO_2 particles into reaction products can be followed using the unreacted nucleus model, considering spherical particles of constant size. The control stage could be the diffusion of reactants through the layers of reaction products or chemical reaction.

Fig. 13 (a) EDS and EBSD patterns of the nucleus of a SiO₂ particle reacted for 5 min at 750°C in molten aluminum, (b) SEM micrograph of the particle, and (c) EDS and EBSD patterns of MgAl₂O₄ in the layers of reaction products

Fig. 14 (a) EDS and EBSD patterns of Al₂O₃ around the nucleus of a SiO₂ particle reacted for 10 min at 750°C in molten aluminum, (b) SEM micrograph of the particle, and (c) EDS and EBSD patterns of MgAl₂O₄ in the outer layers of reaction products

The time at which the diameter of the nucleus becomes zero can be determined experimentally is calculated with the following equation:

$$\tau = \frac{a \rho_{\text{slag}} R_p^2}{24 \rho_{\text{Al}} D_{\text{efec}} C_{\text{Mg}}} \quad (11)$$

where τ = total conversion time of a particle (s), a = stoichiometric factor depending on the chemical reaction considered, ρ_{slag} = slag density (kg/m³), R_p = average particle radius (m), ρ_{Al} = aluminum density (kg/m³), D_{efec} = effective diffusion coefficient of Mg through the layers of reaction

products (m²/s), and C_{Mg} = actual Mg concentration at the solid SiO₂-melt interface (mol/m³).

Data extracted from Fig. 11 can be used to calculate the values of the r_c/R and t/τ ratios. Furthermore, the dependence between these ratios can be determined to establish the kinetic control stage. Figure 15 shows this dependence at 750 °C. According to the shape of the curve of this figure, the controlling kinetic step is the diffusion of Mg and Al through the layers of reaction products. If the chemical reaction was the kinetic controlling step, the shape of the graph should be a straight line between the $r_c/R = 1.0$ and $t/\tau = 1.0$ points.

Regarding the mechanisms of reaction in the SiO₂-melt system studied here, the most accurate explanation is that given by Zhong et al.,^[45] who states that the formation of MgAl₂O₄ is strongly dependent on the initial Mg concentration, as has been thermodynamically calculated and experimentally demonstrated in this work. Therefore, for initial Mg concentrations below 3 wt.%, the stable phase in the range of temperatures from 700°C to 850°C is MgAl₂O₄, a situation that can be corroborated by observing Fig. 1. However, the reaction between SiO₂ particles and magnesium dissolved in molten aluminum will be the most favorable, as indicated by the global reaction given by Eq. 6. The presence of MgO was not confirmed in this work, and according to the literature cited, this phase could occur only for higher initial Mg concentrations, i.e., above 3.5 wt.%. Nevertheless, this concentration is easily attained at the solid SiO₂-melt interface, specifically at the early time points following particle addition, ensuring the formation of a significant amount of MgO. In turn, most MgO is consumed by the MgAl₂O₄ formation reaction.

Some studies have established that the reaction between dissolved Mg and SiO₂ particles takes places rapidly as it can be difficult to determine the nucleation stage of MgO particles. Molins et al.^[18] studied the interfacial reaction between a molten Al₄Mg alloy and Al₂O₃ fibers, and showed that the MgO nucleus remains very small, forming

Fig. 15 Graphic representation of the dependence of r_c/R versus t/τ for the conversion of a SiO₂ particle into reaction products at 750°C

thin layers of about 10 nm thickness. The diffusion of Mg^{2+} cations therefore occurs through the grain boundaries of MgO particles by an infiltration mechanism. The growth process of MgO layers continues until the grains around the interface matrix/reaction zone are large enough to close the intergranular spaces. Hence, the rate-determining step must be the diffusion of chemical species through the layers of reaction products.

The Gibbs free energy of reaction given by Eq. 10 indicates that the reduction of SiO_2 by Al also occurs, as the Al^{+3} cations can diffuse through the spaces left by the released Si . Silicon back-diffusion occurs through the grain boundaries of MgO and Al_2O_3 , and Si dissolves in the molten aluminum phase. On solidification, Si is rejected from the solid solution, remaining as large crystals around foreign particles.

When the stoichiometric amounts of MgO and Al_2O_3 are reached and the equilibrium conditions indicated in Fig. 1 are obeyed, the reaction given by Eq. 1 takes place. In this way, the formation of MgAl_2O_4 and the interdiffusion of Al^{+3} , Mg^{+2} , and Si^{+4} cations occur simultaneously. Once the Mg concentration in the molten alloy falls below 0.30 wt.%, aluminum continues to react with the SiO_2 nucleus, forming more Al_2O_3 at a constant growth rate controlled by the diffusion of Al^{+3} cations through the layers of reaction products. In turn, the small amount of MgO that can be formed through the reaction of Mg^{+2} cations with SiO_2 is dissolved in the Al_2O_3 phase, as shown in Fig. 1. Reactions among molten aluminum and dissolved magnesium with solid SiO_2 require the diffusion of ions, although the diffusion of O^{2-} ions is negligible because of their larger ionic size. The relationship among ionic radii of Mg^{+2} , Al^{+3} , and Si^{+4} with respect to O^{2-} is 0.47, 0.34, and 0.28, respectively, as shown by Zhong et al.^[45] Therefore, the interdiffusion of Mg^{+2} and Al^{+3} cations is kinetically possible through the lattice in the structure of SiO_2 of the O_2 anions or through the Si^{+4} cations resulting from the SiO_2 decomposition. Such reactions are given as follows:

When the Mg^{+2} cations occupy interstitial sites inside the SiO_2 lattice, the positions of O^{2-} anions must be adjusted to retain electrical neutrality and diminish the distortion energy of the lattice. The result is a change in crystal structure. The processes involved in this phenomenon are governed by the chemical potential values of the partial reactions, in this case, those given by reactions (5) or (10). As MgAl_2O_4 is the final reaction product, the reaction given by global Eq. 6 could be accepted, as this satisfies the described mechanism of reaction. However, to minimize interfacial energy, MgAl_2O_4 must form intermediate

reaction products as follows. This situation can be represented in the stoichiometric form $x\text{MgO} \cdot y\text{Al}_2\text{O}_3$, so when $x = 1$ and $y = 13$, the formula will be $\text{MgAl}_{26}\text{O}_{40}$; when $x = 1$ and $y = 1$, the formula will be MgAl_2O_4 (stoichiometric); when $x = 1$ and $y = 0$, the formula will be MgO . Moreover, the relationship $x - y$ of MgAl_2O_4 ensures electrical neutrality in the oxide phase.

A kinetic condition necessary for the diffusion of chemical species is continuous nanoporosity in the layers of reaction products. Zhong et al.^[45] have determined that the formation of MgO over SiO_2 particles involves a volume contraction of 13.6%, whereas the formation of MgAl_2O_4 over SiO_2 particles causes a volume contraction of 27%. Because of these changes, the new phases formed break their unions with the original SiO_2 particles instantly, transforming into thousands of small crystals, producing the necessary voids required for the diffusion of chemical species. This breaking-up is continuous, occurring together with the nucleation and growth of new phases over the former phases. However, for the last stages of SiO_2 chemical reduction by Mg or Al , the mechanism of reaction abruptly changes, as the concentration of Mg at the reaction interface lies below 0.3 wt.%. At this time, the MgO that is formed dissolves in Al_2O_3 . Then, these Al_2O_3 crystals grow continuously until reaching a micron size, closing the spaces for diffusion, and thus stopping the chemical reaction underway.

The above explanations are important from the technological point of view, as unreacted SiO_2 particles can remain entrapped in the molten metal as inclusions. On the other hand, knowing the true nature of the reaction products and the way that the stoichiometry of reaction changes as a function of Mg concentration in the melt and at the reaction interface could be useful for developing specific types of fluxes for removing these particles. Of course, reaction kinetics could be accelerated, diminishing the size of the nucleus of SiO_2 particles added for Mg refining from molten aluminum.

Kinetic Study

According to classical kinetic theory (differential method), the rate of magnesium removal by SiO_2 particle addition could be calculated by the following formula:

$$-V \frac{dC_{\text{Mg}}}{dt} = K (C_{\text{Mg}} - C_{\text{Mg}(\text{eq})})^n S_p \quad (15)$$

where C_{Mg} = actual concentration of Mg in the bath at constant temperature (wt.%), $C_{\text{Mg}(\text{eq})}$ = Mg concentration in the bath, at equilibrium, at constant temperature (wt.%), K = reaction rate constant ($\text{cm} \cdot (\text{wt.}\%)^{1-n} / \text{s}$), t = time (s), n = order of reaction, S_p = total area of reaction (cm^2), and V = volume of the bath (cm^3).

Equation (15) can be simplified considering that the value of $C_{\text{Mg}(\text{eq})}$ is close to zero in the range of temperature

under study. The value of K_p captures the effects of particle size and the volume of the bath, so Eq. 15 could be rewritten as follows:

$$-\frac{dC_{Mg}}{dt} = K_p (C_{Mg})^n \quad (16)$$

This equation can be transformed into a linear equation of the form:

$$-\ln\left[\frac{dC_{Mg}}{dt}\right] = n \ln(C_{Mg}) + \ln(-K_p) \quad (17)$$

The order of reaction n can be obtained from the experimental results through a linear graph of $\ln(dC_{Mg}/dt)$ versus $\ln(C_{Mg})$. The works conducted by Flores et al.^[46] and Escobedo et al.^[9] showed that the value of n is close to 1. The values of K_p for every temperature are directly obtained from the y-intercept of the straight line. In finding an analytical solution of Eq. 16, considering that the value of n is equal to 1, the following expression is obtained:

$$C_{Mg} = C_{Mg}^0 \exp[(-K_p)t] \quad (18)$$

The value of K_p can be used to obtain the activation energy of the process through the following Arrhenius-type expression:

$$K_p = Ae^{-Q/RT} \quad (19)$$

where A = frequency factor, Q = activation energy (J/mol), R = universal gas constant (J/mol-K), and T = temperature (K).

This expression must be transformed into a linear one, yielding the following equation:

$$\ln K_p = \ln A - \frac{Q}{RT} \quad (20)$$

The slope of a linear graph of $\ln(K_p)$ versus $1/RT$, which is shown in Fig. 16, is used to determine the value of activation energy, whereas the y-intercept of the straight line is the value of $\ln(A)$. Macias and Flores^[36] measured the activation energy of the Mg removal process using solid fluxes, reporting that this process requires 11540 cal/mol. This value is close to typical values obtained for the diffusion-controlled metallurgical processes.

Preparation of Al-Cu Alloys Using Aluminothermic Reduction of CuO

Figures 17 and 18 show the increase in Cu concentration in the molten alloy as a function of the CuO addition time, for experiments performed using an aluminum alloy without Mg and an alloy with 1 wt.% Mg, respectively, and a particle size of $<50 \mu\text{m}$, at the indicated temperatures.

Fig. 16 Linear dependence of $\ln(k)$ versus $1/T$ ($\times 10^4$) for determining the values of activation energy for the aluminothermic reduction of SiO_2

Fig. 17 Variation of Cu concentration in the molten aluminum as a function of the CuO addition time for the indicated temperatures. The particle size was $<50 \mu\text{m}$ and absence of Mg

Fig. 18 Variation of Cu concentration in molten aluminum as a function of the CuO addition time for the indicated temperatures. The particle size was $<50 \mu\text{m}$, and the initial Mg concentration was 1.0 wt. %

The graphs in Figs. 17 and 18 reveal significant differences in the reaction rate when an alloy with an initial magnesium concentration of 1 wt.% is used compared to that observed in the absence of magnesium. The increase in copper concentration as a function of treatment time shown in Fig. 17 can be explained as follows. According to Guedes et al.,^[47] a layer of Al_2O_3 forms at the beginning of the reduction reaction of CuO , when no magnesium is present in the molten alloy. The growth of this layer hinders contact between molten aluminum and the reaction front, by working as a diffusion barrier to both Al and Cu transport, which prevents reaction given by Eq. 21 to complete. Nevertheless, the layer of Al_2O_3 is not completely impervious, thus having some porosity through which aluminum can diffuse to the boundary layer, where it reaches the CuO particle surface.

The SEM micrograph of Fig. 4 shows a partially reacted CuO particle taken after 90 min of reaction from the molten bath at 1123 K for an alloy with 0 wt.% Mg, where the porosity of the outer Al_2O_3 -rich layer is slightly evident. The Kikuchi pattern of the Al_2O_3 phase obtained by EBSD is included. In the same micrograph, the Al_2Cu room temperature stable phase is seen at the periphery of the CuO -rich particle. Probably when a critical concentration of Al is achieved, i.e., after about 90 min, the aluminothermic reduction reaction initiates. This reaction is highly exothermic and explosive, as was observed during most experiments; as a consequence, the copper concentration rapidly increases in the molten alloy to approximately 3.6 wt.% after 90 min at 1123 K, meaning an efficiency of reaction of 41.09% (Fig. 19).

Micrographs in Fig. 20 show the evolution of the thickness of the layers of reacted CuO particles as a function of reaction time, taken from the molten metal at the temperature of 1123 K, for particle size of $<50 \mu\text{m}$. It can be observed that after 5 min of addition (Fig. 20a), CuO particles are surrounded by a thin layer of Al_2O_3 that progressively grows until reaction stops due to a change in the mechanism that controls the reaction. After 90 min of contact, the CuO particles started quickly to react with molten aluminum (Fig. 20b), transforming into Al_2O_3 until reaction again stops by the formation of a thick Al_2O_3 layer around the CuO particles (Fig. 20c). The micrographs also show that after 180 min of reaction, the Al_2O_3 layer is so compact that hinders diffusion of Al through the CuO layer, therefore slowing down the aluminothermic reduction reaction. Figure 21 shows the XRD pattern of a sample of slag at the end of the experiment performed at 1123 K with a CuO particle size of $<50 \mu\text{m}$ in the absence of Mg; the main species found were Al, Al_2O_3 , AlN , Al_2Cu , and CuO . CuO particles are those which directly passed to the slag without reacting, particularly when the efficiency of reduction reaction fell down. The AlN is likely to form at 1123 K, according to the following reaction because complete isolation from the atmosphere was difficult to achieve:

The aluminum in the slag results from metal dragging from the molten bath to the slag during sampling, whereas the Al_2Cu particles (θ phase in the corresponding Al-Cu equilibrium diagram) were formed during solidification as Cu was released by the CuO reduction reaction. Finally,

Fig. 19 (a) SEM micrograph of a partially reacted CuO particle taken after 90 min of reaction from the molten bath at 1123 K for an alloy without Mg and (b) EBSD Kikuchi pattern of the Al_2O_3 phase

Fig. 20 SEM micrographs of CuO partially reacted particles obtained from aluminum melts at 1123 K, for initial particle size of <50 µm, after the indicated times

Fig. 21 XRD pattern of the slag sample obtained at 1123 K, for particle size of <50 µm in the absence of Mg

the Al_2O_3 originates from the main reduction reaction of CuO stated by Eq. 21.

Although the final copper concentration in the solidified alloy was similar when using alloys without Mg, the behavior of the aluminothermic reduction reaction is quite different, as it can be seen in Fig. 18. Magnesium enhances reaction rate in two ways: at 973 K, it lowers the surface tension of molten aluminum, from 0.91 to 0.66 N/m for a concentration of Mg equal to 1 wt.%.^[48] This facilitates wettability of the CuO particles by the melt and increases the reactivity of the bath since Mg can also reduce CuO at 960 K, according to the following reaction:

The Gibbs free energy of this reaction can be obtained as follows. As Mg is dissolved in molten aluminum while

released copper also dissolves in the molten phase, therefore the solution must be treated as a diluted one:

$$\Delta G_{1273\text{K}} = \Delta G^0 + RT \ln k \quad (24)$$

Assuming that the activities of CuO and MgO equal 1, k may be expressed as follows:

$$k = \frac{a_{\text{Cu}}}{a_{\text{Mg}}} = \frac{X_{\text{Cu}}}{X_{\text{Mg}}} \quad (25)$$

Raghavan,^[49] Soares et al.,^[50] and Buhler et al.^[51] studied extensively the Al-Cu-Mg system from the thermodynamic point of view. However, they focused on studying phase equilibria during solidification, as many alloys pertaining to this system are widely used in the preparation of engineering parts. Nevertheless, Soares et al. determined that the molar fraction of Mg at 1000 K modifies to 0.0029 (1 wt.%) when the molar fraction of copper is 0.0106 (5 wt.%), very close to the compositions used in this work. Therefore, the value of k given by Eq. 25 can be obtained from these molar fractions as follows:

$$\Delta G_{1273\text{K}} = -418.354 \times 10^3 + 8.314(1273) \ln \frac{X_{\text{Cu}}}{X_{\text{Mg}}} \quad (26)$$

$$\Delta G_{1273\text{K}} = -418.354 \times 10^3 + 8.314(1273) \ln \frac{2.18 \times 10^{-2}}{1.3 \times 10^{-4}}$$

The $\Delta G_{1273\text{K}}$ value of reaction given by Eq. 23 is of -364.14 kJ.

During their experiments on the synthesis of Al/ Al_2O_3 composites, Pai and Ray^[13] found that MgO could be formed through the reduction of Al_2O_3 by the Mg contained in the alloy. This reduction may also occur in the

Fig. 22 (a) SEM micrograph of a partially reacted CuO particle taken after 90 min of reaction from the molten bath at 1123 K for an alloy with 0 wt.% Mg, (b) EBSD Kikuchi pattern of the CuO phase, and (c) EBSD Kikuchi pattern of the MgAl₂O₄

case of the CuO reduction reaction given by Eq. 23. In turn, MgO and Al₂O₃ can react during solidification to form MgAl₂O₄ as the final reaction product, according to the following reaction between pure compounds, whose ΔG° is calculated at 1000 K:

The successive formation of MgO and Al₂O₃ causes expansion and contraction during reaction, which results in the breaking of the crystals into numerous smaller crystallites, thus producing the porosity required for diffusion and back diffusion of Al, Mg, and Cu. SEM observations revealed that the MgAl₂O₄ layer of reaction products is significantly more porous than the layer of Al₂O₃, as is shown in the micrograph of Fig. 22, which corresponds to a partially reacted CuO particle taken from the molten bath after 90 min of reaction at 1123 K, using an alloy with an initial Mg concentration of 1 wt.%. Small light Cu-rich particles that have not reached the boundary layer are seen inside the layer of reaction products. EBSD Kikuchi patterns corresponding to the core of the CuO particle and MgAl₂O₄ as the main compound in the layer of reaction products are included. The evidence at this stage strongly supported why the increase in the initial Mg concentration in the melt favors the kinetic conditions for having an initially higher reaction rate.

For experiments in which an alloy with an initial concentration of 1 wt.% Mg was used, the copper concentration in the melt reached 4.0 wt.% in approximately 90 min, at 1123 K, i.e., 45.66% efficiency. Meanwhile, Mg concentration fell down to a value of 0.28 wt.%. In this sense, Fig. 23 shows the variation in the Mg concentration as a function of CuO injection time, where it can be seen that magnesium continuously reacts during injection, decreasing to a value as low as 0.13 wt.% at the end of experiment. However, when this final concentration of Mg is reached, reduction reaction falls down sharply, attaining similar final efficiencies of reaction as when using alloys without Mg.

In turn, micrographs in Fig. 24 show the evolution of the thickness of the layers of reaction products of CuO

Fig. 23 Behavior of the Mg concentration in molten aluminum as a function of the CuO addition time at 1123 K with a particle size of <50 μm

particles as a function of reaction time, taken from the molten metal at the temperature of 1123 K, for particle size of <50 μm, when using an alloy with an initial Mg concentration of 1 wt.%. As may be observed in the micrographs, layers of Al₂O₃ and MgAl₂O₄ appear since 5 min of sampling. As time elapses, the layer of MgAl₂O₄ prevails, as a continuous and porous layer that keeps always growing. However, the final layer of reaction products is composed of MgAl₂O₄ and CuO, as it can be seen in micrograph (Fig. 24c), which means that the aluminothermic reduction reaction was not fully completed as expected. Figure 25 shows an XRD pattern of a slag sample obtained at the end of the experiment performed at 1123 K, when an alloy with an initial Mg concentration of 1 wt.% and a CuO particle size of <50 μm were used. The main species identified were AlN, Al₂Cu, CuO, and MgAl₂O₄.

If the previous explanation for the presence of CuO and AlN in the slag is valid, then, according to the previous discussion, the global reaction that occurs at 960 K in the alloy that contains initially 1 wt.% Mg is the following:

Fig. 24 SEM micrographs of CuO-reacted particles obtained from Al-1 wt.% Mg melts at 1123 K, for initial particle size of <50 μm , after the indicated times

Fig. 25 XRD pattern of a slag sample taken at the end of the experiment performed at 1123 K, using an alloy with an initial Mg concentration of 1 wt.% and CuO particle size of <50 μm

For this reaction, k is expressed as follows:

$$k = \frac{a_{\text{Cu}} a_{\text{MgAl}_2\text{O}_3}^{1/4}}{a_{\text{CuO}}^{1/2} a_{\text{Al}}^{1/4} a_{\text{Mg}}} \quad (29)$$

Assuming $a_{\text{MgAl}_2\text{O}_3}$, a_{Al} , and a_{CuO} equal 1, and considering the values of molar fraction of Al, Cu, and Mg for evaluating Eq. 25, the following expressions are obtained:

$$\begin{aligned} \Delta G_{1273\text{K}} &= \Delta G^0 + RT \ln k \\ \Delta G_{1273\text{K}} - 221.285 \times 10^3 + 8.314(1273) \ln \frac{X_{\text{Cu}}}{X_{\text{Mg}}^{1/4}} & \quad (30) \\ \Delta G_{1273\text{K}} - 221.285 \times 10^3 + 8.314(1273) \ln \frac{2.18 \times 10^{-2}}{(1.3 \times 10^{-4})^{1/4}} & \end{aligned}$$

$$\Delta G_{1273\text{K}} = -324.227 \text{ kJ} \quad (31)$$

The micrograph in Fig. 26a shows a typical microstructure of a sample of a solidified alloy obtained at 1123 K after 180 min of the CuO addition time, of an alloy with an initial Mg concentration of 1 wt.% treated with particle size of <50 μm . Figure 26b shows the EBSD pattern of the tetragonal Al_2Cu phase.^[52]

Kinetic Measurements

The experimental evidence strongly indicates that the rate of reaction is diffusion controlled. Accordingly, the experimental data obtained at each temperature, for alloys with and without magnesium, were analyzed using the kinetic formulae presented by Brown.^[37] However, in order to fit the experimental data to the kinetic models available, it was assumed that the final observed copper concentration corresponded to the completed reaction and therefore to a final fractional conversion equal to 1. In this sense, it was found that the kinetic data were well fitted by the 1-D parabolic rate law, as is shown in Fig. 27, that corresponds to the experiments where alloys with no magnesium were used, for particle size of <50 μm . This is because the model is not sensible to the effect of initial Mg concentration, so the effect of Mg on reaction rate will be presented and broadly discussed later.

The form of the equation that appropriately fits the experimental results is the following:

$$\alpha^2 = (kt) \quad (32)$$

where α is the fractional conversion, k is the rate constant, and t is the reaction time. From a graph of α^2 versus t , the values of k can be obtained for each temperature, as is

Fig. 26 (a) SEM micrograph of a sample obtained after 180 min at 1123 K, for a particle size of <50 μm and (b) EBSD Kikuchi pattern of the Al_2Cu phase

Fig. 27 Experimental results and prediction of the diffusion 1-D kinetic model, for the temperatures indicated

shown in Table 3, for the indicated alloys. It is worth mentioning that this model assumes that the reaction order (n) is equal to 1.

The linear regression of $\ln k$ versus $1/T$ was plotted in order to obtain the values of activation energy and rate constants using the well-known Arrhenius equation, given as follows:

$$k = k_0 e^{-E/RT} \quad (33)$$

where E is the activation energy (J/mol) and R is the universal gas constant (8.314 J/mol-K).

Figure 28 shows the linear dependence of a plot of $\ln k$ versus $1/T$, for the aluminothermic reduction of CuO for alloys with and without Mg. From the slope of the observed graphs, the values of activation energy of the process obtained were as follows: $E = 88.43$ kJ/mol for alloys containing no magnesium, and $E = 10.93$ kJ/mol for alloys with an initial concentration of Mg of 1 wt.%.

From the values of the kinetic parameters determined in this section, it can be said that, as expected, the higher values of the rate constants indicate that reaction rate is enhanced by the presence of Mg in the alloy, at least initially. This occurs since for reaction times longer than 110 min, the reaction tends to slow down, in agreement with observations in the micrographs of partially reacted particles showing the formation of a thick layer of reaction products over the CuO particles. The same situation

Table 3 Rate constant values determined from the kinetic model of 1-D parabolic rate law, for the temperatures and alloys indicated

Temperature (K)	Alloy (wt.% Mg)	k (1/s)
1023	0	0.071
1073	0	0.12
1123	0	0.18
1023	1.0	0.34
1073	1.0	0.35
1123	1.0	0.39

Fig. 28 Linear dependence of $\ln(k)$ versus $1/T$ ($\times 10^6$) for determining the values of activation energy for the aluminothermic reduction of CuO for the indicated alloys

applies for alloys without Mg, but in this case the particles of CuO show the formation of a thick layer of Al_2O_3 . Furthermore, the activation energy for the aluminothermic reduction reaction of CuO particles when using alloys with 1 wt.% Mg is smaller than that obtained for alloys not containing magnesium.

This effect can be attributed solely to the fact that Mg lowers the surface energy of the melt, thus improving the wettability of the particles by the molten phase. Nevertheless, as it will be explained below, the formation of MgO , and as a consequence the formation of MgAl_2O_4 , gives rise to conditions that facilitate the diffusion of chemical species to the boundary layer and through the layers of reaction products.

CONCLUSIONS

Antimony was removed from molten aluminum by adding powders of a master calcium–aluminum alloy, with as much as 85.2 wt.% of the initial Sb removed. The compounds formed after calcium addition were identified using EBSD in a SEM, identifying phases such as the intermetallic compound Ca_2Sb .

The chemical reaction between magnesium dissolved in molten aluminum and SiO_2 particles reacts according to a mechanism where the diffusion of Al^{+3} , Mg^{+2} , and Si^{+4} ions through the porosity of the layers of reaction products determines the reaction kinetics. EBSD determined the true nature of the reaction products, demonstrating the formation of MgAl_2O_4 and Al_2O_3 over former SiO_2 nuclei. The aluminothermic reduction of CuO has been studied under different experimental conditions in which the temperature, the initial Mg concentration in molten aluminum, and the particle size were varied. Under the best set of experimental conditions, i.e., 1123 K, a <50 μm powder size fraction and a 1 wt.%

initial Mg concentration, copper concentrations in the order of 5 wt.% were attained. The experimental values fit the kinetic equation of the 1-D parabolic rate law model reasonably well, which allowed determining the values of some kinetic parameters of interest. For the different temperatures used, the values obtained for the rate constant varied from $k = 0.34$ – $0.39/\text{s}$. Moreover, the activation energy of the processes based on the Arrhenius equation was determined to be 10.93 kJ/mol. Future work must focus on studying the effect of powder size, temperatures above 800°C , and enhanced agitation conditions on the reaction rate in the systems studied. These findings are important for the commercial production of inclusion-free high-quality Al-Si-Cu alloys.

Recrystallization and Grain Growth

Weimin Mao

University of Science and Technology Beijing, Beijing, China

Abstract

Recrystallization occurs in all heating processes of aluminum alloys subjected to hot or cold deformation. The chemical, physical and mechanical property of aluminum alloys is dependent on recrystallization and grain growth. This article provides an overview of the mechanism and characteristics of deformation microstructure and defect structures in aluminum alloys.

Keywords: Crystallographic deformation; Grain; Growth; Recovery; Recrystallization; Texture.

INTRODUCTION

The human history of using metals can be traced back to tenth millennium BC, during which people in the Middle East could fabricate natural copper and use it.^[1] In the seventh millennium BC people in Anatolia could possibly produce lead and copper.^[2] Towards the end of the fourth millennium BC the people knew already that natural copper could be hardened by cold-working and softened by annealing,^[3] therefore the recrystallization treatment should be one of the oldest physical metallurgical processes used by human being. The concept of “recrystallization” appeared in 19th century^[4] and the corresponding theories have been intensively investigated since then.

The recrystallization will appear in all reheating processes of aluminum alloys which have been hot or cold deformed. All heating processes of aluminum poly-crystalline alloys would induce grain growth. The recrystallization and grain growth will change the chemical, physical and mechanical properties of the alloys. Therefore the corresponding heat treatments have been widely applied in the production of aluminum alloys, such as hot rolling, thermomechanical working, recrystallization annealing, grain growth heating, aging etc.

At the beginning of this chapter the basic formation mechanisms and characteristics of deformation microstructure, as well as the defect structure in aluminum alloys are briefly reviewed. Starting from the deformed state the recovery and primary recrystallization processes including formation of recrystallization texture during annealing are introduced. Then the process of dynamic recrystallization is discussed. At the end of the chapter the processes of normal grain growth as well as anomalous grain growth, i.e. the secondary recrystallization are reviewed.

STRUCTURE OF DEFORMED ALUMINUM

Crystallographic Deformation Process

Aluminum is a crystalline material with rather high stacking fault energy^[5] (SFE, 250 mJ/m²), so its plastic deformation is carried out mainly by dislocation slips in the lattice structure. Under the critical resolved shear stress (CRSS, $7.9 \times 10^5 \text{ N/m}^2$)^[6] on a definite crystallographic plane (slip plane) the dislocation slip will start in a way shown in Fig. 1, in which the unit translation vector b in slip direction of atoms is called Burgers vector. A slip system consists of a slip plane and a slip direction, however, in aluminum and its alloys the slip plane is the $\{111\}$ plane and the slip direction is the $\langle 110 \rangle$ direction.

Different slip systems on several slip planes are very often activated simultaneously during cold deformation, which results in a multi-slip of dislocations. The deformation induced density increase of vacancies, dislocations and grain boundaries act as obstacles to further movement of dislocations and lead to work hardening of deformed aluminum.

Deformation Microstructure

Cold deformation can result in the shape change of grains in polycrystalline aluminum, and the grains could be elongated along the external drawing stress. Figure 2 gives the shape change of grains in a commercially pure aluminum (99.9% Al) during cold rolling. It can be seen that the grains are elongated in the rolling direction. An important microstructure characteristic is the cell structure which can be observed using transmission electron microscopy.^[7] Figure 3 shows the cell structure of an 80% rolled Al-1.3 wt% Mn alloy sheet.^[8] The dislocation density is very low within the

Fig. 1 Fundamental process of dislocation slip in crystallographic lattice (a, b, c, d)

cells but very high in the cell walls. Generally the cell size is $1\text{--}3\text{ }\mu\text{m}$ or less, and the orientation differences between adjoining cells are less than 2° . The cells will become more elongated if the deformation degree increases.

Defects Induced by Deformation and the Stored Energy

Certain crystal defects exist always in aluminum lattice even in an undeformed stable state. The defects include point defects (vacancies, interstitial atoms, substitutional atoms), one-dimensional defects (dislocations), two-dimensional defects (boundaries, stacking fault, etc.) and three-dimensional defects (particles of second phase, impurities, etc.). These defects will act as obstacles to dislocation movement.

During deformation the moving dislocations intersect with other dislocations, and lead to the increase of vacancy density mostly from the non-conservative motion of jogs on dislocations.^[9] Considering the changes of deformation microstructure, e.g. shown in Fig. 2, the length of grain boundaries are also increased in deformed matrix. However, the most important defect increase after deformation should be the dislocation multiplication. When a piece of aluminum is plastically deformed, a large amount of external work is expended. Most of the work is transformed into the form of heat energy, but a small fraction of it will remain in the deformed matrix as stored energy, of which about 80–90% will be the energy due to the generation of dislocations.^[6] The portion of stored energy induced by vacancies is so small that it could be actually neglected, and the most sub-boundaries induced by deformation consist of special dislocation configurations which contribute to the increase of dislocation density.

The dislocation density ρ and the stored energy increases with increasing degree of deformation. It is estimated that the dislocation density in aluminum is $10^{10}/\text{m}^2$

Fig. 2 Cold rolling structure in a commercially pure aluminum (99.9%A1) $\uparrow$ ND $\rightarrow$ RD $\left| \begin{array}{c} 100\text{ }\mu\text{m} \end{array} \right|$ (a) 0% reduction; (b) 45% reduction; (c) 95% reduction

Fig. 3 Cell structure of 86% cold rolled Al-1.3 wt% Mn alloy sheet ($\frac{1}{\mu\text{m}}$). (Courtesy of Dr. P. Yang^[8])

in the annealed state^[10] and $10^{15}/\text{m}^2$ in a heavily deformed state^[5] (cf. Section “Recovery” of this chapter, dislocation energy per unit volume could be estimated at $0.5 \rho G b^2$, where G is about $2.5 \times 10^{10} \text{ N/m}^2$ and b is $3.5 \times 10^{-10} \text{ m}$ for aluminum), therefore the corresponding energy should be roughly 20 J/m^3 and $2 \times 10^6 \text{ J/m}^3$ respectively. So the stored energy in heavy deformed aluminum is about $2 \times 10^6 \text{ J/m}^3$.

The impurity atoms in aluminum lattice increase the stored energy at a given strain, since they hinder the normal dislocation motion and thereby result in an additional dislocation multiplication. The dislocation multiplication is also enhanced by decreasing initial grain size, i.e. more boundaries, or by particles of second phase. These defects act as obstacles to dislocation movement.

Deformation Texture

Grain orientation will be rotated relative to the external stress axes during plastic deformation. If a drawing force $\mathbf{F}$ acts on an aluminum single crystal and leads to activation of a slip system (Fig. 4a), there will be a moment $\mathbf{M} = \mathbf{F} \times$ acting on the deformed crystal (Fig. 4b). The orientation of the crystal will remain unchanged after the dislocation slips to certain extent. The applied moment will result in a rotation of the crystal into a stable state shown in Fig. 4c, after which the crystal orientation has been changed. The similar orientation change could also appear in the compression deformation of an aluminum single crystal (Fig. 5).

If the deformation and the corresponding orientation rotation proceed further, other slip systems can also be activated, which will influence the rotation path of the crystal orientation. But the orientation change will become

Fig. 4 Rotation of an aluminum single crystal during tensile test (a, b, c)

less and less obvious if the crystal has been deformed heavily, i.e. the crystal orientation has approached the final stable position. The orientation changes in a polycrystalline aluminum are more complicated. Figure 6 gives schematically a compressing or rolling process of a polycrystal. The grain orientations have different rotation behaviors, but they will rotate towards one or several final stable orientation positions after heavy deformation, and therefore a deformation texture will be formed, i.e. the grain orientations have a preferred distribution. The most important characteristic of texture is that the orientation distribution of a polycrystal has apparently deviated from the random distribution.

The wire drawing texture in aluminum is $\langle 111 \rangle$ fiber texture,^[11] and the rolling textures are $\{112\}\langle 111 \rangle$, $\{011\}\langle 211 \rangle$ and $\{123\}\langle 634 \rangle$.^[12] The shear deformation, e.g. torsion deformation^[13] or inhomogeneous rolling^[14] produces $\{001\}\langle 110 \rangle$ and $\{111\}$ fiber texture.

Fig. 5 Rotation of an aluminum single crystal during compression test (a,b)

Fig. 6 Deformation process of a polycrystal (a, b)

RECOVERY

Recovery Phenomena

Because of the high stored energy the deformed aluminum is in an unstable state. But at very low temperature the deformed state remains unchanged, since the defect structure is still mechanically stable. On annealing the stored energy induced by heavy deformation is progressively released due to the thermodynamic activation process.

For the first annealing stage at relatively low temperature or for short time the dislocation density is drastically reduced from $10^{15}/\text{m}^2$ down to $1.5 \times 10^{14}/\text{m}^2$,^[5] but the basic deformed microstructure is retained, and therefore this stage is called recovery. The stored energy released during the recovery annealing of deformed aluminum should be entirely caused by dislocation rearrangement and reduction, since vacancies produced by deformation have migrated out of the lattice structure at room temperature.^[15]

At the beginning of annealing the recovery process starts immediately, i.e. no incubation period. There is no migration of high angle boundaries during recovery. After recovery the deformation texture remains, the electrical resistivity is slightly decreased^[16] and 40% of the hardness induced by work hardening could be recovered for deformed pure aluminum.^[17]

Dislocation Mechanism of Recovery

The dislocation mechanism of recovery is based on the interactions of the long range stress fields between dislocations. The shear stress field of an edge dislocation, for instance, is^[18]

$$\tau_{xy} = \frac{Gb}{2\pi(1-\nu)} \frac{x(x^2 - y^2)}{(x^2 + y^2)^2} = \frac{Gb}{2\pi(1-\nu)r} \cos\theta \cos 2\theta \quad (1)$$

where G is the shear modulus, b is length of Burgers vector, ν is Poisson's ratio, r is the distance to the dislocation inducing the stress field. The angle θ is defined in Fig. 7.

If there is another parallel edge dislocation at position (x, y) , of which the length of Burgers vector is also b (Fig. 7), the interaction force F should be

$$F = \tau_{xy} \cdot b = \frac{Gb^2}{2\pi r(1-\nu)} \cos\theta \cos 2\theta \quad (2)$$

If the two edge dislocations of same sign are parallel mutually on the same slip plane ($\theta = 0$), then $F > 0$ is valid and the two dislocations are tend to repel each other. In the reversed case the dislocations of opposite sign will attract, combine and finally annihilate each other (Fig. 8a). When the two edge dislocations of opposite sign are parallel mutually on separated but rather close slip planes (Fig. 8b), then the two dislocations will also attract each other until the angle θ reaches $\pi/4$ or $3\pi/4$ according to Eq. 2. They cannot combine and annihilate each other directly. However there will be a row of vacancies or interstitial atoms formed between the two dislocations, which will approach each other step by step by means of diffusion of vacancies and interstitial atoms, i.e. the climb of edge dislocation, and finally annihilate each other completely. In the case that the two edge dislocations of same sign locate on separated slip planes (Fig. 8c) $F < 0$ will be valid according to Eq. 2 when the value of θ is between $\pi/4$ and $3\pi/4$. The two dislocations will attract each other and keep θ at $\pi/2$, where the $F = 0$ and the dislocation structure becomes stable. A low angle boundary (Fig. 8c, dot-and-dash line) will be formed if more edge dislocations are periodically arranged in this way. With increasing dislocation number and decreasing dislocation distance in the boundary the low angle boundary could become a high angle boundary.

Similar recovery process for screw dislocations will also occur.^[18] The interaction force F between screw dislocations has radial symmetry

$$F = \frac{Gb^2}{2\pi r} \quad (3)$$

Fig. 7 Interaction between edge dislocations

Fig. 8 Migration of edge dislocations with parallel Burgers vectors, (a) unlike dislocation on the same slip plane; (b) unlike dislocations on separated slip planes; (c) like dislocations on separated slip planes

The force between parallel screw dislocations of opposite sign is attractive, and that of same sign is repulsive.

After the dislocation reconfiguration mentioned above the dislocation density is drastically reduced, and the dislocation structure is in a low energy state. During the recovery the low angle boundary will absorb more and more dislocations. In some special cases a high angle boundary could also be formed by a very strong recovery process.

Polygonization

After cold deformation dislocations have piled up on slip planes (Fig. 9a). The stress fields from the dislocation pile-ups will result in torsion of the lattice. The evaluation of dislocation configuration during recovery, e.g. like that shown in Fig. 8c, leads to formation of several low angle boundaries (Fig. 9b). The low angle boundaries divide a deformed grain into several pieces or sub-grains, in which there will be no torsion. The formation process of the recovered sub-grains surrounded by low angle boundaries is called polygonization. Because of the combination effects between the dislocations in the low angle boundaries, the stress fields of the dislocations do not have a long range area.

Fig. 9 Polygonization process (a, b)

On the other hand the cell structure formed in cold deformation could also be transformed into the sub-grain structure, during which the cells are coarsened, the cell walls are thinned and sharpened due to the regulation of dislocations, and the dislocation density within the cells decreases further.

Recovery Kinetics

Concerning the dislocation mechanism the recovery annealing can be described by a second order kinetics^[19]

$$\frac{d\rho}{dt} = -k\rho^2 \quad (4)$$

where ρ is dislocation density during annealing, t is annealing time, k is a constant depending on annealing temperature. In the integrated form Eq. 4 can be expressed

$$\rho = \frac{1}{kt + \frac{1}{\rho_0}} \quad (5)$$

where ρ_0 is dislocation density before annealing. Compared with ρ the initial dislocation density ρ_0 is much higher^[5] and the $1/\rho_0$ could be therefore neglected. In this case the equation can be transformed into

$$\frac{d\rho}{dt} = -\frac{1}{kt^2} \quad (6)$$

The kinetics were confirmed in zone-refined aluminum containing 0.0068 at% Cu.^[20]

PRIMARY RECRYSTALLIZATION

Concept of Primary Recrystallization

The unstable state due to the high defect density of deformed aluminum could result in a recrystallization process at elevated temperature, during which the dislocation density will be reduced down to an equilibrium value (e.g. $10^{10}/\text{m}^2$ ^[10]). Therefore the driving force for the recrystallization is the stored energy. Even after a recovery annealing, in which the stored energy is drastically reduced, the remained dislocation density (e.g. $1.5 \times 10^{14}/\text{m}^2$ ^[5]) is still high enough to drive the recrystallization process.

Recrystallization is a process, in which a new micro-structure with relative equilibrium defect density is formed.

The recrystallization includes nucleation and growth of new grains, in which the new grains grow until they touch each other and the deformed matrix with high defect density is completely or essentially replaced by the new grains. In most cases the grain growth during recrystallization is associated with migration of high angle boundaries.

The recrystallization does not include the process that large grains swallow small grains, of which both have low defect density. So the recrystallization mentioned here is called primary recrystallization, of which the word “primary” is often omitted.

In principle there is no fixed recrystallization temperature and the recrystallization of deformed aluminum could appear at any temperature above OK. But it would take too much time, e.g. several years, to complete the recrystallization at lower temperature, and makes no sense for the industrial purpose. For example, the recrystallization in deformed aluminum with high purity could be completed at 150°C for 50sec, but that in deformed Al-0.01 at% Fe alloy would need more than 10 billion years at 150°C to complete the recrystallization.^[21] So the Al-0.01 at% Fe could practically not be recrystallized at 150°C. The impurity of aluminum is also an important effect factor on practical recrystallization temperature. The commercially pure aluminum, for instance, can be recrystallized at 200–300°C, but the zone refined pure aluminum could be recrystallized even at room temperature.

Nucleation

Nucleation is a thermal activation process, which is rather complicated and appears in the local area of a few hundreds or thousands of aluminum atoms. It is commonly very difficult to catch and observe the initial stage of nucleation, therefore many details of nucleation process are not clear so far.

According to the classic homogeneous nucleation theory^[22] the change of free energy ΔF due to the formation of a spherical recrystallization nucleus consists of the decreasing of stored energy F_s and the area increasing of boundary with the energy γ between nucleus and deformed matrix. If the radius of the spherical nucleus is R , then the ΔF could be written as

$$\Delta F = -\frac{4}{3}\pi R^3 F_s + 4\pi R^2 \gamma \quad (7)$$

ΔF will reach maximum when $d\Delta F/dR$ is equal to zero, and the critical radius of the nucleus R_c can be obtained

$$R_c = \frac{2\gamma}{F_s} \quad (8)$$

The nucleus could grow freely when the condition $R > R_c$ is satisfied. Dislocation energy could be estimated at $0.5Gb^2$, where G is about $2.5 \times 10^{10} \text{ N/m}^2$ ^[23] and b is $3.5 \times 10^{-10} \text{ m}$ for aluminum. Considering that the dominant part of stored energy F_s in deformed aluminum consists of dislocation density ($10^{15}/\text{m}^2$), F_s could be therefore calculated as $1.53 \times 10^6 \text{ J/m}^3$. The boundary energy of 99.99% Al is about $0.6\text{--}1.9 \text{ J/m}^2$,^[23] so according to Eq. 8 the R_c is roughly around $1\text{--}3 \mu\text{m}$, which approaches the size order of deformation cells. Figure 10 gives the calculated relation exhibited by Eq. 7 for aluminum using the data mentioned above. Actually the dislocation is always in homogeneously distributed in the deformed matrix, the R_c should be much smaller in the area with higher dislocation concentration.

In the classic nucleation theory the important point for aluminum and its alloys is that the nuclei must reach a critical size in order to grow freely. It should be indicated that the critical size for recrystallization nuclei is not identical

Fig. 10 The calculated relation between free energy ΔF and nucleus radius R

to that in general phase transformation, i.e. the critical size could be quite different in deformed matrix concerning the local dislocation density around the nuclei.

In many cases the sizes of cells existing in the deformed matrix are smaller than the critical size and the cells are surrounded by the low angle boundaries, which are not very mobile because of their stable dislocation configuration. Therefore the cells could not grow freely. In the initial stage of recrystallization annealing a subgrain coalescence process^[19] could produce a large subgrain greater than the critical size by polygonization and climbing of dislocation. Figure 11 gives a schematic representation of subgrain coalescence. At appropriate temperature the edge dislocations will climb out, and the cells become a large subgrain, during which the cells have to slightly change their orientations in order to be combined into one grain. After several steps of the coalescence the subgrain become larger than the critical size and the boundaries shown in Fig. 11c and d in thick line could be transformed progressively into mobile high angle boundaries.

In some cases the difference of dislocation densities between two sides of a high angle boundary is very distinct because, e.g. the strain is rather in homogeneously distributed among the differently oriented initial grains at low deformation degree. Sometimes inhomogeneous recovery in the heavy deformed matrix could also lead to fairly different reduction of dislocation densities among the grains due to their different initial orientations followed by different deformation experiences and therefore different dislocation configurations. Generally the high angle boundary is very mobile and the different dislocation densities could induce a boundary migration in the direction of high dislocation density, which is called “strain induced boundary migration” (SIBM) and was observed in 20% compressed high purity aluminum (99.99%).^[24] The subgrain behind the high angle boundary on the side of lower dislocation density could be therefore enlarged to a size over R_c and grow up as a recrystallization nucleus.

According to Eq. 8 it is known that R_c will be decreased when the dislocation density, i.e. the stored energy becomes higher. During cold deformation dislocations will pile up

around obstacles like grain boundaries, particles of second phase etc, where the dislocation density is obviously higher than the average value, and therefore the positions around grain boundaries and second phase particles will become preferred places for nucleation.^[25,26] That is the heterogeneous nucleation and relative smaller subgrains could already grow freely. The nucleation preferably along the grain boundaries was observed in high purity Al-0.008 wt% Cu alloy.^[25] Figure 12 exhibits the observed nuclei formed on grain boundary in forged Al-0.01 wt% Ti alloy (Fig. 12a) or around the second phase particles in rolled Al-1.3 wt% Mn alloy (Fig. 12b).^[8]

Grain Boundary Migration

After nucleation the nuclei will grow into deformed matrix by migration of high angle boundaries, which is a thermal activation process and is strongly dependent on recrystallization temperature.

The atoms near grain boundaries will jump from one grain to another by means of overcoming the barrier energy Q_a during the thermal activation. But straight boundaries will not move if the grains are not deformed and in a stable state, since the atom jumps are equalized in mutual directions and lead to a dynamic equilibrium. In the case of growth of a recrystallization nucleus the atom jumps will become quite different. Because of the stored energy F_s the atoms in deformed matrix are in higher energy state, and the energy increase per atom F_{sa} is

Fig. 12 Heterogeneous nucleation. (a) on grain boundary in forged Al-0.01 wt% Ti alloy $\overline{2\mu\text{m}}$; (b) around second phase particles in rolled Al-1.3 wt% Mn alloy.^[8] (Fig. 12b courtesy of Dr. P. Yang^[8])

Fig. 11 Schematic representation of subgrain coalescence (a, b, c, d)

$$F_{sa} = F_s \frac{a^3}{4} = F_s \frac{b^3}{3\sqrt{3}} \quad (9)$$

So the barrier energy for an atom to jump in the direction from nucleus to deformed matrix is $Q_a + F_{sa}$ and in the reversed direction is $Q_a - F_{sa}$ respectively, which results in a boundary migration.

The migration velocity V of the boundaries can be calculated as

$$V = bvc_v \left[\exp\left(-\frac{Q_a - F_{sa}}{kT}\right) - \exp\left(-\frac{Q_a + F_{sa}}{kT}\right) \right] \quad (10)$$

where b is the length of Burger's vector representing the distance of atom jumps, v is vibration frequency of atoms (about $10^{13}/\text{sec}$ [10,27]), k is the Boltzmann constant, c_v is the vacancy density (about 10^{-5} at 700 K and 10^{-4} at 800 K [23]). The Q_a is about $4.5 \times 10^4 \text{ J/m}$, [28] i.e. $7.47 \times 10^{-20} \text{ J/atom}$.

According to Eq. 10 the calculation of the average migration velocity at 700 K is about $0.08 \mu\text{m/sec}$ for heavy deformed aluminum and is about $0.01 \mu\text{m/sec}$ for deformed and recovered aluminum. At 800 K the velocity, according to the calculation, is about $1.85 \mu\text{m/sec}$ and $0.28 \mu\text{m/sec}$ respectively. If the dislocation density in deformed matrix is $10^{16}/\text{m}^2$ instead of $10^{15}/\text{m}^2$, then the velocity is about $0.8 \mu\text{m/sec}$. The calculation results approach the order of practically observed velocity in aluminum. One of the important points of the calculations mentioned here is to observe the influences of temperature and dislocation density on the boundary migration.

An other form of Eq. 10 is

$$V = bvc_v \left[\exp\left(-\frac{Q_a - F_{sa}}{kT}\right) - \exp\left(-\frac{Q_a + F_{sa}}{kT}\right) \right] \quad (11)$$

Because the value of F_{sa}/kT . There is very small the equation could be simplified in first approximation of power expansion as

$$\begin{aligned} V &= bvc_v \exp\left(-\frac{Q_a}{kT}\right) \left[1 + \frac{F_{sa}}{kT} - 1 + \frac{F_{sa}}{kT} \right] \\ &= 2bvc_v \frac{F_{sa}}{kT} \exp\left(-\frac{Q_a}{kT}\right) \end{aligned} \quad (12)$$

It is obvious that Eq. 12 does not consider the influence of solute atoms, particles of second phase and orientation difference between nuclei and deformed matrix.

The grain boundaries provide sites with lower potential energy for impurity or alloy atoms, which will tend to adhere to the moving boundaries. Therefore the boundaries have to overcome additionally the migration resistance induced by the adherence effect of solute atoms, and the migration will slow down if the content c of solute atoms increases. The migration velocity v was found to be inversely proportional to Cu content in aluminum. [29]

Because of the low potential energy an atmosphere of solute atoms could be formed around boundaries, i.e. the concentration of solute atoms in grain boundaries is higher than the average value, in which the solute atoms would be dragged along by the moving boundaries that keep the atmosphere around them. Only when the migration velocity of boundaries driven by, e.g. higher stored energy become greater, and the solute atoms could not accompany the boundary migration, then the boundaries would migrate freely, similar to the case in pure aluminum. [30]

The average distance of atom jumps from one grain to another depends on the orientation difference of the two grains, and therefore the barrier energy Q_a could be also quite different, which will influence the velocity of boundary migration. Figure 13 gives an example of calculated jumping distance for aluminum, in which the orientation difference of two grains is characterized by a rotation of certain angle is θ around a common $\langle 111 \rangle$ axis. [31] So it was found that a boundary would have very high migration velocity if two neighboring grains on two sides of a boundary have a special orientation relationship. [32] For aluminum the velocity reaches a maximum value when the orientation relationship between the deformed matrix and growing grains is characterized by a rotation of about 40° around one of their common $\langle 111 \rangle$ axis. [31,32]

The orientation difference and solute atoms could mutually influence the migration velocity. In the case of two neighboring grains having certain orientation relationship, where a coincidence lattice with low reciprocal density (Σ value) forms, the solute atoms to the boundary would be obviously reduced because of the special atom arrangement of the boundary, and result in a low barrier energy Q_a as well as high boundary mobility. Fridman et al. [33] observed, for example, that the migration velocity of high angle boundaries in pure aluminum with 99.99995 at% Al is very high and independent on the orientation difference. The migration velocity is reduced obviously when the purity is down to 99.9992 at% Al, but is hardly decreased at several points where the orientations of concerned two grains form a special coincidence lattice with low Σ value. [33]

Commonly the particles of second phase will hinder the boundary migration during recrystallization. But if the existence of particles induce a drastic heterogeneous nucleation the recrystallization process will be accelerated, which was observed in aluminum alloys containing particles of Al_2Cu or Al_3Fe . [34]

Recrystallization Kinetics

The primary recrystallization consists of nucleation and grain growth, therefore the nucleation rate N and the migration velocity V will determine the recrystallization process and the final recrystallization grain size.

Fig. 13 Calculated jumping distance for aluminum^[31]

The N and v are defined as

$$N = \frac{\frac{dn}{dt}}{1-x} \quad (13)$$

$$V = \frac{dR}{dt} \quad (14)$$

where x is the volume fraction of recrystallized matrix, t is annealing time, R is the radius of recrystallization grain and n is the number of newly formed nuclei per unit volume. According to Eq. 13 N is the number of newly formed nuclei per unit time and per unit volume of retained deformation matrix.

Observing the recrystallization process started from time point $\tau > 0$, a newly formed spherical nucleus at τ will grow up to a time point $t > \tau$, by which the increase in recrystallized volume V_τ is

$$V_\tau = \frac{4}{3}\pi v^3(t-\tau)^3 \quad (15)$$

where the velocity V is considered to be a constant. According to Eq. 13 the dn at τ could be expressed as

$$dn_\tau = N(1-x)d\tau \quad (16)$$

The nuclei formed at any τ in the interval between 0 and t will contribute to the volume increasement dx as

$$\begin{aligned} dx &= V_\tau dn_\tau \\ &= \frac{4}{3}\pi N v^3(t-\tau)^3(1-x)d\tau \end{aligned} \quad (17)$$

which could be transformed into a format of definite integral

$$\int_0^x \frac{dx}{1-x} = \int_0^t -\frac{4}{3}\pi N v^3(t-\tau)^3 d\tau \quad (18)$$

and therefore the fraction of recrystallized volume x could be obtained as

$$x = 1 - \exp\left(-\frac{1}{3}\pi N v^3 t^4\right) \quad (19)$$

which is called Johnson-Mehl equation.^[35] It can be seen in Eq. 19 that the recrystallized volume x changes from 0 to 1 while the annealing time runs from 0 to infinity, which could be qualitatively confirmed by the recrystallization annealing at 300°C of a 95% rolled high purity (99.998 wt% Al) aluminum sheet (Fig. 14).^[36] In most cases the v and N are not constants during the recrystallization of aluminum,^[37] but the deduction process described above could still give us an important impression about the kinetics of the primary recrystallization.

Define t_c as

$$t_c = \left(\frac{3}{\pi N v^3}\right)^{\frac{1}{4}} \quad (20)$$

then Eq. 19 can be written as

$$x = 1 - \exp\left[-\left(\frac{t}{t_c}\right)^4\right] \quad (21)$$

If t is equal to t_c then about 63% of the deformed matrix has been recrystallized. It could be estimated that the recrystallization grains have been in contact with each other at t_c and the recrystallization grain size is roughly fixed. So considering Eq. 20 the recrystallization grain size d , i.e. the diameter of a primary recrystallization grain can be calculated as

$$d = 2R = 2 \int_0^{t_c} v dt = 2vt_c = 2\left(\frac{2v}{\pi N}\right)^{\frac{1}{4}} \quad (22)$$

and t_c is the characteristic recrystallization time. It is should be noticed that the grain size of primary recrystallization is

Fig. 14 Recrystallized volume of a 95% rolled high purity (99.998 wt% Al) aluminum

mainly determined by the ratio of v/N according to Eq. 22 from which the grain size d will be increased by increasing v or decreased by increasing N respectively.

Anderson and Mehrl^[37] have investigated the nucleation rate N and migration velocity v during the recrystallization annealing of elongated pure aluminum. They found that the ratio v/N is increased with increasing tensile deformation or with arising annealing temperature, which would result in refined grain size after the primary recrystallization.

Recrystallization in situ (Continuous Recrystallization)

After primary recrystallization not only the deformed structure has been eliminated but the orientation distribution of deformed matrix has also disappeared completely. Therefore the process is called discontinuous recrystallization.

During annealing of deformed aluminum there could be another recrystallization process, in which the deformation structure is eliminated in a quite different way. When aluminum has experienced a special range of deformation degree and the migration of boundaries is obstructed drastically, e.g. by precipitates, only an extremely strong recovery process could appear, in which high angle boundaries would be slowly formed by gradual subgrain coalescence. In this case an entirely new structure with very low defect density is formed though there will be no migration of the high boundaries. In order to differ from the normal recrystallization this recrystallization process is called recrystallization in situ or continuous recrystallization. The important characteristic of continuous recrystallization is that the grain orientations in deformed matrix are not changed essentially during annealing.^[38]

Figure 15a shows the deformation structure of commercially pure aluminum (99.9 wt% Al) which has been forged 25% in two mutually vertical directions. The original grain boundaries before deformation can be observed. After annealing at 350°C for about 40 min the continuous recrystallization is completed, in which the newly formed grains are still in the area of original grains (Fig. 15b, left part). The deformed structure has been transformed into new grains by a very strong recovery while the orientations of deformation grains remain. Obvious boundary migration over original grain boundaries was not observed since the precipitates containing the common impurity atoms like iron, silicon etc. were accumulated on the original boundaries and obstruct the boundary migration during annealing.

Ito et al.^[39] have investigated the recrystallization behaviors of high-purity aluminum-iron alloys. They found that the continuous recrystallization would appear obviously around 400°C when the content of iron exceeds 0.01 wt% because there will be many precipitates of FeAl_3 on the boundaries.

RECRYSTALLIZATION TEXTURE

Texture is a significant characteristic of polycrystalline aluminum and accompanies almost all kinds of physical metallurgical processes. A {100} fiber texture in aluminum ingots, for instance, is established very often^[40] because of the oriented heat conduction and corresponding growth selection of grains during solidification. Different textures are surely formed after hot or cold deformation as well as annealing. Therefore a piece of polycrystalline aluminum without texture could be hardly found. Many aluminum alloys are used in annealed state and it is important to reveal the formation mechanisms of recrystallization texture, by which the induced anisotropy has significant influence on many useful properties.

Pole Figure Determination

Pole figure is a conventional method to describe texture in aluminum and is obtained by means of measuring diffraction data of polycrystals, for which commonly the X-ray diffraction technique^[41] or neutron diffraction technique^[42] are used. Figure 16 demonstrates schematically the structure of an X-ray texture goniometer, on which the pole figures of aluminum samples are measured using reflection technique.

According to Bragg-law used for the pole figure measurement^[11] there is:

$$2d_{hkl} \sin \theta = n\lambda \quad (23)$$

where λ is the wavelength, d_{hkl} is the distance constant of certain {hkl} lattice plane, θ is the Bragg angle and n

Fig. 15 Microstructure showing continuous recrystallization in aluminum $\left(200 \mu\text{m}\right)$, (a) forged; (b) annealed

should be one for the first order reflection. If an incident beam initiated by X-ray tube and certain $\{hkl\}$ lattice plane of a sample are so located that the corresponding angle θ between them is obtained according Eq. 23, then the diffraction intensity can be recorded in direction 2θ by a detector (Fig. 16). During the measurement the rotation angle $\alpha(0 - \pi/2)$ and $\beta(0 - \pi)$ should be so changed that the intensity $I(\alpha, \beta)$ in all sample directions can be obtained (Fig. 16). For an aluminum powder sample with random texture the intensity I_p should be a function of angle α , i.e. $I_p(\alpha)$. Because of the geometrical structure of the goniometer the $I_p(\alpha)$ is decreased with increasing α and is independent on β . On the other hand a part of the measured intensity belongs to the background $I_b(\alpha)$,^[41] and should be reduced from the $I_p(\alpha, \beta)$. Figure 17 gives the changes of the $I_r(\alpha)$ and $I_b(\alpha)$ data taken from an aluminum powder sample, where the relative random intensity $I_r(\alpha)$ is:

$$I_r(\alpha) = \frac{I_p(\alpha) - I_b(\alpha)}{I_p(0^\circ)} \quad (24)$$

Fig. 16 Structure of an X-ray texture goniometer, (1) X-ray tube; (2) incident beam; (3) sample; (4) reflection beam; (5) detector

Fig. 17 $I_r(\alpha)$ and $I_b(\alpha)$ of an aluminum powder sample

representing the relative changes of $I_p(\alpha)$,

Therefore the measured pole figure data $P_{hkl}(\alpha, \beta)$ should be expressed as:

$$P_{hkl}(\alpha, \beta) = \frac{I(\alpha, \beta) - I_b(\alpha)}{I_r(\alpha)} \frac{1}{N} \quad (25)$$

where N is the normalized factor and can be deduced by

$$\frac{1}{2\pi} \int_0^{\pi/2} \int_0^{2\pi} P_{hkl}(\alpha, \beta) \sin \alpha d\alpha d\beta = \frac{1}{2\pi} \quad (26)$$

$$\sum_{\alpha=0(\Delta\alpha)}^{\pi/2} \sum_{\beta=0(\Delta\beta)}^{2\pi} P_{hkl}(\alpha, \beta) \sin \alpha \Delta\alpha \Delta\beta \equiv 1$$

where $\Delta\alpha$ and $\Delta\beta$ are the measuring steps.

Description of Recrystallization Texture

Figure 18 shows the stereographic $\{111\}$ projection of a grain at the center of a unit sphere,^[43] in which a coordinate system relative to rolling specimen is taken as an example.

The coordinate position in the pole figure (Fig. 18c) can be expressed as (α, β) according to the geometry of spheres. Figure 19 gives the measured $\{200\}$ and $\{111\}$ pole figures of a recrystallized pure aluminum sheet, of which the measured data have been corrected according to Eqs. 25 and 26.

Generally a pole figure gives the information about stereographic density distribution $P_{hkl}(\alpha, \beta)$ of corresponding $\{hkl\}$ planes, which could be expressed as series expansion of spherical harmonics^[44]

$$p_{hkl}(\alpha, \beta) = \sum_{l=0}^{\infty} \sum_{n=-l}^l F_{l(hkl)}^n K_l^n(\alpha, \beta) \quad (0 \leq \alpha \leq \pi, 0 \leq \beta \leq 2\pi) \quad (27)$$

where $K_l^n(\alpha, \beta)$ is the known spherical harmonics and F_l^n is a group of constants.

An orientation has three independent parameters, therefore Bunge^[44] defines three rotation angles, i.e. φ_1 , Φ and φ_2 showing in Fig. 20 to describe grain orientation, for example, in the coordinate system relative to rolling specimen, where the grain orientation could be obtained by individual φ_1 , Φ and φ_2 rotations of crystalline coordinate in the specimen coordinate. Hence a Euler space^[44] can be established with three mutually perpendicular axes of φ_1 , Φ and φ_2 which are called Euler angles. The miller index $\{hkl\}$ $\langle uvw \rangle$ are often used to express an orientation in rolling samples, and the relationship of miller index and Euler angles can be described as

$$\begin{bmatrix} \cos\phi_1\cos\phi_2 - \sin\phi_1\sin\phi_2\cos\Phi & \sin\phi_1\cos\phi_2 + \cos\phi_1\sin\phi_2\cos\Phi & \sin\phi_2\sin\Phi \\ -\cos\phi_1\sin\phi_2 - \sin\phi_1\cos\phi_2\cos\Phi & -\sin\phi_1\sin\phi_2 + \cos\phi_1\cos\phi_2\cos\Phi & \cos\phi_2\sin\Phi \\ \sin\phi_1\sin\Phi & -\cos\phi_1\sin\Phi & \cos\Phi \end{bmatrix} = \begin{bmatrix} u & kw - lv & h \\ v & lu - hw & k \\ w & hv - ku & l \end{bmatrix} \quad (28)$$

Fig. 18 Stereographic {111} projection of a grain (a, b, c)

Fig. 19 Pole figures of a recrystallized pure aluminum sheet, ■ Cube {001}, <100> ● R {124}<211>, □ Goss {011} <100>, (a) {200}; (b) {111}

Table 1 gives some important texture components frequently observed in aluminum alloys. Using the Euler space the texture of polycrystalline materials can be obviously better represented by the orientation distribution function (ODF) $f(\phi_1, \Phi, \phi_2)$ like

$$f(\phi_1, \Phi, \phi_2) = \sum_{l=0}^{\infty} \sum_{m=-l}^l \sum_{n=-l}^l C_l^{mn} T_l^{mn}(\phi_1, \Phi, \phi_2) \quad (29)$$

$$(0 \leq \phi_1 \leq 2\pi, 0 \leq \Phi \leq \pi, 0 \leq \phi_2 \leq 2\pi)$$

where $T_l^{mn}(\phi_1, \Phi, \phi_2)$ is the known generalized spherical harmonics and C_l^{mn} is a group of constants. According to the mathematical relation between Eqs. 29 and 27 the following equation can be obtained^[44]

$$F_{l(hkl)}^n = \frac{4\pi}{2l+1} \sum_{m=-l}^l C_l^{mn} K_l^{*m}(\alpha_{hkl}^*, \beta_{hkl}^*) \quad (30)$$

where $K_l^{*m}(\alpha_{hkl}^*, \beta_{hkl}^*)$ is the known conjugate complex function of $K_l^m(\alpha, \beta)$, and $(\alpha_{hkl}^*, \beta_{hkl}^*)$ are the spherical polar coordinates of direction $\langle hkl \rangle$ with respect to the crystalline coordinate system according to the geometry of spheres.

Fig. 20 Definition of Euler angles

Table 1 Important texture components in aluminum alloys

Component name	$\{hkl\} \langle uvw \rangle$	$\varphi_1, \Phi, \varphi_2$
Cube	$\{001\} \langle 100 \rangle$	$0^\circ, 0^\circ, 0^\circ$
Rotated cube	$\{001\} \langle 110 \rangle$	$45^\circ, 0^\circ, 0^\circ$
Copper	$\{112\} \langle 112 \rangle$	$90^\circ, 35^\circ, 45^\circ$
Brass	$\{011\} \langle 211 \rangle$	$35^\circ, 45^\circ, 0^\circ$
Goss	$\{011\} \langle 100 \rangle$	$0^\circ, 45^\circ, 0^\circ$
S	$\{123\} \langle 634 \rangle$	$59^\circ, 37^\circ, 63^\circ$
R	$\{124\} \langle 211 \rangle$	$57^\circ, 29^\circ, 63^\circ$
—	$\{111\} \langle 112 \rangle$	$90^\circ, 55^\circ, 45^\circ$

An ODF can be obtained by several sets of measured pole figure data $P_{hkl}(\alpha, \beta)$ and the calculation using Eqs. 27, 30 and 29,^[44] which can be represented as density distributions on different φ_2 sections. Figure 21 gives an example of ODF section analysis for the recrystallization texture in 95% rolled and annealed high purity aluminum. Commonly a recrystallization texture consists of several texture components, of which the volume fraction and the scattering width^[45] can be also calculated according to the ODF. Because of the symmetry existed in the aluminum polycrystalline the Euler space is commonly reduced down to $0 \leq \varphi_1, \Phi, \varphi_2 \leq \pi/2$ (Fig. 21).

Formation of Recrystallization Texture

The two basic processes of recrystallization, i.e. the nucleation and the following grain growth which will contribute to the recrystallization texture, have to be considered for the interpretation of texture formation.

One of the most prevailing interpretations for the formation of recrystallization texture is the theory of oriented nucleation proposed by Dillamore and Katoh.^[46] During deformation the grain orientations will rotate along certain orientation lines from unstable divergent zone in the Euler space towards several symmetrical stable convergent zones. Between the symmetrical orientation variants transition bands consisting of continually neighboring subgrains will be formed over the original unstable orientation. Around the original orientation and several points in the orientation lines, where the orientation gradient is often rather high, the subgrains will be surrounded frequently by the very mobile high angle boundaries after the polygonization and several steps of subgrain coalescence during annealing.

The enlarged subgrains can grow up as nuclei rapidly, and their orientations will determine the final recrystallization texture. The theory could explain, for example the formation of cube texture $\{001\} \langle 100 \rangle$ and R texture $\{124\} \langle 211 \rangle$ in annealed aluminum sheets.

Another important interpretation for the formation of recrystallization texture is the theory of growth selection proposed mainly by Lücke.^[47] The theory is based on the direct statistic measurements of the boundary migration rate in growth selection experiments in several hundreds of deformed single aluminum crystals.^[32] It was found, that a boundary between the deformed matrix and growing grains in aluminum would have very high migration velocity if the orientation relationship of the two neighboring grains is characterized by a rotation of about 40° around one of their common $\langle 111 \rangle$ axis^[32] because of the special atomic structure in the boundaries.^[31] The orientation relationship is often called briefly $40^\circ \langle 111 \rangle$.

Fig. 21 ODF analysis of recrystallized pure aluminum sheet (a, b), ■ $\{001\} \langle 100 \rangle$, ● $\{124\} \langle 211 \rangle$, □ $\{011\} \langle 100 \rangle$

Fig. 22 $\{111\}$ pole figures of 95% rolled aluminum after primary recrystallization, (density levels: 2, 4, 7, 11, 16). (a) 240°C, 600 sec and 300°C, 3162 sec (Max = 14.5); (b) 300°C, 316 sec (Max = 20.2)

The theory could also explain the formation of cube texture $\{001\} \langle 100 \rangle$ and R texture $\{124\} \langle 211 \rangle$ in annealed aluminum sheets.

The common texture components of rolled and annealed pure aluminum sheets are the cube texture $\{001\} \langle 100 \rangle$, R texture $\{124\} \langle 211 \rangle$ and sometimes also the Goss texture $\{011\} \langle 100 \rangle$ (Figs. 19 and 21). Conventional impurity atoms have obvious influence on the recrystallization texture components.^[39] The impurity atoms will generally reduce the cube texture but increase the R texture, especially when they precipitate during the recrystallization annealing. If the precipitation temperature is avoided the volume of cube texture will be increased, and therefore the annealing temperature is very important for the texture formation.^[39]

Due to the strong reduction of stored energy the recovery annealing prior to primary recrystallization will change the annealing time and the texture composition. Figure 22 gives an example showing the influence of recovery annealing prior to primary recrystallization

on the final primary recrystallization texture. Ninety-five percent rolled pure aluminum sheet (99.998 wt% Al) is annealed at 240°C for 600 sec and then at 300°C for 3162 sec, after which strong cube texture and R texture have been obtained (Fig. 22a). The 240°C annealing here is only a recovery treatment and the recrystallization does not occur. But the texture components become multivariate if the sheet is directly annealed at 300°C without recovery treatment (Fig. 22b). The analysis of texture components for the two annealing processes is listed in Table 2, in which the clear effect of recovery treatment can be observed. The recovery treatment has obviously reduced the recrystallization driving force so that the primary recrystallization could be carried out slowly, during which some specially oriented subgrains or nuclei could grow up more rapidly^[32,46] and dominant the formation of recrystallization texture, i.e. the cube and R texture. But if the high stored energy is not obviously reduced by the recovery treatment before primary recrystallization the recrystallization becomes a rash process, in which many differently oriented subgrains or nuclei have the possibility to grow up rapidly due to the high driving force, and therefore leads to the multivariate recrystallization texture.

Table 2 Texture components of 95% rolled and 300°C annealed pure aluminum

Annealing	Texture component	Volume fraction
240°C, 600 sec	$\{001\} \langle 100 \rangle$	54%
300°C, 3162 sec	$\{124\} \langle 211 \rangle$	26%
No recovery annealing	$\{001\} \langle 100 \rangle$	12%
300°C, 316 sec	$\{011\} \langle 611 \rangle$	8%
	$\{013\} \langle 100 \rangle$	6%
	$\{149\} \langle 511 \rangle$	15%
	$\{225\} \langle 554 \rangle$	8%
	$\{239\} \langle 311 \rangle$	10%
	$\{269\} \langle 354 \rangle$	23%

Recrystallization Controlled by Oriented Nucleation

According to the prediction of Dillamore and Katoh^[46] the orientation $\{001\} \langle 100 \rangle$ in aluminum rolling sheet is located in the divergent zone, and the $\{011\} \langle 211 \rangle$ is located in the convergent zone. During rolling deformation the grains oriented around $\{001\} \langle 001 \rangle$ will rotate at first towards the $\{011\} \langle 100 \rangle$ in two directions. Then the orientations move towards the two variants of $\{001\} \langle 211 \rangle$, i.e. the $(011)[\bar{2}11]$ and $(011)[2\bar{1}\bar{1}]$. The paths of orientation changes are demonstrated by the vector lines in the $\varphi_2 = 0^\circ$

section of the ODF (Fig. 23a), which shows the orientation chains of the subgrains including the $\{001\}\langle 100\rangle$ and $\{011\}\langle 100\rangle$ in the transition bands mentioned by Dillamore and Katoh.^[46]

It is obvious that the formation of the transition bands depends on the initial distribution of grain orientations, i.e. the initial texture. Figure 23b gives the initial texture of an Al-0.01 wt% Ti alloy sheet,^[48] in which a strong $\{011\}\langle 100\rangle$ texture and certain density distribution around $\{001\}\langle 100\rangle$ are observed. After 95% rolling reduction the grain orientations have moved to the $\{001\}\langle 211\rangle$ (Fig. 23c) and the trace of the transition bands can still be observed. During annealing at 300° C the transition bands are generally strengthened (Fig. 23d—f) which indicates the recrystallization process is controlled by the oriented nucleation in the transition bands. However the main texture components after the recrystallization are the $\{011\}\langle 100\rangle$ and $\{001\}\langle 100\rangle$ (Fig. 23f).

The cube orientation $\{001\}\langle 100\rangle$ has certain metastability during rolling deformation and some of its subgrains could survive even after heavy rolling,^[49] which results in the formation of cube texture in the following annealing (Fig. 23f). The strong Goss texture $\{011\}\langle 100\rangle$ after annealing (Fig. 23f) is obviously induced by the strong initial Goss texture (Fig. 23b) and the corresponding higher nucleation possibility in the transition bands.

Titanium atoms in the aluminum alloy should be in the form of TiAl_3 and precipitated at initial boundaries before rolling deformation. In this case the grains could hardly grow over the initial boundaries during annealing. The

oriented nucleation process in the areas of original boundaries could be carried out without interruption,^[48] and show the strong effect on the final recrystallization texture.

Recrystallization Controlled by Growth Selection

It is assumed according to the observation of Ibe et al.,^[32] that there should be differently oriented nuclei formed during annealing. But the cube and R texture would be dominant in the annealed rolling sheet, since both the orientations have an orientation relation of $40^\circ \langle 111\rangle$ to the S texture $\{123\}\langle 634\rangle$ which is the main rolling texture in aluminum and its alloys.

Figure 24a gives the $\{111\}$ pole figure of a 95% rolled pure aluminum sheet (99.998 wt% Al),^[50] which shows more than 60% S texture. At the initial stage of annealing the nuclei form in the deformation transition bands while the matrix is not changed apparently. Figure 24b shows that the orientations of the nuclei are located in the transition bands between cube and S orientation^[50] and the density is increased in the corresponding positions in the $\{111\}$ pole figure, while the main rolling texture remains unchanged. With increasing annealing time the growth rate of the nuclei is quite different. Figure 24e gives the optical structure of 316sec annealed sheet. In the deformation matrix the size of newly formed grains is very different. Using a $\{100\}$ plane etching technique the individual grain orientations could be determined.^[50] The results indicate that all the huge grains have the cube or R orientation.

Fig. 23 The texture evaluation during rolling and annealing in an Al-0.01%Ti alloy sheet (ODF ($\varphi_2 = 0^\circ$ section, density levels: 1, 3, 7, 13, 21.), ■ $\{001\}\langle 100\rangle$, □ $\{011\}\langle 100\rangle$, ◇ $\{011\}\langle 211\rangle$). Fig. 24 {111} pole figures and microstructure of 95% rolled and 300°C annealed pure aluminum sheet (99.998 wt% Al, density levels: 1, 2, 4, 7, 10), (a) 95% rolled (max = 11.0); (b) 100 sec annealed (max = 11.6); (c) 316 sec annealed (max = 9.4); (d) 31620 sec annealed (max = 12.8); (e) microstructure of c

The corresponding pole figure (Fig. 24c) shows also the strong density increase around cube and R orientation in the transition bands (by reference to Fig. 19b). Because of the high purity of the sheet the growth competition among the nuclei is rather freely without strong obstructs induced

by the impurity atoms. Figure 24e demonstrates the obvious advantage of the grains oriented around cube and R orientation in the growth competition due to the special boundary structure,^[31] and finally the cube and R texture become dominant in the annealed sheet (Fig. 24d).

DYNAMIC RECOVERY AND DYNAMIC RECRYSTALLIZATION

Dynamic Recovery

Because of the work hardening effect the flow stress for plastic deformation will be increased with increasing strain. It is known that the work hardening is associated with the dislocation density in deformed aluminum alloys. The rate of dislocation multiplication and therefore the work hardening rate at high strain are commonly reduced by certain softening mechanism, of which the softening effect is defined as dynamic recovery. Sometimes the work hardening effect in aluminum could be fully compensated by the softening effect of the dynamic recovery which can be strengthened at elevated deformation temperature, and the flow stress will reach its maximal value.

The mechanism of dynamic recovery is generally similar to that of the normal recovery, i.e. static recovery. The dislocation density will be reduced because of the cross-slip of screw dislocations as well as the climb of edge dislocations. For many fee metals the perfect dislocations will dissociate on their {111} slip planes into two partial dislocations, between which a stacking fault is created.^[51] The dissociation width depends on the stacking fault energy of the alloys, and for aluminum and its alloys the dissociation width is generally very small due to their very high stacking fault energy. For the cross-slip and the climb the dissociated two partial dislocations must first recombine into a perfect dislocation over a certain length by thermal activation, which depends strongly on the deformation temperature. The necessary activation energy of the dynamic recovery is inversely proportional to the stacking fault energy. The polygonization process of static recovery could also appear in the dynamic recovery.

Dynamic Recrystallization

With increasing deformation temperature the tendency for a recrystallization process arises continuously out of the increasing thermal activation. If the temperature and the strain are high enough the corresponding recrystallization could really appear during deformation, which is defined as dynamic recrystallization. The strong softening effect of the dynamic recrystallization induced by the elimination of large numbers of dislocations by the migration of high angle boundaries will lead to a drop in flow stress after it has reached a maximum. Comparing with the dynamic recrystallization the primary recrystallization is a static recrystallization. But the word “static” is commonly omitted.

The behavior of dynamic recrystallization is expressed very often in a flow stress curve against strain. Two typical flow stress curves in hot deformed metals could be observed. One shows a single peak in flow stress and the other shows multiple peaks frequently with decreasing

Fig. 25 Typical flow stress curves of dynamic recrystallization

amplitude against the strain. Figure 25 demonstrates schematically the two curves, between which a transition could appear, e.g. the cyclic peak curve could be transformed into single peak curve as the strain rate is increased or the deformation temperature is decreased.^[52]

The recrystallization during hot deformation is based on a similar way shown in Fig. 14. The first recrystallization period will start if the strain ϵ reaches a critical value ϵ_c ,^[53] where the stored energy is high enough. The stored energy in the corresponding recrystallized grains will increase immediately because of the continuous deformation process, and the next recrystallization period will start if the ϵ_c in the recrystallized grains of last recrystallization period is reached again. Therefore the dynamic recrystallization is consisted of a series of recrystallization periods.^[53]

In the case of high deformation temperature or low strain rate, a great part of deformed matrix in the last recrystallization period has recrystallized before the next recrystallization period starts, therefore a multiple peak curve with relative low stress level would be obtained (Fig. 25).

In the case of low deformation temperature or high strain rate, the great part of deformed matrix in the last recrystallization period has not recrystallized before the next recrystallization period starts already. The hardening and softening effects in different recrystallization periods during hot deformation will overlap and be integrated, so that a single peak curve with relative high stress level would be obtained (Fig. 25). At very high strain a balance between hardening effect and softening effect could be reached and the stress would become rather constant. But the flow stress at high strain could also arise when the strain rate is increased continuously, e.g. in the case of hot compression with constant compression speed.^[54–57]

Hot Deformation Behavior in Pure Aluminum and Aluminum Alloys

Many commercial aluminum alloys will experience hot deformation at elevated temperature. Figure 26a gives the microstructure of a hot rolled (522–294°C) Al-0.0035 wt% Cu alloy, which shows a typical deformation structure. The recrystallization structure was obtained only after an additional annealing of the hot band (Fig. 26b).

Fig. 26 Microstructure of Al-0.0035 wt% Cu alloy $\overline{100\mu\text{m}}$. (a) hot rolled; (b) hot rolled and annealed

For a long time many people believe that pure aluminum did not undergo dynamic recrystallization,^[58,59] since aluminum is noted for the very strong effect of simultaneous dynamic recovery during hot deformation. Due to the very high stacking fault energy the dislocation density in deformed aluminum would be reduced drastically by the dynamic recovery at elevated temperature. In this case the dynamic recrystallization could not start because of clearly decreased driving force, though recrystallized structure was observed after following cooling or annealing, which should be introduced by a static recrystallization process, i.e. a primary recrystallization process.^[59]

It is clear that the stored energy after a heavy recovery in hot deformation is still high enough for a recrystallization process, and the static recrystallization could always appear during cooling or annealing afterwards.^[58–60] But under the condition of drastically reduced stored energy the extended incubation period becomes so long that the recrystallization cannot really start during hot deformation. Yamagata found in his compression experiments that only under very low deformation speed (0.06 mm/min or 1 mm/min) the typical mechanical behavior of dynamic recrystallization could be observed in single crystal and polycrystal aluminum with high purity (≥ 99.999 wt% Al),^[54–56] where the incubation period could be exceeded during hot deformation. However if the purity is reduced, e.g. down to 99.99 wt% Al, the dynamic recrystallization could not be observed any more.^[57] It seems that the impurity atoms in pure aluminum would inhibit the migration

Fig. 27 Mechanical behavior of hot compressed polycrystal pure aluminum (according to Yamagata^[54,57])

of high angle boundaries of dynamic recrystallization and prolong the incubation period further.

Figure 27 gives schematically the mechanical behavior of hot compressed poly-crystalline aluminum with the purity of > 99.999 wt% Al and 99.99 wt% Al respectively, which was observed by Yamagata.^[54,57] The aluminum with the purity of > 99.999 wt% Al (containing Cu: 0.5, Fe: < 1 , Si: 1, Mg: 1 and Ag: < 2 , all in ppm) was compressed at 341°C under a speed of 1 mm/min,^[54] and the aluminum with the purity of 99.99 wt% Al (containing Cu: 10, Fe: 36 and Si: 26, all in ppm) was compressed at 310°C under a speed of 0.06 mm/min.^[57] A clear dynamic recrystallization behavior was observed in high purity aluminum, but was not when the purity is reduced down to 99.99 wt% Al.^[57] The relatively high flow stress level of the high purity aluminum was induced by the higher compression speed.

Blade has ever investigated the effects of common impurity atoms on the recrystallization behavior after hot deformation.^[60] Based on a super-purity aluminum the addition of Fe, Si and Cu would influence the volume fraction of recrystallization after 50% hot rolling and 30 sec delay before quenching. It can be seen in Figure 28^[60] that Fe will inhibit clearly the static recrystallization process, which should also occur during dynamic recrystallization.

For the aluminum alloys the alloyed elements or increasing impurity atoms will preferentially accumulate around the dislocations induced by hot deformation, and reduced therefore the stacking fault energy. In this case the dynamic recovery could not reduce so much stored energy like that appeared in high purity aluminum, and the dynamic recrystallization will start during hot deformation.^[61] Figure 29 demonstrates schematically the mechanical behavior in Al-Mg alloy system during 50% hot compression,^[59] in which the tendency for dynamic recrystallization increases with increasing magnesium addition in solid solution. The similar behavior was also observed in Al-Mn and Al-Mg-Mn alloy systems as well as in commercial purity aluminum (99.5 wt% Al).^[62]

NORMAL GRAIN GROWTH

Concept of Normal Grain Growth

Normal grain growth or continuous grain growth is defined as the homogeneous increase of average grain size in polycrystalline aluminum during annealing, of which the word “normal” or “continuous” is sometimes omitted. Figure 30 gives the observed evaluation of grain size during annealing of an Al-3 wt%Mg alloy.^[63] The normal grain growth can be a process following primary recrystallization, or occur in an initially undeformed material. In fact, the grain growth will appear in almost all annealing processes.

The normal grain growth is carried out essentially by the migration of high angle boundaries, which differs from the subgrain coalescence process discussed in Section “Recovery” of this chapter (Fig. 11). During the normal grain growth curved boundaries migrate frequently towards the centers of curvature, therefore the relative large grains will grow up by means of consuming the small neighboring grains.^[64] But the growing grains could be consumed either if they have touched a larger

Fig. 30 Microstructure of 95% rolled and 500°C annealed Al-3 wt% Mg alloy^[63] $\frac{200 \mu\text{m}}$. (a) 40 sec; (b) 80 sec; (c) 160 sec. (Courtesy of Dr. X. Zhao.)

grain. The migration rate of high angle boundaries, i.e. the consumption rate of the small neighboring grains becomes more rapidly just as the small grains are about to disappear (see Eqs. 32 and 33). In two-dimensional structure observed in single phase aluminum alloys the grain boundary angles tend frequently towards 120° when they meet each other (Fig. 30).

Driving Force for Normal Grain Growth

It can be seen in Fig. 30 that the total grain boundary area per unit volume decreases during the grain growth. Therefore the decrease of boundary energy is the driving force for the normal grain growth. The total grain boundary energy per unit volume F_b could be estimated as

$$F_b = \frac{\frac{4\pi R^2 \gamma}{2}}{\frac{4}{3}\pi R^3} = \frac{3\gamma}{2R} \quad (31)$$

which is shown in Fig. 31 where the average radius of spherical grains is R and the boundary energy γ of pure aluminum should be roughly 1.0 J/m^2 .^[23]

So according Eq. 31 the decrease of total grain boundary energy per unit volume will be, e.g. about $1.5 \times 10^4 \text{ J/m}^3$ if the average radius of spherical grains increases from $50 \mu\text{m}$ to $100 \mu\text{m}$.

Kinetics of Normal Grain Growth

The boundary tension ΔP which induces the migration of curved boundaries towards the curvature centers can be expressed as

$$\Delta P = \frac{2\gamma}{R} \quad (32)$$

where the R is the curvature radius representing the grain size. If the size of a shrinking grain is R_s while its neighboring grain with size R is growing (Fig. 32), the boundary migration velocity v can be written as

$$v = -\frac{dR_s}{dt} \quad (33)$$

which is proportional to the boundary tension ΔP . Comparing Eqs 32 and 33 the relation of grain size R_s and annealing time t can be statistically deduced as

$$R_s^2 = R_{s0}^2 - C\gamma t \quad (34)$$

where R_{s0} is the initial size of the shrinking grain at $t = 0$ and C is a constant concerning annealing temperature. Correspondingly the following equation

$$R^2 = R_0^2 - C\gamma t \quad (35)$$

can be obtained for the growing grain on the assumption that the large grain grows homogeneously in all directions. Equation 35 could roughly express the increase of average grain size while the annealing proceeds, i.e. the average grain size R is proportional to $\sqrt{t}$.

Figure 33 demonstrates the evaluation of grain size distribution during annealing of a 95% rolled Al-3 wt% Mg alloy^[63] (cf. Fig. 30), in which the increase of grain size during annealing is observed. In many cases the size of the largest grains is 3–4 times of the average size.

Obstructs of Normal Grain Growth

It has been mentioned in Sec. 3 of this chapter that impurity atoms will reduce the boundary migration velocity. It was observed that increasing the impurity content of copper in zone-refined aluminum from 4.3 to 258 (at.) ppm drops clearly the grain boundary velocity.^[29]

Lücke and Detert^[65] have established an atomistic theory to explain the impurity effect. The impurity atoms in solid solution tend often to segregate to grain boundaries due to interaction between impurity atoms and grain boundaries that are the energy sinks for impurity atoms. Therefore the grain boundary impurity concentration C_B can be expressed as

$$c_B = c \exp\left(-\frac{Q_B}{kT}\right) \quad (36)$$

where c is bulk impurity concentration and Q_B is interaction energy between impurity atom and grain boundary. If impurity atoms are attracted to the boundaries the interaction energy Q_B will be negative.

Supposing that a grain boundary starts to pull away from the impurity atoms, there will be a drag force created by the impurity atoms which compel the boundary to carry them along and obstruct the normal grain growth.

Concerning Eq. 36 the segregation of impurity atoms in grain boundaries is reduced when the interaction energy Q_B is very low or annealing temperature T is very high. In this case the boundary migration is rather free like that in pure aluminum. On the other hand, the grain boundaries can also migrate freely if the driving force (Eq. 31) is high enough to induce a very rapid boundary migration so that the impurity atoms cannot be dragged along any more.^[65]

When a boundary is moving over second phase particles there will be a restraining force acting on the moving boundary, which is called Zener force^[66] P_z and can be expressed as

$$P_z = \frac{3f\gamma}{2r} \quad (37)$$

where r is radius of second phase particles, f is the volume fraction of the second phase and γ is the grain boundary energy. According to Eq. 32 the boundary tension ΔP which drives grain growth is reduced with increasing average grain size R . If the ΔP in an aluminum alloy containing second phase particles is reduced down to a level of corresponding P_z , i.e. $\Delta P = P_z$ then the grains will stop growing. In this case a stable average grain size R_c can be estimated using Eqs. 32 and 37, i.e.

$$R_c = \frac{2\gamma}{P_z} = \frac{4r}{3f} \quad (38)$$

Equation 38 indicates that the grain size in an aluminum alloy containing second phase particles could only be increased to a limited value R_c during annealing, which is influenced by particle radius and volume fraction of the second phase.

ANOMALOUS GRAIN GROWTH (SECONDARY RECRYSTALLIZATION)

Phenomenon of Anomalous Grain Growth

In some cases the normal growth of most grains are obstructed during annealing and only very few grains could grow anomalously. This process is the anomalous grain growth or discontinuous grain growth. The few growing grains are called here secondary grains, the most obstructed and then consumed grains are called matrix, and therefore the process is also called secondary recrystallization. Figure 34 gives an example of the anomalous grain growth in Al-3 wt% Mg alloy.^[63]

Fig. 34 Microstructure of 95% rolled 300°C 10min and 500°C 160sec annealed Al-3 wt% Mg alloy^[63] $\left[\frac{200 \mu\text{m}}{\quad} \right]$ (Courtesy of Dr. X. Zhao)

The phenomenon that the normal growth of most grains are obstructed could be induced by second phase particles, textures or sample surfaces.

Anomalous Grain Growth Induced by Second Phase Particles

To insure the fine grain structure and the corresponding mechanical properties the second phase particles are often designed and treated to precipitate in many aluminum alloys, and concerning Eqs. 37 and 38 the particles can obstruct the grain growth. During the normal grain growth the large size grains have high potential to grow and the small size grains have high potential to shrink. During high temperature annealing the second phase particles could grow, coalesce themselves or be resolved in the matrix, i.e. the r value in Eq. 37 is increased, which will reduce the restraining force. In this case the boundaries of very large and very small grains could overcome the obstruction and migrate. In other words the large grains would overcome the obstruction and grow up when their sizes are large than certain upper limit, and the small grains would also overcome the obstruction and shrink when their sizes are smaller than certain low limit. Because of the obstruction of second phase particles the increase of average grain size, i.e. the grain size of the matrix becomes very slow or even come to a stop during annealing while few large grains over the upper limit could continuously grow, which will result in an anomalous grain growth.

Anomalous Grain Growth Induced by Texture

In many annealed aluminum alloys there is often a very strong single texture component in company with same other weak texture components. In this case a grain oriented in the strong texture component neighbors frequently with the grains oriented in the same texture component, and therefore the boundaries between them are low angle boundaries that are not very mobile. So the grains of the strong texture component could hardly grow. At same

time grains oriented in the weak texture component neighbor also frequently with the grains oriented in the strong texture component, and reversely the boundaries between them are generally very mobile high angle boundaries. These grains oriented in weak texture components will disappear very fast if their sizes are very small, but they can grow rapidly as secondary grains and result in an anomalous grain growth when their sizes are larger than the grains oriented in the strong texture component.

Eichelkraut has observed the anomalous grain growth induced by texture in a 95% rolled Al-1 wt% Mn alloy.^[67-69] The primary recrystallization of 95% cold rolled alloy sheet was completed after annealing at 620° C for 1 sec and a very strong cube {001} 〈100〉 texture component is formed, of which the volume fraction is about 87%. During the following annealing two periods of anomalous grain growth or secondary recrystallization have appeared (Fig. 35).^[67-69] In the first period the texture component {011} 〈133〉 has replaced the cube texture, and in the second period the texture component {001} 〈320〉 has replaced the {011} 〈133〉 (Fig. 35a). Simultaneously the growing rate of average grain size shows two corresponding steps of rapid increase (Fig. 35b).

Zhao et al. have investigated the anomalous grain growth induced by texture in a 95% rolled Al-3 wt% Mg alloy in more detail.^[63,70-72] The primary recrystallization is completed during annealing at 300° C for 200 sec, after which the rolling texture component {011} 〈211〉, {112} 〈111〉 (Fig. 36b) as well as {123} 〈634〉 have disappeared and a strong cube texture {001} 〈100〉 and a very weak R texture {124} 〈211〉 near {112} 〈312〉 are formed (Fig. 36c). When the alloy sheet is heated at 400° C for 20 sec after annealing at 300° C for 600 sec, the cube texture is strengthened further and the orientation density reaches 119.9 (Fig. 36d). With increasing annealing time the cube texture is consumed and disappears, and the texture component {112} 〈312〉 and {001} 〈490〉 appear and are strengthened (Fig. 36e and f) after the secondary recrystallization is completed.

Figure 37 demonstrates the corresponding evaluation of texture components and average grain size.^[63] It is clear

Fig. 35 Texture and grain size evaluation of 95% rolled Al-1 wt% Mn alloy during annealing at 620°C^[67] (■ {001} 〈100〉 ● {011} 〈133〉 ◆ {001} 〈320〉), (a) texture components; (b) average grain size (Courtesy of Dr. H. Eichelkraut)

Fig. 36 Evaluation of orientation distribution in $\phi_2 = 45^\circ$ section for the 95% rolled Al-3 wt% Mg alloy during annealing^[63] (density levels: 2, 4, 8, 16, 32, 64, 99), (■ {001}⟨100⟩; ▲ {001}⟨490⟩; ● {112}⟨312⟩; ◇ {011}⟨211⟩; △ {112}⟨111⟩), (a) orientation positions in $\phi_2 = 45^\circ$ section; (b) 300°C, 0 sec (95% rolled) max = 19.6; (c) 300°C, 200 sec max = 46.1; (d) 300°C, 600 sec 400°C, 20 sec max = 119.9; (e) 300°C, 600 sec 400°C, 3500 sec max = 16.0; (f) 300°C, 600 sec 400°C, 4800 sec max = 18.5 (Courtesy of Dr. X. Zhao)

Fig. 37 Texture and grain size evaluation of 95% rolled Al-3 wt% Mg alloy during annealing at 400°C after annealing at 300°C for 600 sec.^[63] (a) texture components, ■ {001}⟨100⟩; ◆ {112}⟨312⟩ and {001}⟨490⟩; (b) average grain size, □ for grains oriented around {001}⟨100⟩, ◇ for grains oriented around {112}⟨312⟩ and {001}⟨490⟩, ▲ for all grains (Courtesy of Dr. X. Zhao)

that the anomalous grain growth is a process in which the texture components {112}⟨312⟩ and {001}⟨490⟩ replace the strong cube texture in the way discussed above. After 1000 sec at 400°C the survived grains oriented around {112}⟨312⟩ and {001}⟨490⟩, of which the number has been consumed by cube texture (Fig. 37a), should have relative large size and then grow in the cube grains while the cube grains cannot grow quickly because of the frequent low angle boundaries.

Observing the evaluation of average grain size in Fig. 37b it can be seen that in primary stage of annealing at 400°C before 3000 sec the average size of all grains is roughly identical to the average size of cube grains. The few large grains oriented around {112}⟨312⟩ and {001}⟨490⟩

do not distinctly influence the average size of all grains. In the following annealing stage large number of cube grains are consumed drastically by the very large grains oriented around {112}⟨312⟩ and {001}⟨490⟩, so that their average size is reached rapidly by the average size of all grains, after which the cube grains have disappeared and the anomalous grain growth is completed.

Anomalous Grain Growth Induced by Surface

When aluminum alloys are very thin and the ratio between surface area and grain boundary area is relatively high the decrease of surface energy could control the process of grain growth and induce an anomalous grain growth.

Fig. 38 Result of surface induced anomalous grain growth in high purity aluminum, (a) microstructure $\overline{40\mu\text{m}}$ (b) $\{111\}$ pole figure (max = 30.8, levels: 1, 2, 4, 8, 14, 22, 30)

In this case only the grains could grow up, of which their surface' energy is very low, and other grains with rather high surface energy will be consumed. It could be imaged that this anomalous grain growth will lead to a strong texture. Figure 38 gives an example of thin (less than 0.1 mm) high purity aluminum foil (>99.99%Al), in which the grain thickness is identical to the foil thickness after final annealing (Fig. 38a) and the a very strong cube texture is formed (Fig. 38b) which indicates that the surface energy of $\{001\}$ planes in the annealing atmosphere is the lowest.

SUMMARY

Aluminum is a fee metal with high stacking fault energy, of which the dislocation density multiplied by cold deformation will be clearly reduced in the recovery process during annealing or heating. The recrystallization in aluminum and its alloys is commonly a process including nucleation and growth of new grains, of which the driving force in deformed matrix is the energy stored in the lattice defects consisting mainly of dislocations. Both of the homogeneous nucleation as well as the heterogeneous nucleation on grain boundaries and around second phase particles are possible.

The grain growth rate are influence by the purity, impurity atoms, temperature, precipitates, boundary misorientations etc. Textures will be formed after the primary recrystallization. The dynamic recrystallization during hot deformation could only appear in the aluminum alloys easily, in which the stacking fault energy and therefore the recovery effect are drastically reduced by the alloyed elements or impurity atoms. The grains in annealed aluminum and its alloys will grow normally or anomalously during heating process, of which the basic driving force is the grain boundary energy. The anomalous grain growth induced by texture or surface will produce very sharp textures. The corresponding mechanisms of the processes mentioned in this chapter including recovery, primary recrystallization, dynamic recrystallization, normal grain growth as well as anomalous grain growth have been discussed.

Recycling of Aluminum

Jorge Alberto Soares Tenório and Denise Crocce Romano Espinosa

University of São Paulo, São Paulo, Brazil

Abstract

Aluminum is the second most used metal in the world because of its properties including good corrosion resistance, low density, high electrical conductivity and good thermal conductivity. However, the negative environmental impact from production of primary aluminum is due to the corresponding impact of red mud and release of fluorides which is devastating to forests and the space required for waste disposal. Recycling, in addition to reducing the impact of disposal of the by-products of primary aluminum production also consumes a great amount of electricity. Therefore, recycling of aluminum scrap is of increasing interest. In this article, the following factors involved in aluminum recycling are discussed: environmental and energy impact, secondary metallurgy of aluminum, fundamentals of aluminum recovery using salt flux, recovery of aluminum drosses by milling and preliminary treatments of scrap.

Keywords: Dross; Oxidation; Recycling; Salt flux; Saltcake; Scrap.

SECONDARY ALUMINUM PRODUCTION

Aluminum is the most abundant metal in the earth crust.^[1] Bauxite, which is the ore from which metallic aluminum is produced, is composed basically of aluminum hydroxide, iron oxide, hydroxides and silicates, carbonates of magnesium, calcium and iron, quartz, kaolin, titanium compounds and a small fraction of other metals; among the other metals are calcium, sodium, potassium, chromium, zirconium, phosphorus, gallium, and vanadium.^[2] The aluminum hydroxide is the bauxite's main component, and also is the compound that makes the difference between bauxite and clay. Clays are composed essentially of hydrated aluminum silicates.

The main physical properties of aluminum appear in Table 1.^[3] Aluminum crystallizes in the face-centered cubic system; this metal is characterized by its high stretch, as indicated in Table 2.^[3] One can notice that the tensile strength and the yield point of pure aluminum are fairly low, which reduces the applicability of this metal in structural uses. However, aluminum alloys can achieve tensile strength over 600 MPa after heat treatment.^[3]

One can verify that the specific weight of the aluminum is about one-third of the specific weight of iron or copper. So, the resistance limit becomes a better value when mechanical components are compared.

Aluminum also has other characteristics that make it an important metal for various applications. Aluminum is the second most used metal in the world; some of the characteristics that make this metal so important are good corrosion resistance, low density, high electric conductivity, and good thermal conductivity.

Figure 1^[4] shows the main aluminum applications. The packing sector can be highlighted because this material is the one which present the shorter life cycle and, hence, it can be more rapidly recycled.

ALUMINUM RECYCLING: ENVIRONMENTAL AND ENERGETIC IMPACT

The secondary metallurgy of aluminum, as many other recycling processes, allows an economy of raw materials and energy. The production of one metric ton of aluminum from bauxite requires about 17,000 kWh of electricity, while the same amount of recycled aluminum consumes approximately 750 kWh. Therefore, the recycled aluminum substitutes primary aluminum with a gain of 95%.

Another positive aspect of aluminum recycling is the environmental impact. The production of one metric ton of primary aluminum requires about four metric tons of bauxite and it produces around two metric tons of red mud. Beside the generation of red mud, the production of primary aluminum also releases fluorides.

The mining of bauxite is also an activity that causes problems to the environment, because this activity devastates forests and needs space to dispose of the wastes.

Accordingly, the favorable energy balance makes the aluminum an excellent product to recycle, since the main cost of the production of primary aluminum is electricity. Aluminum also presents another advantage, its scrap has a higher market aggregate value than many other materials used in packing.

Fig. 1 Aluminum consumption per sector^[4]

Table 1 Main physical characteristics of aluminum^[3]

Properties	
Crystalline structure	fcc
Atomic weight	26.98154
Specific mass at 20°C (g/cm ³)	2.6989
Solidification shrinkage (%)	6.5
Fusion temperature (°C)	660.4
Ebullition temperature (°C)	2494

Specific heat at 25°C (J/kg °C)	900
Latent heat of fusion (kJ/kg)	397
Combustion heat (MJ/kg)	31.07
Volumetric electric conductivity (% IACS)	64.94
Thermal conductivity at 25°C (W/m °C)	247

Table 2 Main mechanical properties of pure aluminum^[3]

Property	Annealed	Hard-drawn (90%)
Tensile strength (MPa)	40–50	120–140
Yield point (MPa)	15–20	100–120
Brinell hardness (kgf/mm ²)	12–16	27
Stretch	50–70	8–12

For all these advantages, the recycling rate of aluminum cans has been increasing. Figure 2^[4] shows the evolution of the recycling rate of aluminum cans from 1991 to 1999. One can notice from Fig. 2 that the three countries that have the biggest recycling rate of aluminum cans are Japan, Brazil and the USA.

Table 3 presents the data for the world production of secondary aluminum. North America is the leader of the

world, and is responsible for around 50% of the world's secondary aluminum production. In fact, almost all the aluminum recycled in the North America is recycled in the USA (3,310,000 tons in 1996^[5]). Nevertheless, the USA data contemplate the so-called old and new scrap. In the USA, figures around 50–60% are for the new scrap.^[6,7] New scrap indicates preconsumer sources.

The supply of old scrap (a product becomes an old scrap when it completes its useful product life) is affected by the amount of short-life products; so, used beverage cans (UBCs) are, in most cases, the main source of old scrap.^[7] In the United States, UBCs account for more than one-half of the old scrap.^[8] The greatest part of the UBCs is collected to produce new beverage cans. Most of the remaining old scrap is used to produce cast alloys for automotive or aerospace industry. Furthermore, the majority of secondary smelters is located near the automotive manufacturing areas.^[7,9,10] All over the world, the prices of aluminum products are based on the values of the London Metal Exchange (LME).

The overall aluminum-recycling rate of different countries appears in Fig. 3.^[4] The world average is about 35%. Some countries such as Holland, USA, and England are above this average. European countries, in general, follow the world average; while less developed countries have usually a low aluminum-recycling rate.

Fig. 3 Overall aluminum-recycling rate per country^[4]

ALUMINUM SECONDARY METALLURGY

Aluminum secondary metallurgy can be divided into two major groups: the melting of scraps, and the processing of white drosses.

Drosses are produced during the aluminum melting processes. Due to the high aluminum reactivity with oxygen, the formation of a superficial layer of oxide occurs. This layer becomes a physical barrier between the melt aluminum and the oxidant atmosphere, hence protecting the bath against oxidation. Turbulence generated by the handling of the liquid metal makes a new exposure of aluminum, which causes an increase in the oxide layer.^[11] At the end of the melting process, this oxide layer is removed. During the removal of the oxide layer, some amount of aluminum is dragged along with the oxide; the material generated in this operation is composed basically of oxides, metallic aluminum and impurities that are found on the surface of the bath.

Oxidation is a superficial phenomenon; thus, the thickness of the raw materials to be melted influences the amount of oxide produced during the process, i.e., the thinner the raw material, the higher the oxide formation. This behavior occurs because the relation surface/volume becomes high when dealing with thin raw material.

Thus, the secondary metallurgy of aluminum aims to recover the aluminum of the scraps and drosses, as well as give an adequate destination to the sub-products of these operations.

High Temperature Oxidation of Aluminum

The oxidation process of aluminum alloys depends on the superficial condition of the sample, on the alloy composition and on the temperature. Some disagreement exists in the literature related with the oxides formed and also

with the process kinetics.^[12–37] During the initial stages of oxidation, aluminum and its alloys develop an amorphous, superficial, thin, and resistant layer ($\gamma\text{-Al}_2\text{O}_3$), which follows parabolic kinetics. This layer provides a barrier between the metal and the atmosphere, and the initial layer influences the oxide growth at high temperatures.^[12,13,28]

In the range of 425–450°C, the $\gamma\text{-Al}_2\text{O}_3$ amorphous coating suffers a discontinuous change of structure. A fast migration of oxygen through the oxide/metal interface happens at this range of temperature, providing the nucleation and growth of a $\gamma\text{-Al}_2\text{O}_3$ crystalline phase, under the initial amorphous layer.^[12]

However, the $\gamma\text{-Al}_2\text{O}_3$ amorphous layer continues to grow by cation diffusion to the oxide/gas interface, concurrent to the growth of the $\gamma\text{-Al}_2\text{O}_3$ crystals which are formed in the oxide/metal interface and grow to the interior of the metal after an incubation period.^[12]

The oxide films developed in aluminum alloys at high temperatures are characteristically coupled, composed of amorphous and crystalline structures.^[12,13,17]

Small Mg additions cause an increase of the $\gamma\text{-Al}_2\text{O}_3$ nucleation rate, which is responsible for the decrease to 400°C of the temperature formation of crystalline $\gamma\text{-Al}_2\text{O}_3$. Additions above 1 at.% Mg cause MgO crystal precipitation instead of crystalline $\gamma\text{-Al}_2\text{O}_3$.^[17] The MgO precipitation occurs initially at the oxide/metal interface. However, with the oxidation process advancement, the precipitation of MgAl_2O_4 may occur, which can be stable depending on the Mg concentration.^[17]

Smeltzer^[16] performed a thermogravimetric study in an Al-3 wt% Mg alloy in the temperature range of 200–550°C. The surface condition effect on the oxidation rate was observed. Above 400°C, there was an increase in the oxidation rate. Between 450°C and 550°C, a parabolic behavior followed by a linear growth step was observed.

According to Hine and Guminski,^[37] the increase of Mg content in the alloy causes an increase in the oxidation rate.

Figure 4 refers to the oxidation kinetics of aluminum-can body alloy, Fig. 5 exhibits the aluminum-can lid alloy behavior and, in Fig. 6, a comparison between the results obtained for the two alloys in the temperatures of 500°C and 700°C is made.

The lid oxidation tests (Fig. 5) show different behaviors, according to the applied temperature. There is a linear behavior between 450°C and 500°C, suggesting a non-protecting characteristic for the oxides. Above 550°C, there is a parabolic behavior, evidencing the beginning of the protection by the superficial oxide.^[38]

The melting interval for the lid alloy ranges from 580°C to 637°C. Thus, in tests from 450°C to 550°C, the material was in the solid state, while in the 600°C test, the alloy was in the liquid + solid field, the other tests corresponding to the liquid condition. The test results for the bodies are shown in Fig. 4. The observed behavior is similar to the lid tests.

Fig. 4 Alloy 3004 thermogravimetric tests. Atmosphere: air

Fig. 5 Alloy 5182 thermogravimetric tests. Atmosphere: air

Fig. 6 Comparison between the results obtained for the lid and body alloys in the temperatures of 500°C and 700°C

The greatest difference is due to the deviation presented by the 800°C kinetic curve. The lid material oxidation kinetics are greater to the body. The 800°C curve exhibits a mixed behavior. The initial stage shows a parabolic progression, while the posterior shape (approximately after 10 min) indicates a change to a linear behavior. This change suggests loss in the initial protecting characteristic presented by the material (parabolic kinetics). This behavior was also found at 750°C, but for longer test periods.^[38]

Figure 6 shows greater kinetics for the lid alloy, in both temperatures. This result is related to the higher magnesium content.^[13,17,18,27,32,33] This element has greater affinity for oxygen than for aluminum.

The largest practical interest result refers to the great deviation shown by the body alloy at 800°C oxidation. In fact, the body represents 75% of the aluminum-can mass, so it is considered that its behavior will dictate the general characteristics in the recycling process. The obtained data indicate that during the process of recycling of the considered alloys, the used temperatures should avoid permanence in the limits of 800°C.

According to Tenório and Espinosa,^[38] the oxidation products are constituted of MgO for the 5182 alloy and MgO·Al₂O₃ for the 3004 alloy.

The effect of the atmosphere composition is shown in Fig. 7.^[38] Ar+5% O₂ simulate a weak rotary furnace oxidizing condition, while the atmospheres Ar+1% O₂ and CO₂ simulate typical stoichiometric combustion conditions.

In order to analyze the atmosphere effect in the oxidation process, some values were extracted from the data which originated Fig. 7. These values are illustrated in Table 4. Comparison between the weight gain for different atmospheres is shown in Table 5.

The use of close stoichiometric atmospheres produces a 4–7 times reduction in the oxidation process. On the other hand, atmospheres with a small amount of excess oxygen produce quite the same oxidizing effect as air.

When stoichiometric mixtures are used, furnace atmospheres produced by burners, which use air, should not present high oxidation potential. Pieces of equipment, which use oxygen and operate with neutral atmospheres, can reach a significant aluminum loss reduction.

Scrap Melting

The melting of scraps is usually performed in rotary furnaces. Small foundries may also use crucible or reverberatory furnaces. Molten salt fluxes are often used in the melting of scraps. Typically, the volume of these fluxes is not higher than 2 wt% of the charge. The molten aluminum goes to the teeming or holding furnaces, and the white dross is stored in steel containers by the furnaces.

The volume of salt fluxes might be higher than 2 wt% of the charge when the raw material is composed mainly of light-gauge scraps or contains organic coatings such as aluminum chips, beverage cans or aluminum foils.

Fig. 7 Atmosphere effect in the oxidation process for alloy 3004

Table 4 Weight gains (mg/cm²) from different oxidation conditions

Time (s)	CO ₂	1% O ₂	5% O ₂	Air

1500	5.08×10^{-6}	9.50×10^{-6}	2.43×10^{-5}	3.56×10^{-5}

Table 5 Weight gain relation among different oxidation conditions

Time (s)	CO ₂	1% O ₂	5% O ₂	Air
1000	7.32	3.83	1.47	1
1500	7.01	3.75	1.47	1

The range of temperature employed in the processes of aluminum melting is 700–800°C. The same range of temperature is used to recover aluminum from drosses.

Due to the higher formation of dross, the processes of recycling light-gauge aluminum scraps are analogous to the processes to recover aluminum from drosses.

Table 6 shows the main sources of aluminum scraps and the most common physical impurities associated with each kind of scrap.

Aluminum Recovery from Drosses

White drosses, as aforementioned, are a consequence of the process of aluminum melting. Typically, 15–25 kg of dross are produced per metric ton of molten aluminum.^[39] The literature^[11] separates drosses into three different classes:

- **White Dross.** It is from the primary metallurgy of aluminum, extrusion plants, lamination plants, and foundries. The main characteristics that differ this class of dross from the others are the absence of salt fluxes and the fact that this dross is usually whitish or grayish or

Table 6 Scrap source and its main impurities^[11]

Scrap	Physical impurities
Cables	Fe, Zn, Cu and organic material
Stamped material	Varnish, ink and organic material
Aluminum shapes	Fe, Cu, plastics
Aluminum sheets	Fe, oxides, earth
Aluminum foil	Oil, food remains, paper
Chips	Oil, Fe, Zn, Cu, Si

Tubes	Fe, ink, plastic
Radiators	Fe, Sn, Pb, plastic
Engine block	Fe, Zn, Sb
Piston	Fe, Cr, oil, organic material
Beverage can	Fe, Cu, Mg, ink, varnish

presents a light color. The *white dross* may contain from 15% to 70% of metallic aluminum.^[39]

- **Black Dross.** It is produced in the secondary metallurgy of aluminum. This process uses salt fluxes and the produced dross presents dark colors.
- **Saltcake.** It is the result of the aluminum recovered from white and black drosses. It is characterized by the high concentration of salt and by its darkish color. This class of dross contains from 1% to 7% of metallic aluminum.

Actually, there are not much differences between the *t* dross and the saltcake.

Main Compounds of the Drosses

Drosses contain 5–60% of aluminum. Beside aluminum, drosses may contain other compounds. Stewart^[40] suggested that the following phases might be present in drosses: Al₂O₃, AlN, AlC, MgF₂, NaAlCl₄, KAlCl₄, SiO₂, MgO, MgO·Al₂O₃, and the salt constituents.

During the recovery of scraps that have Mg, Mg may react with fluorites forming the compound, MgF₂. It was

suggested^[39] that MgF_2 is a product of the reaction between the KF or NaF of the salt flux and the Mg of the alloy, because MgF_2 is thermodynamically more stable than KF and NaF. Thus, it is necessary to compensate this loss or use other types of salt flux.

Depending on the concentration of Mg in the alloy, the formation of $\text{MgO} \cdot \text{Al}_2\text{O}_3$ ^[41] in the dross is also possible, which turns the dross dark.

Unger and Beckmann^[42] studied the treatment of drosses. They found the following compounds in the washed residue: Al_2O_3 , $\text{MgO} \cdot \text{Al}_2\text{O}_3$, $(\text{Ba}, \text{Sr}, \text{Ti})\text{Al}_2\text{O}_4$, $x\text{Al}_2\text{O}_3 \cdot y\text{SiO}_2$, AlN , $\text{NaAl}_{11}\text{O}_{17}$, Al_4C_3 , SiO_2 , $x\text{Na}_2\text{O} \cdot y\text{SiO}_2$, Na_4SiFe , CaF_2 , $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ and other components with concentrations lower than 1%.

Hryn et al.^[43] analyzed the composition of the products from several plants that treat dross in the USA; the results are listed in Table 7.^[43]

Aluminum hydroxide is not a natural product from the treatment of aluminum or drosses, but it is the result of the reaction between aluminum and alkaline water. The alkalinity of the water is due to the presence of AlN in the dross.^[43]

Aluminum recovery from drosses and light-gauge scraps with low thickness must be done under the condition of charge protection against oxygen. Thus, the processes can be divided into two classes:

1. Melting using salt fluxes.
2. Melting without salt fluxes.

The main by-product of these processes is a new type of dross. This dross has a low aluminum content, between 1 and 7 wt%, with or without salt depending on the melting process. The dross generated in the process that uses salt fluxes must be treated to remove the salt before the dross can be discharged. Next, the fundamental aspects of these two classes of melting processes are going to be described, as well as the main by-product destination.

Table 7 Compounds present in the wastes from the dross treatment^{[43]a}

AlN		—	—	—	—
Other phases			SiO_2		SiO_2
			CaF_2		CaF_2

^a+, Large concentration; —, small concentration; and n.d., non-detected.

Melting Using Salt Fluxes

The processes to recover aluminum from drosses or from light-gauge scraps are performed in rotary furnaces using salt fluxes. Typically, these furnaces have the capacity to process 1–10 metric tons of dross or scrap per cycle. It burns fuel as the energy source; the selection of the fuel depends on the local availability of fuel. Rotary furnaces are used because they promote a constant agitation of the charge, enhancing the yield of the process.^[44]

The main function of the saline fluxes is to act as a barrier between the liquid aluminum and the oxygen of the atmosphere, diminishing the process of superficial oxidation of aluminum. The salt flux is added into the furnace at the beginning of the heating and the amount of salt flux varies between 20 and 65wt% of the charge.^[42,45] The fluxes should have the following characteristics:

- melting point below 720°C
- low viscosity
- easily detachable from the liquid bath
- must not react with the metal
- must not add impurities into the metal
- must not be hygroscopic
- low vapor pressure
- low cost
- low treatment cost

The main functions of the salt fluxes are the following:

- protect the molten metal from oxidation
- help in the removal of the superficial oxide layer; this layer is formed previously or during the heating of the rotary furnace
- promote the coalescence of aluminum drops
- maintain the oxides in suspension

The salt fluxes are composed of NaCl and KCl mixtures; the most common composition is an equimolar mixture of these chlorides, because it constitutes the composition of the minimum point of the system. Besides these chlorides, fluorides are added to the fluxes. The main fluorides used are Na_3AlF_6 , NaF, KF, CaF_2 , and MgF_2 .^[41]

Figure 8 shows a sketch of the rotary furnace. The main advantages of the process using rotary furnaces and salt fluxes are the low-cost energy source (fossil fuel), the low initial investment, and the ease of operation.

The main oddity of this process is the production of a sub-product that contains salt and needs to be treated before the final disposal. Alternative processes for the use of the rotary furnace and salt flux aim to obtain comparable or even higher yields, but without the use of salt. In a process that does not use salt, the formed dross would not need treatment before the final disposal. These alternative processes also generate fewer fumes, as will be explained afterward.

Fig. 8 Sketch of the rotary furnace for aluminum recovery from drosses or light-gauge scraps

Processing of the Saltcake

The dross from the processes that use salt flux needs to be treated before its final disposal. The soluble salt content is responsible for the necessity of treatment of this waste. The treatment aims primarily to diminish the content of soluble salt in order to meet the local environmental law. The saltcake presents the following composition:

- 60–63% salt
- 7–8% Al
- insoluble material

Several steps compose the saltcake processing: milling, leaching with water, decantation, filtering, and drying of water for the salt recover.^[46–51] During the leaching with water, a gas with bad smell is released. The gases that can be formed during this step are shown in the following:^[46,52]

- Hydrogen: $\text{Al} + 3\text{H}_2\text{O} = \text{Al}(\text{OH})_3 + \frac{3}{2}\text{H}_2$
- Ammonia: $\text{AlN} + 3\text{H}_2\text{O} = \text{Al}(\text{OH})_3 + \text{NH}_3$
- Methane: $\text{Al}_4\text{C}_3 + 12\text{H}_2\text{O} = 4\text{Al}(\text{OH})_3 + 3\text{CH}_4$
- Phosphine: $\text{AlP} + 3\text{H}_2\text{O} = \text{Al}(\text{OH})_3 + \text{PH}_3$
- Sulfur hydroxide: $\text{Al}_2\text{S}_3 + 6\text{H}_2\text{O} = 2\text{Al}(\text{OH})_3 + \text{H}_2\text{S}$
- Hydrochloric acid: NaCl or $\text{KCl} + \text{H}_2\text{O} = \text{NaOH}$ or $\text{KOH} + \text{HCl}$
- Hydrofluoric acid: $\text{NaF} + \text{H}_2\text{O} = \text{NaOH} + \text{HF}$

Leaching is common in Europe and in other countries that have space restrictions. In the majority of the countries of the world, the saltcake is disposed of in landfills. The

processing of the saltcake is predominantly performed by another company, which treats the materials recovering the salt. The salt is sent back to the recycling aluminum plant.

As shown by the equations, the reactions produce some gases that need to be treated. Gases are cleaned through the use of activated carbon filters and also by the use of sulfuric acid that reacts with the NH_3 producing $\text{NH}_4(\text{SO}_3)$.

Fundamental Aspects of Aluminum Recovery Using Salt Flux

The main fundamental aspects highlighted in the literature related to the recovery of aluminum using salt fluxes are the following:

- phase diagrams of the chlorides and fluorides
- metal/salt interfacial tension
- coalescence power of the fluxes
- interaction between aluminum and salt
- effect of composition on the yield

Phase Diagrams Involving the Chlorides and Fluorides

NaCl–KCl System The NaCl–KCl system is the base of the process that uses salt fluxes. The fusion temperature of the NaCl is 802°C and the KCl fusion temperature is 775°C. The system is isomorphous with a minimum point at the temperature of 667°C and the composition of 49.3 mol% of KCl, as shown in Fig. 9.^[53] The system also has an immiscibility line in the solid state.

Fig. 9 NaCl-KCl system^[53]

The processes that melt drosses and light-gauge scraps generally use an equimolar mixture of NaCl and KCl, because this composition is near the minimum point of the NaCl-KCl system. This mixture melting point fulfills one of the requirements for a salt flux, which is, that the melting point must be under 700°C, the temperature compatible with the processes of aluminum melting.

NaCl-KCl-NaF System Figure 10^[54] shows the ternary phase diagram, NaCl-KCl-NaF. NaF additions promote a lowering in the fusion temperatures of equimolar mixtures of NaCl and KCl until reaching a eutectic reaction.

NaCl-KCl-CaF₂ System The ternary diagram, NaCl-KCl-CaF₂, shown in Fig. 11,^[54] is fairly similar to the diagram shown in Fig. 10. The primary crystallization field is narrower.

Na₃AlF₆-CaF₂-Al₂O₃ System The phase diagram, Na₃AlF₆-CaF₂-Al₂O₃ appears in Fig. 12.^[55] One can identify in this diagram a large solubility of alumina in calcium fluoride and cryolite. There is also an invariant eutectic reaction at 867°C.

Interfacial Tension

The effect of fluoride additions to equimolar NaCl-KCl salt fluxes on the interfacial tension between the salt flux and the liquid aluminum bath was first studied by

Fig. 10 NaCl-KCl-NaF^[54]

Fig. 11 NaCl-KCl-CaF₂ ternary diagram^[54]

Martin-Garin et al.^[56] Later on, other researchers^[57-60] complemented these studies using a wider range of fluorides and also by verifying the effect of the Mg content of the aluminum. Fluoride additions up to 10mol% diminish the interfacial tension between the aluminum and the salt flux.^[56-59] The fluoride efficiency was compared to each other and, were arranged in a crescent order of efficiency:^[58]

Some of the results obtained by these researchers appear in Fig. 13.

According to Ho and Sahai,^[57,58] when adding fluorides to NaCl-KCl equimolar mixtures, NaF becomes

Fig. 12 $\text{Na}_3\text{AlF}_6\text{-CaF}_2\text{-Al}_2\text{O}_3$ phase diagram^[55]

Fig. 13 Effect of fluoride additions to equimolar NaCl-KCl mixtures on the interfacial tension salt/aluminum^[58]

more effective than KF for additions higher than 10 mol%.

The value of the interfacial tension between the pure liquid aluminum and the equimolar mixture NaCl-KCl at 740°C is 740 dyn/cm², while the value of the interfacial tension between the liquid alloy of the body of beverage cans and the equimolar mixture NaCl-KCl is 550 dyn/cm².^[58] The interfacial tension decrease is related to the increase in the activity of surface-active elements.^[61]

Aluminum Coalescence in the Salt Flux

When studying aluminum recycling, coalescence can be explained as the capacity of junction and growth of aluminum drops, firstly dispersing in the salt flux, forming bigger drops which have better conditions to be decanted into a pond under the flux. The literature^[59,62] points to the fact that this coalescence is a consequence of the flux capability to remove the superficial layer of oxide.

Peterson^[62] observed the behavior of aluminum fragments added to molten salt fluxes at 750°C. A transparent

quartz crucible was used in these experiments and the aluminum fragments were of about 1–2 mm. Various kinds of fluorides and chlorides were added to an NaCl-KCl mixture. The NaCl-KCl mixture was done with the same weight of each salt. The results achieved are in Table 8.^[62]

One can notice from Peterson results that the chlorides have little influence on the coalescence. On the other hand, in general, the fluorides effectively enhanced the coalescence. The fluorides, Na_3AlF_6 , AlF_3 , BaF_2 , KF and SrF_2 , stood out because they promoted the coalescence in less than 60 sec.

The impurities of the AlF_3 caused an increase in the time of the coalescence. The main impurity found in this compound was alumina. Thus, the presence of alumina, even at low concentrations (0.65%), caused difficulties in the contact of aluminum drops, making the coalescence more difficult. Sully et al.^[63] studied the effect of oxide concentration on the viscosity of molten salts. They observed that oxide additions higher than 10% decreased the aluminum coalescence.

Table 8 Effect of fluoride and chloride additions on the coalescence of aluminum in the salt flux^[62]

Additions (wt%)	Coalescence	Time for the coalescence (sec)
Cryolite	Complete	30
CaF ₂	Moderate	222
NaF	Complete	> 270
AlF ₃ (87% pure)	Moderate	> 60

BaF ₂	Almost complete	37

Figures 14 and 15 exhibit the curves for the variation of viscosity as a function of the fluoride addition to the equimolar mixture of NaCl and KCl at 760°C and 810°C, respectively.^[64]

Through the observation of Figs. 14 and 15, it is possible to conclude that the fluoride additions decrease the viscosity of the molten salt, and NaF presents approximately the same behavior as KF. The same behavior was observed by Roy et al.^[65]

This decrease of the viscosity explains partially the results of Tenório and Delgado^[66] who observed an increase in the aluminum recovery as the amount of fluoride increases in the molten salt. The decrease in the

viscosity facilitates the movement of the small aluminum drops trapped within the salt layer, or in other words, promotes better conditions for aluminum coalescence.

The effect of interfacial tension seems to be less relevant in relation to aluminum recovery. Ho and Sahai^[58] observed that Na₃AlF₆ exerts lesser influence on the interfacial tension than on other fluorides; on the other hand, Peterson^[62] and also Tenório and Delgado^[66] showed that Na₃AlF₆ causes an effective increase in the aluminum yield.

Although the literature presents little information about the solubility of alumina in molten chlorides,^[43,67] it is known that its solubility of the chlorides is much less than the solubility of molten fluorides; therefore, an increase in the solubility of alumina as the concentration of fluorides increases is expected.

Consequently, the result of fluoride additions can be considered as the sum of the capacity of attacking the oxide layer plus the decreasing of the viscosity.

The work of Ye and Sahai^[68,69] describes tests performed in a way similar to the tests of Peterson.^[62] The results for fluoride additions of 5wt% to equimolar NaCl–KCl mixtures are shown in Fig. 16.^[68] One can notice that the additions of NaF, KF, LiF, and Na₃AlF₆ had excellent results.^[62]

These two studies presented conflicting results concerning NaF, LiF, and AlF₃. Additions of KF and Na₃AlF₆ presented excellent results in both the studies.

Ye and Sahai^[68] also showed that the superficial condition of oxidation influences on the capacity of coalescence of the fluxes. Therefore, the equimolar NaCl–KCl flux could act as a real flux only for alloys with less than 1% of Mg. The flux made of only chlorides could not break the oxide layer of aluminum alloys containing more than

**Fig. 14** Variation of viscosity as a function of the fluoride additions to the equimolar mixture of NaCl and KCl at 760°C^[64]

Fig. 15 Variation of viscosity as a function of the fluoride additions to the equimolar mixture of NaCl and KCl at 810°C^[64]

Fig. 16 Effect of fluoride additions to salt fluxes on the aluminum coalescence^[68]

2% of Mg. Additions of only 1.5% of NaF were enough to promote the coalescence, breaking the oxide layer.

The salt flux, composed only of chlorides, was not capable of breaking the oxide layer of aluminum alloys that did not contain Mg when the oxide layer was grown thicker by heating the aluminum previously under air. Fluxes, with the addition of 1.5% of NaF, promoted the coalescence uniquely for alloys with less than 1% of Mg.^[68]

Salt/Oxide Interaction

The literature presents few data about the oxide solubility in molten salts.^[43,67] Na_3AlF_6 can dissolve up to 12wt% of Al_2O_3 at 955°C. NaF dissolves on the order of 5wt% of Al_2O_3 at 985°C, and CaF_2 dissolves roughly 25wt% of

Al_2O_3 at 1275°C. NaCl additions to cryolite cause a strong decrease in the alumina solubility in cryolite. The solubility of alumina in chlorides is practically 0 and additions of NaF enhance the alumina solubility. Hence, not much can be affirmed concerning the effect of alumina solubility in the salt fluxes used in the aluminum-recycling processes.

Figures 17 and 18^[64] show the alumina dissolution in salt fluxes (P values) for the tests performed, respectively, using 2.5 wt% and 5 wt% of fluorides, and also present the behavior of the equimolar mixture of NaCl and KCl without any addition and also saturated in alumina. Figure 18^[64] shows the P values for the tests performed with different NaF concentrations.

According to Figs. 17–19, the addition of fluorides enhanced the alumina dissolution in the salt flux. The most effective was NaF, followed by CaF_2 and KF. As expected, the equimolar mixture of NaCl and KCl presented poor performance.

Even when the molten flux is saturated in alumina, the process of diameter reduction occurs, and this implies that dissolution is not the only effect observed. There is an effective diminution of diameter due to a corrosive attack process. This corrosive attack explains why the fluoride additions are so effective on the stripping of oxide layer, and stripping is exactly the step before coalescence.

The results of viscosity measurements and dissolution showed the complexity of the mechanisms involved in the recycling of aluminum in the rotary furnace using salt flux. Nevertheless, Ye and Sahai^[68] showed only indirectly the action of fluorides. Thus, the increase in the recycling yield promoted by the additions of fluorides to the equimolar mixture of NaCl and KCl is attributed^[64]

Fig. 17 P values for the tests performed using 2.5 wt% of fluorides, and also present the behavior of the equimolar mixture of NaCl and KCl without any addition and also saturated in alumina^[64]

Fig. 18 P values for the tests performed with 5 wt% of fluorides, and also present the behavior of the equimolar mixture of NaCl and KCl without any addition and also saturated in alumina^[64]

to the simultaneous action of two factors: the decrease of flux viscosity that favors the aluminum coalescence and an increase in the corrosion attack of the oxide layer, which is related to the stripping of the oxide layer.

Although it is believed that the salt fluxes promote the removal of the oxide layer, only few data are known about the mechanisms that rule this removal. West apud Ye and Sahai^[68] suggested that the fluorides of the molten

Fig. 19 P values for different NaF concentrations in the equimolar mixture of NaCl and KCl^[64]

salts attack the external oxide layer, allowing the access of chloride ions to the interface metal/oxide. The removal of the oxide layer is attributed to the formation of aluminum chloride, which is volatile at the temperature of the recycling processes.

Sully et al.^[63] suggested that the oxide layer removal is due to the interfacial tension strength between the liquid metal and the oxide layer. Later, this hypothesis was studied again by Ho and Sahai.^[58] Ho and Sahai showed that with the available data, the relation $\gamma_{\text{metal/salt}} + \gamma_{\text{oxide/salt}} < \gamma_{\text{metal/oxide}}$ cannot be verified.

Van Linden and Stewart^[45] suggested that the molten salt intensively wets the external oxide layer, which has its boundaries dissolved by the salt. This would lead to the disaggregation of the oxide layer.

Maason and Taghiei^[70] proposed that the coalescence of metallic drops dispersed within the salt is influenced by the formation of a salt layer, which has a high melting temperature, on the interface between the molten alloy and the salt. The oxidation of the Mg present in the alloy is an important step for the formation of such salt layer. This layer was detected and identified as KMgF_3 or K_2NaAlF_6 . Johnston and Peterson^[41] showed that low yields could be caused by the effect of the Mg content of the alloy or by the high concentration of the spinel in the dross.

Based on the microscopic observation, Tenório and Espinosa^[71] concluded that the drosses are essentially composed of oxides and trapped aluminum. Figure 20^[71] shows a typical microstructure of dross from a melting process where no salt was used. Clusters of grayish particles and an

Fig. 20 Back scattered image. Electron micrograph of the dross composed of oxide particles (dark) apparently in an aluminum matrix^[71]

apparently continuous bright phase can be observed. The grayish phase corresponds to the oxide and the light phase to the aluminum. In this case, the oxide is mainly composed of $\text{MgO} \cdot \text{Al}_2\text{O}_3$ because the samples were obtained to form an aluminum-can recycling facility. XRD also confirmed the composition of the oxide.

The amount of aluminum in Fig. 20 could give the impression of being higher than the amount of oxides; however, this might be a false appearance. During the process of cutting and metallographic preparation, the aluminum may deform and spread. On the other hand, the oxides might break, because oxides are brittle phases.

After the selective etch to remove the aluminum, an apparent continuous net of oxides was observed, as shown

in Fig. 21.^[71] The oxides exhibit the feature of slightly rough plates; consequently, this structure has a significant amount of specific surface area, which promotes the aluminum entrapment. The oxides in the dross remain solid at the standard temperatures of aluminum foundry, and the oxides have high strength at such temperatures. Hence, these two facts plus the high surface area explain the higher metal losses that occur in the aluminum recycling compared to other metals.

Studying the interaction between the molten salt and the dross at high temperature (700°C), Tenório et al.^[64] observed that the liquid salt breaks the oxide structure, and transforms this net into a great number of small fragments that turn into the shape of plates or small clusters of plates. Figure 22^[71] presents the microstructure of the oxides after the interaction with the liquid salt. In Fig. 22, all the aluminum was released from the dross due to the salt action. In this specific case, the salt was removed before the SEM observation by dissolution in water.

This mechanism of salt etch is favored by the low interfacial tension between the salt and oxide and also between the aluminum and salt. Fluoride additions decrease the interfacial tension between molten salt and aluminum,^[64] and consequently, this favors the overall process of the oxide net breaking. The viscosity of the molten flux can also influence this mechanism,^[64] once the salt has to percolate the dross and allow the separation of aluminum from the broken oxide particles.

The aluminum freed from the oxide entrapment started to coalesce, generating small drops of about 1 mm, which began to cross the viscous salt plus oxide layer. Figure 23^[71] shows the formation of such small drops in the inferior part of the dross layer.

Therefore, the molten flux breaks the long oxide nets and promotes the oxide fragmentation, as well as liberates the aluminum drops that have a propensity to coalesce.

Figure 24^[71] shows schematically the suggested process of oxide removal from the molten aluminum surface.

Fig. 21 Back scattered image. Electron micrograph of the dross. After the selective dissolution of aluminum, it is possible to notice that the oxide particles are united in a net^[71]

Fig. 22 Back scattered image. Electron micrograph showing the oxide net fragmented after the molten salt action^[71]

Fig. 23 Back scattered image. Electron micrograph of aluminum drop generation subsequent to the introduction of the molten salt^[71]

Initially, the salt corrodes the oxide grain boundaries (Fig. 24b). According to Tenório et al.,^[64] chloride salt flux has the capacity to corrode oxides even under saturated conditions, and this ability is increased by fluoride additions. The molten salt accumulates near or at the oxide aluminum interface (Fig. 24c), and causes the spalling of the scale (Fig. 24d). Finally, aluminum drops are generated, which keep distributed in the inner portion of the salt layer (Fig. 24e).

This behavior is similar to the hot corrosion process where a metal that develops a protective oxide layer is submitted to an atmosphere containing chlorides. Under these conditions, chlorine or chloride penetrates the scale and an increase in the chlorine concentration occurs near or at the interface between the oxide and the metal. This accumulation of chlorides causes a weakness in the mechanical stability of the oxide layer, which becomes susceptible to blistering, cracking or spalling.^[72] Thus, a similar mechanism may be acting in the interaction between molten salt and oxides.

Fig. 24 Sketch of the oxide detachment caused by the molten salt^[71]

Effect of the Flux Composition on the Aluminum Recovery

As previously reported, salt additions make a remarkable effect on the yield of aluminum recovery especially in rotary furnaces. These fluxes typically contain 95–100% of an equimolar NaCl/KCl mixture with fluoride additions.

The effect of the equimolar mixture of NaCl/KCl on the aluminum recovery is shown in Fig. 25.^[73] Only a small amount of salt in the charge is enough and the recovery can reach an 85% yield level.

Van Linden and Stewart^[45] showed that the metal recovery is more efficient with the increase of fluoride concentrations up to 10 wt%. Above this concentration, the yield decreases for CaF_2 or MgF_2 additions, and remains constant for NaF and KF.

Johnston and Peterson^[41] studied the effect of magnesium in the fluxing process. It was found that magnesium promotes the formation of spinel $\text{MgO} \cdot \text{Al}_2\text{O}_3$ or MgAlO_4 in the dross, with a black color. It was also suggested that poor recoveries might be an effect of the magnesium concentration in the alloy or high concentration of spinel in the dross.

Tenorio and Delgado^[66] studied the effect of fluoride additions to the equimolar NaCl/KCl mixture. Figures 26, 27, and 28 show, respectively, the influence of KF, CaF_2 and Na_3AlF_6 on the aluminum recovery.

Fig. 25 Effect of the NaCl/KCl equimolar flux in the aluminum recovery^[73]

Fig. 26 Effect of KF ratio in the equimolar flux on the yield^[66]

Fig. 27 Effect of CaF_2 ratio in the equimolar flux on the yield^[66]

An increase of KF in the flux increases the yield up to 95%. The yield observed for CaF_2 and Na_3AlF_6 additions are approximately 92% and 94%, respectively. Consequently, additions of 2.5 wt% of fluorides in the flux are

Fig. 28 Effect of Na_3AlF_6 ratio in the equimolar flux on the yield^[66]

sufficient to increase the yield by 5% at least, and also, the fluoride efficiency grows up in the following sequence: $\text{CaF}_2 < \text{NaF} < \text{Na}_3\text{AlF}_6 < \text{KF}$.^[66]

Melting Without Salt Fluxes

Due to increasing environmental restrictions related to the disposal of the drosses that contain salt, since the end of the 1980s, alternative processes to recycle aluminum scrap are being developed. This process does not use saline fluxes; the oxidation of the charge is avoided by means of lessening the oxygen potential inside the furnace. The main techniques that are being developed are the fusion in rotary furnace heated by a plasma torch,^[74–76] fusion in electric arc furnaces^[77,78] and fusion burning fuel enhanced with oxygen.^[79,80]

Process Using the Plasma Torch

This process is being developed since 1991 by ALCAN. Nowadays, there are two plants that produce about 150,000 metric tons of aluminum per year. The process is performed in a rotary furnace heated by a plasma torch. The gas employed is oxygen, but nitrogen also can be used with an increase in the energy consumption. Figure 29 schematically depicts the process.^[77]

Fig. 29 Sketch of the process that uses plasma torch Adapted^[77]

The main advantages of this process in comparison with the conventional one that uses salt fluxes are:

- the dross has no salt content
- better heat transfer
- less amount of generated gases

On the other hand, the main odds are:

- the use of electric energy
- the process needs trained people to operate and maintain the system

Process Using Electric Arc Furnace

In 1992, Hydro-Quebec^[77,78] began the development of a process to recover the aluminum content of drosses. This process uses an electric furnace, where the heating is done by an electric arc. The sketch of this furnace operation appears in Fig. 30.^[77]

The DROSCAR process furnace consists essentially of a rotary furnace with graphite electrodes. Argon is purged for the stabilization of the arc and, to create an inert atmosphere.

According to the literature,^[77,81] the main advantage of this piece of equipment over the plasma furnace is that there is less generation of gases. Only three cubic meters of gas are generated by a metric ton of treated dross, while 30 and 300 m³ of gas are produced in the plasma and conventional processes, respectively.

Processes Based on the Control of the Burners

One of the most recent alternative processes developed is the ALUREC.^[79,80,82] This process has been developed by AGA since 1994. It uses a rotary furnace similar to the furnace used in the conventional process, but no salt is used here. Instead, the heating is done by the burning of fossil fuel (oil or gas) with oxygen, not with air. Hence, with the optimization of the combustion, the generated gases are about 25% of the volume generated in the conventional process.

The literature points out a yield 5% superior than the yield reached in the conventional recycling process of dross. This increase in the yield is thought to be due to the non-utilization of air, so the formation of NO_x and aluminum nitrates is avoided. Figure 31^[79] shows a sketch of the ALUREC process.

Processes Based on Submerging the Scrap into the Bath

Another way to avoid or minimize the oxidation of aluminum is the fast immersion of the solid scrap into the molten aluminum pool. The vortex method^[83] uses a rotating

Fig. 30 Sketch of the DROSCAR process^[77]

Fig. 31 Sketch of the ALUREC process^[79]

disk to produce a vortex on the bath surface that sinks the scrap into the pool.

Another alternative to put the scrap quickly inside the bath is the metal pumping into a bowl, in which the pumped metal enters the upper portion of a cylindrical bowl tangentially causing a swirling action that quickly melts light-gauge scrap added into the bath. The charge is performed through the use of molten-metal pumps circulating the hot metal from the furnace hearth to an attached side-well melting area. Argon can be used to prevent oxidation of the scrap during the transport stage.^[84–86]

Both methods, vortex and side-well, are all employed on reverberatory-style melting furnaces.

Recovery of the Aluminum of the Drosses by Milling

Another alternative used in order to avoid the use of salt fluxes consists in the milling and classification of drosses that do not contain salt.^[87–89] Firstly, the dross that does not contain salt is milled in a ball mill. Then, the milled material is classified into different size range (sieve classification).

The fraction of the material that has more than about 4 mm is rich in metallic aluminum; the metallic aluminum content is about 85%. This fraction goes to the melting. The fraction of material between 1 and 4 mm has

approximately 70% of metallic aluminum; this material can be sold to plants that produce exothermic powders. The fraction of the classified material that has less than 1 mm contains roughly 25% of metallic aluminum. This fraction can be sold as an insulating cover for the teeming processes in steel making industries.

An analogous processing to the beforehand described is carried out on drosses that contain salts, before the leaching with water. In this case, the fraction composed of the biggest material is returned to the fusion and the fraction composed of the smallest material is forwarded to the leaching step.^[46,47]

Aluminum Scrap Preliminary Treatments

Frequently, aluminum scraps hold contaminants; in most cases, these contaminants are ferrous alloys or organic compounds. Consequently, it is necessary to clean the scrap before processing it.

Most of the time, the cleaning can be carried out as simply as separating the contaminants manually, which can be done by the furnace operators who know the scrap by looking at it and can identify the contaminants.

When the production is relatively high, manual separation becomes unfeasible; in this case, an investment in milling and physical separation techniques is necessary,^[87,90] as an example of these steps can be cited the magnetic separation followed by baling.^[91]

There are inks and varnishes on the beverage can scrap. These inks and varnishes correspond to 2–3% of the total mass of the can 7 they are applied on the interior and exterior walls for protection and product identification (brands). These coatings are composed essentially of organic resins (vinyl, epoxy, and acrylic) and pigments.^[92] Besides these compounds, in the interior of the cans, it is possible to exist residues that are basically water and sugar. The sum of all these compounds represents in average 4–5% of the total mass of the scrap.^[90]

It was demonstrated that the presence of organic compounds on the scraps might diminish the yield of recovery by up to 10%.^[93]

Therefore, there exist some plants that perform a preliminary step of drying, and removal of ink and varnish.^[87,90,92,94–97] This step must remove the contaminants without oxidizing the aluminum and releasing no pollutant. The cleaning process is carried out by heating the scrap up to 500–600°C;^[87,90,94–97] during this treatment, there is a partial pyrolysis and oxidation of the coatings. The oxygen concentration in the emitted gas is within the range from 6% to 8%.^[94] The gases from the furnace are further incinerated in order to diminish the emission of volatile organic compounds and CO₂.^[90,94,96]

Drosses can also be submitted to a preliminary treatment to avoid oxidation during their slow cooling. The process must be performed where the dross is originally produced. It consists essentially of the quenching of the dross preferentially under an inert gas atmosphere.^[98,99] Another usual treatment is to carry out a hot pressing of the dross. This technique promotes the flow of a part of the aluminum trapped in the dross.^[100,101]

Recycling of EN AW 2011 Aluminum Chips without Remelting

Branimir Lela and Jure Krolo

*Faculty of Electrical Engineering, Mechanical Engineering and Naval Architecture,
University of Split, Rudjera Boskovicica 32, Split, 21000, Croatia*

Abstract

This article deals with the direct recycling of EN AW 2011 aluminum alloy chips, which are formed by turning, into semifinished products using forward hot extrusion process. Direct recycling without re-melting is usually called solid-state recycling. The main aim of this article is to investigate the influence of depth of cut (size of chips) in the aluminum alloy turning process, extrusion temperature, and compaction force on mechanical properties, surface roughness, and extrusion force of recycled samples. An original approach to solve this problem is mathematical modelling of the process using the design of experiments. The influence of main research factors on yield strength ($R_{p0.2}$), hardness (HV), extrusion force (F), and surface roughness (R_a) of recycled samples has been studied. The study has shown that the most influential factor on mechanical properties, surface roughness, and extrusion force was extrusion temperature.

Keywords: Aluminum recycling; Cold compaction; Hot extrusion; Solid-state recycling; Turning.

INTRODUCTION

In modern society, global warming has become a great problem. So scientists and engineers have been looking for new ways of manufacturing and new industrial processes, which will reduce energy consumption and CO₂ emission. One way to reduce environmental pollution is scrap recycling, and aluminum is one of the most recycled metals. In the course of industrial and manufacturing processes, a lot of aluminum scrap results from machining processes (chips); and during conventional re-melting, a lot of material is lost due to burning and mixing with slag. Hence, the main aim of this article is to investigate new ways to recycle aluminum alloy chips to reduce losses. The recycling process without melting phase, so-called solid-state recycling (SSR), was studied. So in this study, chips were cold compacted into billets, and then hot extruded into new semifinished products. The influence of process parameters on the mechanical properties of recycled samples was investigated. Mathematical modeling and statistical methods were used to study the influence of the process parameters on the mechanical properties of the recycled samples and on the extrusion force during processing.

PREVIOUS INVESTIGATION

In the last few years, global awareness about environmental pollution, greenhouse emissions, global

warming, and climate change is emphasized. One of the most important steps to reduce global warming is recycling of metal scrap.^[1–12] Aluminum is the second most widely used metal, and it is commonly recycled by re-melting, which is both economically and ecologically beneficial when compared to primary production because re-melting needs only 5% of the energy required for obtaining aluminum from its ore.^[4] On the other hand, in re-melting, approximately up to 20% of aluminum is lost due to burning and mixing with slag, and this waste is irreversible, so there is a great interest for direct or solid-state recycling through cold compaction and hot extrusion without re-melting, where 95% of aluminum is recovered.^[4,5] Furthermore, according to Chiba et al.,^[12] there is 70% reduction in energy consumption while using SSR, compared to the existing melting method. There are a few ways to realize direct recycling. SSR or direct recycling processes in former investigations are performed via cold compaction, cold and hot extrusion, sintering, friction stir extrusion, and cold and hot rolling, and finally some of the so-called severe plastic deformation-SPD processes are mentioned. Overall, 70% lower impact on environment is achieved by direct recycling using equal channel angular pressing (ECAP), or 62% by spark plasma sintering (SPS) in accordance with the ReCiPe endpoint Europe H/A LCIA method.^[6] Tekkaya et al.^[8] investigated the possibility of recycling aluminum alloy AA 6060 through cold compaction with subsequent hot extrusion and concluded that the

semi-finished samples are possible to produce when high pressure, temperature, and strain level inside the extrusion container are guaranteed. Mechanical and microstructural tests of extruded samples show yield strength to be more than 90% of the conventional solid billet extruded samples, but samples show metallurgical imperfection. Tang W. and Reynold A.P.^[11] researched production of wire from aluminum alloy chips using friction extrusion. Haase M. and Tekkaya A.E.^[13] compared extrusion through a flat face die and ECAP. With both dies and relatively low extrusion ratio 8.5:1, it is possible to produce samples without surface defects. Although ECAP-recycled samples show 10% lower ultimate tensile strength in comparison with the extruded as-cast reference sample using a flat face die, they show 45% higher elongation. Duflou et al.^[6] also mentioned a completely new method for SSR—SPS. Chips bonding is achieved in combination of pressure and joule heat generated by means of high-pulsed DC current flow. Sample hardness is comparable with the as-cast aluminum. Furthermore, various researchers investigated solid-state recycling of various aluminum alloys.^[7–10,12] Obtained samples show mechanical properties similar to the cast material, and also profiles suffered some blistering and internal poring. However, despite the researches described here, solid-state recycling of aluminum chips created by turning or milling is rarely mentioned as well as the influence of turning parameters on direct recycling. Furthermore, one of the main problems in performing SSR is chip contamination with cooling lubricant during milling or turning. Cui J. et al.^[14] investigated thermal and chemical degreasing of aluminum chips. The proposed heating temperature to decompose lubricant is around 294°C, while for chemical degreasing acetone was used. A more detailed explanation of chemical cleaning with acetone and ultrasonic bath can be found in the paper published by Shamsudin S. et al.^[15] They followed ASTM G131-96 standard practice for cleaning materials by ultrasonic techniques, where aluminum chips are degreased with acetone inside an ultrasonic bath for 10 min. In SSR processes, aluminum alloys from the 6xxx families were most investigated, and in this article recycling of chips of EN AW 2011 is presented. This alloy usage is expanded in manufacturing processes. The main aim of this article is to find mathematical models that relate the influence of process parameters with the properties of recycled samples. Experiments were performed and analyzed using response surface method and Box-Behnken design.

EXPERIMENTAL PROCEDURE

Design of Experiment

The main aim of this study is to create mathematical models that relate influence parameters for SSR utilizing hot extrusion process with the mechanical properties of

recycled samples. As influence parameters, according to the previous investigation, aluminum chips size (related with turning depth a_p), cold compaction force (F), and extrusion temperature (T) were selected. A mathematical model can be obtained through design of experiment (DOE), which was realized using the Box-Behnken response surface design (BBD). DOE is followed by analysis of variance (ANOVA) and regression analysis (RA). In the experimental research and modeling, BBD is very often used because it offers optimization possibility and reduction in the number of experiments. Three factorial BBD of experiment demands 12 experiments (each factor on 3 levels), and 5 central experiments, what makes a total of 17 experiments ($N = k^2 + k + c_p$, where k is the number of factors, and c_p is the number of central point replications). Software package Design-Expert was used to generate 17 experimental points shown in Table 1.

Production of Aluminum Chips

Chips of EN AW 2011 were produced by turning a bar using an Iskar tool composed of the tool holder SVJCR 2020K-16 and the cutting insert VCGT 160404-AS IC20. The aluminum bar was in T6 condition, and its chemical composition can be seen in Table 2.

Machining was carried out on a Universal lathe “Prvo-majska” D-420/1500. Cutting speed of $v_c = 350$ m/s and feed rate $f = 0.16$ mm/rev were kept constant. In order to create chips without any lubricant contamination, cooling

Table 2 Chemical composition (wt%) of EN AW 2011

Si	Fe	Cu	Mn	Mg	Zn	Ti	Pb	Bi	Hg	Cd	Al
0.1414	0.5070	5.6631	0.0225	0.0150	0.0120	0.0059	0.5860	0.5603	0.0001	0.0002	92.4492

was achieved using vortex tube Cold Air Gun 610BSP with a dual point nozzle. The temperature of compressed air was -2°C . Cutting depth a_p is a variable factor, and according to the experimental setup its values were 0.5, 1.125, and 1.75 mm. Figure 1 shows three types of aluminum chips obtained during machining. During the turning with a depth of cut 1.75 mm, chips of type A were created, with a long continuous spiral shape and a length of approximately 200 mm, but they were cut into smaller lengths of 25 mm. Type B was created with a depth of cut 1.125 mm. This type of chip also showed a continuous spiral shape, but with lower thickness and length ranged from 25 to 50 mm. The third chip type, labelled as C, was created with a depth of cut 0.5 mm, and these chips were very small, with lengths of a few millimeters and lower thickness. A big difference in chip geometry will serve the purpose in the analysis of its influence on direct-recycling process.

Compacting

The cold compacting phase was performed on a hydraulic press with a maximum force of 1 MN. According to experimental plan, chips were compacted with different forces of 200, 350, and 500 kN to create 17 billets with a minimum height and diameter of 50 and 38 mm, respectively. Compacting force and punch displacement were measured with HBM load cell C6A 1 MN and inductive displacement sensor HBM WAT-50, respectively. Punch velocity was 1 mm/s. Force for ejecting compacted billets out of the die was in the range from 50 to 100 kN depending on the compacting force. Plastic deformation and pressure during the cold pre-compaction did not lead to a sufficient metallic bonding of the individual aluminum chips, and further processes were required. Because of huge reduction in volume, it was needed to compact chips in a few steps so as to achieve the billets with good quality. With first compaction, initial volume was obtained, and new chips were added until a length of at least 50 mm was achieved. For chips created with a depth of cut 0.5 mm, 4–5 steps were needed, for chips created with a depth of cut 1.125 mm, 5–7 compacting steps were needed, and finally for chips created with a cutting depth of 1.75 mm, 7–9 compacting

steps were needed. Compaction rig and compacted billet for sample 4 can be seen in Fig. 2. The cold compaction step to create billets for hot extrusion was time consuming, because it is a discontinuous process with a lot of compaction steps. Some continuous process to achieve billets for extrusion should be investigated in the future.

Hot Extrusion

Hot extrusion was carried out using self-made extrusion rig and the same hydraulic press used for compacting step (Fig. 3). Hot extrusion rig was mounted on the press along with the punch displacement sensor WDS-1000-P60-SR-U and K-type temperature sensor. According to the experimental setup, three temperatures were selected for the hot extrusion process: 300°C , 400°C , and 500°C . Temperature was controlled using Omron temperature regulator E5CC and relay G3PE-225B DC12-24. Each compacted billet was preheated before extrusion on the appropriate extrusion temperature for 30 min. The diameter of the circular orifice of the die was 15 mm, and the diameter of the extrusion container was 40 mm, so an extrusion ratio of 7.11 was achieved. The ram speed was 1 mm/s.

After hot extrusion, some samples show very good surface quality without any blistering or cracks, but some products show little imperfections occurred due to impurities in material, but for all samples the overall surface quality was rather good. It can be noticed that the beginning of the process has not provided sufficient chip bonding due to lack of pressure and plastic deformation, and the first part of the produced sample was not used for any mechanical properties investigation.

RESULTS AND ANALYSIS

In order to determine $R_{p0.2}$ of extruded products, testing of mechanical properties was carried out on a universal testing machine Instron 8801. Specimens for the tensile testing were prepared in accordance with the EN 10002-1 standard (gauge diameter was 5 mm). Figure 4 shows a broken sample after tensile testing.

**Fig. 1** Different sizes of chips

Fig. 2 Compaction rig (left), compacted billet (right)

Fig. 3 Extrusion rig (left) and die (right)

Yield Strength

The $R_{p0.2}$ was obtained by drawing a line at the same slope as the initial portion of the stress–strain curve through the point 0.002 on the strain axis. This line intersects the stress–strain line slightly after it begins to curve, and that intersection is defined as the $R_{p0.2}$ with a 0.2% offset. Results of $R_{p0.2}$ measurement for all 17 samples are given in Table 3.

Recycled specimens show yield strengths from 79 to 137 MPa. Highest $R_{p0.2}$ of 137 MPa was obtained for

sample 12, which is obtained with 300°C extrusion temperature, 1.75 mm cutting depth (biggest chips), and 350 kN compaction force. Analysis of the results was done by ANOVA and RA using computer software “Design-Expert”. A quadratic mathematical model was suggested for $R_{p0.2}$ and ANOVA showed that compaction force and interactions AC and BC are insignificant factors. After insignificant factors were excluded (except those that support mathematical hierarchy), the equation for predicting $R_{p0.2}$ model was given in the following form:

$$R_{p0.2} \text{ (MPa)} = 340.799 + 54.54 \cdot A - 1.1095 \cdot B - 0.3026 \cdot C - 0.192 \cdot A \cdot B + 14.336 \cdot A^2 + 1.56 \cdot 10^{-3} \cdot B^2 + 4.489 \cdot 10^{-4} \cdot C^2 \quad (1)$$

where A , B , and C are depth of cut, extrusion temperature, and compaction force, respectively. Figure 5 graphically presents the influence of extrusion temperature, depth of cut, and compaction force on yield strength. R -Squared, Adj R -Squared, Pred R -Squared, and Adeq Precision for this model were obtained as 0.93, 0.87, 0.79, and 13.3, respectively.

Surface in Fig. 5 shows that for the highest depth of cut, $R_{p0.2}$ increases when extrusion temperature decreases, while the compaction force remains constant. $R_{p0.2}$ also

9	94		

Fig. 4 Sample after tensile testing

Fig. 5 Graphical presentation of extrusion temperature and effect of depth of cut on yield strength (compaction force remains constant, $F = 500$ kN)

increases when the depth of the cut increases, and the extrusion temperature is within the range of 300°C–400°C.

Thus, bigger chips are better for achieving higher $R_{p0.2}$ at lower extrusion temperature. However, for extrusion temperature between 400°C and 500°C, the yield strength slightly decreases with the depth of cut increment. According to some authors, chip size has no influence on mechanical properties,^[8] but on the other hand, according to Marcel W.,^[16] chip size influence on mechanical properties is important. Furthermore, according to Fogagnolo et al.,^[17] a small extrusion ratio of 6.25, which is closer to the 7.11 extrusion ratio used in this case, is not enough to produce recycled samples free of voids and cracks. These imperfections could have a big impact on yield strength. Microstructure investigation is suggested for future research.

Hardness

Hardness was measured using the Vickers testing device. A diamond pyramid penetrates into the specimen and leaves an imprint onto the surface. Based on the size of the pyramid imprint hardness can be calculated. Measured hardness values for each sample are given in Table 4.

Recycled specimens had hardness in the range from 58.12 to 75.58 HV. These samples were not submitted to heat treatment after extrusion process. So they showed lower values than the reference sample made of EN AW 2011, which was in T6 condition. Results were analyzed with computer software “Design-Expert,” and a linear mathematical model was obtained as follows:

$$HV = 66.28 + 2.80 \cdot A + 5.36 \cdot B - 1.14 \cdot C \quad (2)$$

Table 4 Vickers hardness of all samples

Sample	Hardness (HV)	Sample	Hardness (HV)
1	61.7	10	64
2	58.9	11	73.2
3	63.9	12	72.7
4	71.2	13	74.4
5	64.7	14	66.6
6	58.1	15	75.6
7	61.2	16	74.2
8	58.9	17	63.4
9	63.9		

In Figs. 6 and 7, the influence of extrusion temperature, compaction force, and depth of cut on hardness of recycled specimens can be seen. According to Figs. 6 and 7, it can be seen that hardness increases when extrusion temperature increases. That is also confirmed with ANOVA, which confirmed that the extrusion temperature is the most significant factor regarding its influence on hardness. Also, according to RA, the hardness values decrease if solid-state recycling is carried out with smaller values of depth of cut or smaller chips. Explanation for hardness increment with higher extrusion temperature is because solution temperature for aluminum AW 2011 alloy is around 500°C. In this

process, preheating time was 30 min and for some samples extrusion temperature was 500°C. It is possible that after the extrusion process, natural aging occurred in recycled specimens. Natural aging contributes in the creation of fine precipitations. These precipitations are intermetallic compounds usually characterized as Al_2Cu . Precipitations increase hardness due the interactions with dislocations.^[19]

Thus, recycled samples with bigger chips have better hardness. Furthermore, according to the surfaces in Figs. 6 and 7, hardness values slightly decrease with higher compaction force, but ANOVA showed that the cold compaction force has the least impact on hardness.

Surface Roughness

The surface roughness measurement was carried out after machining by turning a bar using an Iskar tool composed of the tool holder SVJCR 2020K-16 and the cutting insert VCGT 160404-AS IC20. Machining was carried out on a Universal lathe “Prvomajska” D-420/1500. Surface roughness measurement was carried out utilizing an SJ 301 device manufactured by Mitutoyo.

The R_a is the area between the roughness profile and its central line, or the integral of the absolute value of the roughness profile height over the evaluation length. It is necessary to calibrate device on a reference sample before measurement. Furthermore, in order to determine R_a , it is necessary to define the reference length. The mentioned length is defined in accordance with the type and fineness of the sample surface. The adopted reference length for these experiments was 2.5 mm. In Table 5, results of surface roughness for each sample are presented.

Surface roughness for recycled specimens is in the range from 3.17 to 9.505 μm . A minimal value of R_a was obtained for samples extruded on 500°C, with $a_p = 1.75$ mm and $F = 350$ kN. ANOVA procedure indicated that the insignificant factor is cutting depth and insignificant interactions are AB , AC , A^2 , and B^2 . Insignificant members are discarded and a quadratic mathematical model was obtained as follows:

$$R_a = 5.93 - 0.19 \cdot A - 1.22 \cdot B - 0.92 \cdot C + 1.17 \cdot B \cdot C + 1.39 \cdot C^2 \quad (3)$$

Figure 8 is a graphical representation of the obtained model. According to the picture and the model, most significant factor is extrusion temperature. That is also confirmed with ANOVA and RA.

According to the obtained mathematical model and Fig. 8, surface roughness is decreased using a higher temperature for SSR. When the process is performed at lower extrusion temperature of 300°C, according to Fig. 8, a higher compaction force (350 to 500 kN) significantly reduces surface roughness. When SSR is performed at 500°C, the cold compaction force influence on surface roughness is negligible. Results are very interesting because usually higher process temperatures cause crystal grain coarsening, which increases surface roughness. In this case, the higher temperature is better to achieve recycled samples without any cracks and voids. Higher temperature reduces flow stress and creates better bonds between recycled chips.^[18] Compaction force as well can attribute for better chip connection, especially when the SSR process was performed at 300°C. On the other hand, compaction force does not have influence on $R_{p0.2}$ and hardness.

Table 5 Measurement results of surface roughness (R_a) for recycled samples after machining

Maximal Extrusion Force

In this article, extrusion force necessary to preform SSR was also investigated. Maximal extrusion force for each sample was determined indirectly by measuring the pressure inside the hydraulic press cylinder, using a pressure sensor P15RVA1/500. In Table 6 values of extrusion force obtained for each sample are given.

Maximal extrusion force is in the range from 209.6 to 531.6 kN. According to ANOVA, insignificant factors are pre-compaction force and the interactions AC , BC , A^2 , and C^2 . These insignificant members are discarded and a mathematical model is suggested in the following form:

$$F = 306.41 + 19.05 \cdot A - 138.19 \cdot B + 7.81 \cdot C - 24.72 \cdot A \cdot B + 51.9 \cdot B^2 \quad (4)$$

Table 6 Measurement results of extrusion force necessary to perform SSR

Sample	Maximal extrusion force (kN)	Sample	Maximal extrusion force (kN)
1	420.2	10	291.9
2	495	11	229.7
3	314.4	12	539.2
4	209.6	13	223.5
5	320.3	14	294.5
6	531.6	15	217.7
7	315.5	16	311.1
8	296.6	17	300.7
9	312.7		

Graphical representation of the obtained model is shown in Fig. 9. According to this model, the most influence factor on extrusion force is temperature, as expected. More interesting is cutting depth influences at lower extrusion temperature. When the extrusion process is performed at 300°C, the extrusion force is highest, but for smaller chips ($a_p = 0.5$ mm) it is slightly reduced than that for bigger chips ($a_p = 1.75$ mm). When process is performed at 500°C, chips size influence is negligible.

CONCLUSION

1. Extrusion temperature is the most significant factor that influences $R_{p0.2}$. With higher extrusion temperature, $R_{p0.2}$ decreases. The range of $R_{p0.2}$ for all samples was from 79 to 137 MPa. Smaller chips reduce $R_{p0.2}$ at extrusion temperature in the range from 300°C to 400°C, while for extrusion temperature in the range of 400°C to 500°C, yield strength decreases with the depth of cut increment. Additional heat treatment was not performed and is suggested for future investigation.
2. Hardness increases with higher extrusion temperature and with the higher depths of cut (bigger chips). The range of hardness was from 58.12 to 75.58 HV.
3. Most influence factor on surface roughness is extrusion temperature. At lower extrusion temperature, R_a can be significantly reduced using higher pre-compaction force. Chip size influence is negligible.
4. As was expected using higher extrusion temperature, maximal extrusion force was reduced. When process is performed at lower temperature, extrusion force can be reduced using smaller chips. Pre-compaction force has minor influence on extrusion force.

Design-Expert® Software

Extrusion force (kN)

X1 = A: Cutting depth (mm)

X2 = B: Extrusion temperature (°C)

Actual Factor

C: Compaction force (kN) = 350.0000

Fig. 9 Graphical presentation of extrusion temperature and, effect of depth of cut on extrusion force (compaction force remains constant, $F = 350$ kN)

Higher extrusion temperature reduces extrusion force as well as surface roughness. If a process is performed at lower temperature, to spend less energy, higher pre-compaction force and smaller chips are suggested to reduce extrusion force as well as surface roughness. Furthermore, to achieve higher values of yield strength, bigger chips and lower extrusion temperature are suggested. On the other hand, to increase hardness it is better to perform process at 500°C. According to previous investigations, an extrusion ratio of 7.11 was not enough to create samples without voids and cracks at 300°C,^[17] so future investigations on microstructure should be carried out.

Abstract

Stamping-forging processing can significantly reduce the residual stress of sheet metal parts. First, the variation of residual stress field during stamping-forging processing and the influence of relative bending radii and forming temperature on the residual stresses of stamping-forged V-shaped parts have been studied by finite-element analysis. Then, the stamping-forging processing has been employed in the forming of 2024 aluminum alloy square cups with nonuniform thickness to investigate the effects of process parameters, such as punch radius, die entrance radius, and die corner radius, on the residual stresses of stamping-forged square cups. The optimum process parameters of stamping-forging have been obtained, which can produce square cups with low residual stresses, that is, the maximum residual stress value can be reduced from 190 MPa for deep drawn square cups to around 60 MPa for stamping-forged square cups. Therefore, it is indicated that the stamping-forging processing can significantly reduce the residual stress of sheet metal parts.

Keywords: 2024 Aluminum alloy, Finite-element simulation; Sheet metal; Stamping-forging processing; Residual stress.

INTRODUCTION

The stamping-forging process is a metal-forming technology, which combines the stamping and forging of sheet metal parts. In a stamping-forging process, stamping or drawing is used to form the spatial shape of the part first, and a bulk forming is then employed to form the local thickened feature.^[1] This forming method can not only produce sheet metal parts that have local thickened or small radius features but also adjust the residual stress of sheet metal parts. In recent years, the stamping-forging process has been widely used in sheet metal plastic forming. Wang et al.^[2] proposed a stamping-forging process to make a double-layer cup with different wall thicknesses. The outer cylinder was first formed by forward drawing, and then the inner cylinder was formed by powerful backward drawing. In the end, the inner cylinder was thickened from 2 to 4 mm by upsetting. Wang et al.^[3] also adopted a stamping-forging process to form flywheels with thickened walls, which were traditionally formed by methods such as cutting and weld assembling. By upsetting the cup wall after stamping, the wall thickness of flywheel was increased from 10 to 17 mm. Tan et al.^[4] developed a two-stage forming process of tailor blanks and conducted local thickening to control the distribution of wall

thickness of stamped parts. The target portion of the sheet for local thickening was drawn into the die cavity in the first stage, and then the drawn portion was compressed with a flat die in the second stage, a 12% increase in the blank thickness was obtained. Wu and Altan^[5] upset the flange wall after flanging during forming clutch hubs, aiming to obtain a sharp external radius at the flange bottom. Mori et al.^[6] developed a two-stage cold stamping process to form magnesium alloy square cups having small bottom radii from magnesium alloy sheets. In the first stage, a square cup having large radius at the bottom circular arc was formed by deep drawing using a punch with a large radius, and then the radius of the bottom circular arc of the square cup was decreased by compressing the side wall in the second stage.

Residual stresses are self-equilibrium internal stresses that exist in manufactured parts without external forces and constraints.^[7] The mechanical properties and dimensional stability of parts are significantly affected by residual stresses. For materials with specific yield points, the existence of residual stresses plays the role of pre-stressing and causes changes in the yield strength.^[8] In addition, the residual tensile stresses on the material surface are undesirable as it can lead to the reduction of fatigue life and make the material vulnerable to stress corrosion cracking.^[9–11]

Even worse, in the subsequent machining processes, the release and redistribution of the residual stresses usually result in distortions, which significantly reduce the dimension accuracy of products.^[12] Therefore, it is necessary to reduce the residual stress in manufactured parts.

During stamping-forging, the tensile stress, which is generated by the tensile deformation in the stamping step, can be offset by the compression deformation in the subsequent upsetting step. Hence, residual stresses can be reduced in the sheet metal parts after unloading. This principle of tensile and compressive stress offsetting each other and reducing residual stresses in parts is also used in many forming processes. Ragab^[13] showed that by reducing the tool clearance, ironing occurred simultaneously with deep drawing, through which a great reduction of residual stresses was realized. M. Koc et al.^[14] utilized compression and stretching processes to reduce the residual stress of quenched 7050 aluminum alloy forged blocks and found that both methods can reduce the residual stress by more than 90%. Maeda et al.^[15] give a light press on the sheet metal edge for reducing tensile residual stress of sheet metal. Their results showed that the optimum pressure is proportional to 1% proof stress, and the proportion ratio was 110%–130% regardless of the maximum residual stress and mechanical properties.

In this study, the variation of residual stress field during stamping-forging process and the effects of relative bending radii and forming temperature on the residual stresses of stamping-forged V-shaped parts were first studied by the finite-element analysis. The stamping-forging processing was then employed in the forming of 2024 aluminum alloy square cups with nonuniform thickness to investigate the effects of process parameters, such as punch radius, die entrance radius, and die corner radius, on the residual stresses of stamping-forged square cups. In the end, the optimum process parameters of stamping-forging were obtained, which can produce square cups with low residual stresses.

RESIDUAL STRESS DURING STAMPING-FORGING

Finite-Element Model of Bending-Upsetting

In order to investigate the variation regularity of residual stress field during stamping-forging processing, a bending-upsetting model of V-shaped parts was proposed in this study, as shown in Fig. 1. r is the inner radius of the bending round corner, t is the thickness of sheet, α is the bending angle, and s is the distance between punch and sheet. The relative bending radius is calculated by r/t . The thickening degree of upsetting can be determined by the ratio of s to t . First, the punch is pushed down until the distance between the die and the punch reaches t . In this process, the bending deformation of sheet occurs. Then the punch is fixed after it is shifted up to a distance of s . Both pressing blocks on each side are pushed along the inclined

Fig. 1 Schematic of the stamping-forging processing

wall of the die. The thickening of sheet is realized with upsetting force, and the sheet finally fits with the punch. In the upsetting process, plastic deformation occurs at both the round corner and straight side of the sheet.

Three relative bending radii ($r/t = 2, 3, 4$) and two temperatures ($T = 25^\circ\text{C}$, and 200°C) were selected in the numerical analysis of the stamping-forging of 2024 aluminum alloy V-shaped parts. The bending angle α was 90° , and the thickening degree s/t was 10%. The material used in this study was cold-rolled 2024 aluminum alloy plates with 60mm in width and 2mm in thickness. The length of V-shape part was assumed very long, its deformation can be regarded as a plane-strain problem. Thus, a 2D finite-element model of the stamping-forging processing was established by Abaqus/Explicit. The Young's modulus and Poisson's ratio of the material were 72 GPa and 0.31, respectively. The friction coefficient between blank and tools was 0.1. During bending-upsetting process, the bending punch moved downward at a speed of 2 mm/s until the blank was bended to 90° angle. Then, the punch was shifted up 0.2mm. The upsetting punch upset the side wall also at a speed of 2 mm/s. The upsetting stroke was 5 mm along the side wall. Finally, all dies were removed, and the residual stress field of the part was calculated by Abaqus/Standard.

Residual Stress Field after Bending and Upsetting

After stamping-forging, the distribution of x -axis residual stress σ_x along the thickness at the bending section was determined. The measurement path of σ_x is shown in Fig. 2. The variation of the residual stresses in the V-shaped part ($\alpha = 90^\circ$, $r/t = 3$, $T = 25^\circ\text{C}$, and 200°C) during stamping-forging are shown in Fig. 3.

As shown in Fig. 3, the residual stress in bended parts is tensile in the inner surface and presents a

Fig. 2 Measurement path of x -axis residual stress at the bending section

Fig. 3 Comparison of residual stress field before and after stamping-forging ($\alpha = 90^\circ$, $r/t = 3$)

tensile-compressive-tensile-compressive distribution from the inner surface to the outer surface. On both sides of the plate's neutral layer, there exist two peak values of residual tensile and compressive stresses. However, the residual stress distribution after upsetting has been changed. The residual tensile stress in the inner surface is transformed into residual compressive stress, and the residual stress distribution along the thickness direction varies as compressive-tensile-compressive from the inner surface to the outer surface.

When the forming temperature is 25°C , the maximum residual tensile stress can be reduced from $+256.1$ MPa in the bended part to $+74.3$ MPa in the stamping-forged part, with a reduction magnitude of 70.9%. The maximum residual compressive stress can be reduced from -299.8 to -76.3 MPa, with a reduction magnitude by 74.5%. When the forming temperature is 200°C , the maximum residual tensile stress and the maximum compressive stress values in the V-shaped part are reduced by 82.3% and 86.6%, respectively. According to the aforementioned analysis, the stamping-forging processing can significantly reduce the residual stress in sheet metal, and the maximum residual stress reduction is more than 70% after stamp-forging.

The stamping-forging processing can adjust the residual stress field by changing the deformation mode of the bending round corner. The plate is divided into two regions in the bending process. The inner layer is compressed, and compressive strain occurs. The Outer layer is stretched, and tensile strain occurs. During the upsetting process, the tensile strain of the outer layer is compensated and tends to be compressive strain. Hence, residual stresses can be reduced in the V-shaped parts after unloading.

Effect of Bending Process Parameters on Residual Stresses

The residual stress distributions in the stamping-forged V-shaped parts under various deformation conditions are

shown in Fig. 4. According to the simulation results, by increasing the relative bending radii from 2 to 4 mm, the residual stresses in the stamping-forged V-shaped parts can be reduced from -100 to $+100$ MPa to -60 to $+40$ MPa. It is indicated that increasing the relative bending radius can reduce the residual stress.

Increasing the forming temperature leads to lower residual stress. For example, when the relative bending radii is 2 mm, by increasing the forming temperature from 25°C to 200°C , the residual stresses in the stamping-forged V-shaped parts can be reduced from $+96.2$ to -90.2 MPa to $+52.3$ to -47.3 MPa, the maximum residual stress value is reduced by 45.6%.

STAMP-FORGING FORMING OF SQUARE CUPS WITH LOW RESIDUAL STRESS

Features and Property Requirement of Square Cup

An aluminum alloy flanged square cup, which is commonly used as a support structural part in satellites, is shown in Fig. 5a. Figure 5b shows the dimensions of the longitudinal section of the square cup along the symmetrical curve OM. As shown in Fig. 5b, this part exhibits large surface area and nonuniform thickness distribution. The side-wall thickness is 3.5 mm, while the bottom and flange thicknesses are both 5 mm. At the same time, in order to ensure the reliability of the part, when it is used in space, low values of residual stresses are required.

Stamp-Forging Forming Scheme of Square Cup

Considering the structural characteristics and mechanical property requirements of the square cup, authors prompt the stamping-forging process to make this type of sheet metal parts. The spatial shape of the square cup is formed by stamping first, and then forging is used to adjust and control the wall thickness and residual stress. The three steps of the stamping-forging process are deep drawing, ironing, and upsetting. An aluminum alloy sheet with a thickness of 5 mm is deep drawn in the first step to obtain the spatial shape. Then the side-wall thickness of the square cup is reduced from 5 to 3.5 mm by ironing. In the last step, the flange of the ironed square cup is gradually flattened. Meanwhile, the residual stress in the square cup is adjusted. Figure 6 shows the schematic diagram of the three steps of the stamping-forging processing.

Finite-Element Model of Stamp-Forging Forming

The effects of process parameters, such as punch radius R_p , die entrance radius R_d , and die corner radius R_c on the residual stresses of stamping-forged square cups were investigated by FE analysis. As shown in Fig. 7, a

Fig. 4 The simulated residual stress after stamping-forging under different deformation conditions: (a) $r/t = 2$, (b) $r/t = 3$, and (c) $r/t = 4$

Fig. 5 The aluminum alloy square cup with nonuniform thickness: (a) the three-dimensional figure of the square cup, and (b) the dimensions of the square cup

3D elastic-plastic coupled thermo-mechanical FE model of deep drawing of square cups with 2024 aluminum alloy sheet blanks was established by using ABAQUS/Explicit. Due to symmetry, only a quarter of the model was simulated. The tools were considered to be rigid but non-isothermal.

The mechanical and thermal properties of the 2024 aluminum alloy material are listed in Table 1. In order to assure that the sheet blanks have enough ductility to stamp-forging of square cups, the forming temperature was

selected at a temperature of 400°C. The initial temperature of the dies was 200°C. Stamp-forging non-isothermal calculations were carried out by using an explicitly coupled temperature-displacement formulation. The friction coefficients were 0.1 between blank and tools. During the stamping-forging process, the blank was deep drawn at a speed of 10 mm/s first until the height of side wall is 60 mm, and then the drawing dies were removed. The drawn part was stayed for 3 s to simulate the temperature change of part transfer from drawing dies to ironing dies.

Fig. 6 Schematic diagram of the three steps of the stamping-forging processing of square cup of (a) deep drawing, (b) ironing, and (c) upsetting

Fig. 7 The FE model of the square cup deep drawing based on ABAQUS/Explicit

Table 1 Mechanical and thermal property parameters of the 2024 aluminum alloy

Parameters	Values
Density (kg/m ³)	2780
Poisson's ratio	0.31
Young's modulus (GPa)	72~ 40 (temperature-dependent)
Specific heat (J/(kg·K))	924
Thermal expansion coefficient (1/K)	6.6e-5
Thermal conductivity (W/(m·K))	190
Heat transfer coefficient (blank-tools) (W/(m ² ·K))	2000
Heat transfer coefficient (blank-environment) (W/(m ² ·K))	40

Then the drawn part was ironed also at a speed of 10 mm/s in preheated ironing dies with a temperature of 200°C. After ironing, the ironing dies were removed immediately,

and the ironed part was also stayed for 3 s. Finally, the part was upset in preheated upsetting dies at a speed of 10 mm/s. After upsetting, the upsetting dies were removed, and the part was cooled down to room temperature (25°C). Then, the residual stresses in the stamping-forged square cups were calculated based on an implicit formulation.

Residual Stress Analysis during Stamp-Forging Forming

Before analyzing the simulation results of residual stresses, two characteristic points were selected at the bottom and the cup wall of square cup along the symmetrical curve OM, as shown in Fig. 8. These two points are named as Points O, and A, respectively. Moreover, in order to accurately analyze the variation of the residual stresses along the thickness direction in the square cups during stamping-forging, the points at the two locations of the square cup kept consistent, respectively, under various steps.

The variation of the residual stresses along the thickness direction in the square cups during stamping-forging was investigated, by setting the punch radius R_p as 14 mm, die entrance radius R_d as 10 mm, and die corner radius R_c as 17 mm. The width direction and tangential residual stress distributions in the bottom and cup wall of square

Fig. 8 Locations of the points O and A and residual stresses directions

Fig. 9 Width direction and tangential residual stress distributions along the thickness direction at point O during stamping-forging processing of (a) width direction residual stress and (b) tangential residual stress

cup during stamp-forging processing are shown in Figs. 9 and 10, respectively.

It is seen in Figs. 9 and 10 that the residual stress values in the bottom and cup wall of square cups decrease gradually during stamping-forging processing. In the deep drawn square cup, the width direction and tangential residual stress along the thickness direction of the bottom are tensile in the outer layer while compressive in the inner layer. However, in the stamping-forged square cup, they change to a compressive-tensile-compressive distribution from the outer surface to the inner surface. The width direction residual stresses at point O can be reduced from +176.9 to -55.8 MPa in the deep drawn square cup to +1.5 to -33.2 MPa in the stamping-forged square cup (Fig. 9a), the maximum residual stress value is reduced by 81.2%, the tangential residual stresses at point O can be reduced from +131.2 to -105.7 MPa in the deep drawn square cup to +30.6 to -13.2 MPa in the stamping-forged square cup (Fig. 9b), the maximum residual stress value is reduced by 76.7%.

In the deep drawn square cup, the width direction and tangential residual stress along the thickness direction of the cup wall are a compressive-tensile-compressive distribution from the outer surface to the inner surface. However, in the stamping-forged square cup, they change to a compressive in the outer layer and tensile in the inner layer. The width direction residual stresses at point A can be reduced from +49.2 to -166.9 MPa in the deep drawn square cup to +8.0 to -46.8 MPa in the stamping-forged square cup (Fig. 10a), the maximum residual stress value is reduced by 72.0%, the tangential residual stresses at point A can be reduced from +135.2 to -190.0 MPa in the deep drawn square cup to +48.0 to -61.2 MPa in the stamp-forged square cup (Fig. 10b), the maximum residual stress value is reduced by 67.8%.

According to the above analysis, the maximum residual stress value can be reduced from 190 MPa for a deep drawn square cup to around 60 MPa for a stamping-forged square cup; the maximum value is reduced by 70%.

Effect of Process Parameters on Residual Stresses

Effect of Punch Radius on Residual Stresses

The effect of punch radius on the residual stress was investigated, by changing the punch radius from 8 to 14 mm with an interval of 2 mm. At the same time, the die entrance radius was 10 mm, and the die corner radius was 17 mm. The width direction residual stress distributions in the bottom and cup wall of hot stamping-forged square cup with various punch radii are shown in Fig. 11.

Increasing the punch radius gives lower values of the residual stresses in the bottom and cup wall of hot stamping-forged square cups. According to the simulation results, by increasing the punch radius from 8 to 14 mm, the width direction residual stresses at point O can be reduced from +31.5 to -75.2 MPa to +1.5 to -33.2 MPa (Fig. 11a), the maximum residual stress value is reduced by 55.9%, the width direction residual stresses at point A can be reduced from +15.7 to -59.3 MPa to +8 to -46.8 MPa (Fig. 11b), the maximum residual stress value is reduced by 21.1%.

Effect of Die Entrance Radius on Residual Stresses

The effect of die entrance radius on the residual stress was investigated, by setting the die entrance radius as 10, 13, 15, and 17 mm, respectively. At the same time, the punch radius was 14 mm, and the die corner radius was 17 mm. The width direction residual stress distributions in the bottom and cup wall of hot stamping-forged square cup with various die entrance radii are shown in Fig. 12.

It is seen in Fig. 12 that a smaller die entrance radius reduces the residual stresses in the bottom and cup wall of hot stamping-forged square cups. According to the simulation results, by decreasing the die entrance radius

Fig. 10 Width direction and tangential residual stress distributions along the thickness direction at point A during stamping-forging processing of (a) width direction residual stress and (b) tangential residual stress

Fig. 11 Width direction residual stress distributions along the thickness direction under various punch radii of (a) point O and (b) point A

Fig. 12 Width direction residual stress distributions along the thickness direction under various die entrance radii of (a) point O and (b) point A

Fig. 13 Width direction residual stress distributions along the thickness direction under various die corner radii of (a) point O and (b) point A

from 17 to 10 mm, the width direction residual stresses at point O can be reduced from +29.6 to −64.7 MPa to +1.5 to −33.2 MPa (Fig. 12a), the maximum residual stress value is reduced by 48.7%, the width direction residual stresses at point A can be reduced from +31.1 to −61.2 MPa to +8 to −46.8 MPa (Fig. 12b), the maximum residual stress value is reduced by 23.5%.

Effect of Die Corner Radius on Residual Stresses

Investigations on the effect of die corner radius on the residual stress were carried out by using dies with die corner radii of 8, 10, 13, 15, and 17 mm. At the same time, the punch radius was 14 mm, and the die entrance radius was 10 mm. The width direction residual stress distributions in the bottom and cup wall of hot stamping-forged square cup with various die corner radii are shown in Fig. 13.

It is shown that a large die corner radius reduces the residual stresses in the bottom and cup wall of hot stamping-forged square cups. According to the simulation results, by increasing the die corner radius from 8 to 17 mm, the width direction residual stresses at point O can be reduced from +26.6 to −68.6 MPa to +1.5 to −33.2 MPa (Fig. 13a), the maximum residual stress value is reduced by 51.6%, the width direction residual stresses at point A can be reduced from +22.8 to −71.7 MPa to +8 to −46.8 MPa (Fig. 13b), and the maximum residual stress value is reduced by 34.7%.

Hot Stamp-Forging Experiments and Residual Stress Measurement

During the stamping-forging experiments, the forming temperature was 400°C, punch radius R_p was 14 mm, die entrance radius R_d was 10 mm, and die corner radius R_c was 17 mm. Stamping-forging experiments were performed on a 500 tons double action deep drawing hydraulic press.

Before the stamping-forging experiments, both the die and the punch were heated to 400°C by using electric heating rods and the blank was heated in a box resistor-stove. Both surfaces of the die and punch were lubricated by spraying water-based graphite at the beginning. After the blank had reached the forming temperature, it was placed on the pre-heated die and stamped immediately. The punch speed was 10 mm/s.

In this research, the layer removal and X-ray diffraction were employed to determine the tangential residual stresses distribution along the thickness direction for the stamping-forged square cups. Electro-polishing was applied for removing the material with a thin layer. The layer thickness removed in each increment of electro-polishing test was 0.2 mm. After the layer had been removed, the X-ray diffraction method was applied to determine the residual stress magnitudes at the surface. All the measurements were finished using an X-350A X-ray stress analyzer. The operation voltage and current were 27 kV and 7 mA. Al (311) was selected as the measured crystal face, and the diffraction angle 2θ ranged from 136° to 143°.

Figures 14a,b display the tangential residual stresses at point O and A obtained from FE simulations and experimental measurements carried out at $R_p = 14$ mm. The residual stress values of experimental measurement are a little larger than that in FE simulation. Even so, the FE simulation results agree well with the experimental measurement data not only at residual stresses distributions but also at residual stresses values.

CONCLUSION

The residual stress during stamping-forging processing of 2024 aluminum alloy sheet metal was studied in the presented study by both finite-element analysis and

Fig. 14 Tangential residual stresses obtained from FE simulations and experimental measurements of (a) at point O and (b) at point A

experimental approach. The following conclusions can be obtained:

1. The stamping-forging process can adjust the residual stress field by changing the deformation mode of sheet metal. After stamping-forging, the maximum residual stress value of V-shaped part is reduced by more than 70%.
2. Increasing the relative bending radius and forming temperatures results in lower residual stress in stamping-forged V-shaped parts.
3. Larger punch radius and die corner radius, and smaller die entrance radius are conducive to obtaining lower residual stresses in stamping-forged square cup.
4. The maximum residual stress value can be reduced from 190 MPa for a deep drawn square cup to around 60 MPa for a stamping-forged square cup; the maximum value is reduced by 70%.

Abstract

Retrogression and re-aging (RRA) treatment was introduced to increase the stress corrosion cracking (SCC) resistance while retaining the strength attainable in T6 (peak aged) temper. Retrogression is a short-term heat treatment at an elevated temperature wherein a partial dissolution of metastable precipitates occurs, which are responsible for the hardening. During the next step, the material is re-aged in the regime of typical age hardening parameters to restore the strength with improved ductility. Response of RRA treatment has been reported on AA7XXX series Aluminum alloys such as AA7075, AA7050, AA7150, AA7049, and AA7010. Studies have been done on the effect of RRA on microstructure, mechanical properties such as tensile and hardness, corrosion, exfoliation corrosion, and SCC resistance by various researchers. The key characteristic of RRA is retrogression, which makes the re-precipitation in the matrix and coarsening of grain boundary precipitates such as MgZn_2 , η' . The retrogression treatment however requires high temperature and a short time, which limits the industrial application of RRA, especially in the heat treatment of the components with large cross section, due to the inherent thermal conductivity limitations. Hence, further work needs to be done in this area to apply this specialized heat treatment for industrial applications. This article brings out a comprehension of the changes in microstructure, tensile properties, and corrosion resistance of the various commonly used AA7XXX Aluminum alloys in structural applications with RRA heat treatment. The future scope of the work in RRA heat treatment is also discussed in this article.

Keywords: AA7XXX; AA7049; AA7075; AA7150; Corrosion resistance; Exfoliation corrosion; Fatigue; Mechanical properties; Microstructure; PFZ; Retrogression and re-aging; SCC.

INTRODUCTION

Aluminum alloys belonging to the AA2XXX (Al–Cu–Mg), the AA6XXX (Al–Si–Mg), and the AA7XXX (Al–Zn–Mg–Cu) series have been the most widely used materials in aircraft industries during the last few decades.^[1–3] They are well known as precipitation-hardenable alloys that rely on the precipitation of fine coherent precipitates for strengthening the material. AA7XXX series alloys have applications in transport field including marine automotive and aviation due to their high specific strength ratio. However, this series is prone to stress corrosion cracking (SCC) when used in high strength temper (T6). The corrosion resistance of the AA7XXX series Al alloys can be modified by heat treatment. It is known that the AA7XXX series Al alloys when heat treated to T6 temper possess

high strength, but their SCC resistance gets deteriorated.^[4] In AA7XXX Aluminum alloys, the precipitation sequence is as shown below:^[5–7]

The supersaturated solid solution results in metastable η phase precipitation, which causes peak hardening in T6 temper. Guinier Preston (GP)-I and/or GP-II zones are precursors to the η' phase. The ageing behavior, sequence of precipitation and dissolution reactions, and microstructural features of the Al–Zn–Mg alloys have been assessed by various techniques.^[8–13] The control of size and volume fraction of these phases during the early stages is important for obtaining optimized properties in the AA7XXX Aluminum alloys.^[14] The chemical composition, morphology,

size, and shape of η' phase have been studied widely. The η' and η phases have been found to have composition similar to MgZn_2 . These phases have hexagonal plate-like structure that grow preferentially on the $\{111\}$ plane of the Al matrix.^[6,7,14,15]

An increase in corrosion resistance has been achieved by overaging to T73, T74, T76, and T77 heat treatment/thermo mechanical treatment. However, the strength of the overaged AA7XXX series Al alloys is decreased by 5%–10%.^[16] Retrogression and re-aging (RRA) treatment was introduced by Cina et al.^[17] to increase the SCC resistance, while retaining the strength of the T6 temper.^[18] Retrogression is a short-term heat treatment at an elevated temperature, wherein a partial dissolution of metastable precipitate occurs, which is responsible for the hardening.^[19] In the next step of the RRA heat treatment, the material is re-aged with parameters typical of the age hardening regime.^[17]

LITERATURE

RRA treatment has been studied in different AA7XXX series Aluminum alloys such as AA7075, AA7050, AA7150, AA7049, and AA7010. The typical compositions of these alloys are shown in Table 1. Studies have been done on the microstructure, mechanical properties such as tensile and hardness properties, and SCC resistance in these alloys. AA7075 is widely used in aircraft structural applications, where the material is prone to both SCC and exfoliation corrosion (EC). The effect of RRA treatment on microstructure and corrosion properties of AA7075 were extensively studied.^[20–23] A study on the effect of RRA heat treatment on the microstructure and the mechanical properties of Aluminum alloy AA7050 was also carried out.^[24–26] The influence of retrogression temperature on the mechanical properties and EC behavior of Aluminum alloy AA7150 has been studied.^[26–27] The influence of multistage heat treatment on the properties and microstructure of AA7049 Aluminum alloy was investigated.^[28] The influence of RRA treatment on short transverse tensile properties including the ductility of AA7010 Aluminum alloy extrusions was studied.^[29]

The retrogression treatment produces rapid initial coarsening of the grain boundary (GB) precipitates and results in an increase in the volume per unit GB area.

RRA treatments were done for the alteration in the microstructure of the Aluminum AA7XXX series alloys to combine the high strength attainable with T6 (peak aged) condition and the better stress corrosion resistance associated with T73 (overaged) condition.^[17] The schematic of RRA heat treatment is shown in Fig. 1. It involves carrying out retrogression treatment at elevated temperatures (180°C–260°C) on a material in T6 temper for a time interval (1 min–3 h), then quenching and final re-aging treatment equivalent to the original T6 heat treatment.

Retrogression treatment produces rapid coarsening of GB precipitates and results in an increase in volume of precipitates per unit GB area. Initial investigations of RRA were mainly applied to AA7075.^[30–33] Zirconium-containing alloys such as AA7050, AA7150, and AA7055 receive commercial RRA treatments designated as T77 type.^[34] The key characteristic of RRA is retrogression, which makes the re-precipitation in the matrix and grain boundary precipitates (GBPs) to coarsen. The retrogression treatment requires high temperature and a short time duration of only several minutes. This limits its industrial scale application, especially in the heat treatment of the components with large area of cross section.

The following sections discuss the effect of RRA on the microstructure, mechanical properties, corrosion resistance, EC resistance, SCC resistance, and fatigue crack growth resistance (FCGR) in the commonly used AA7XXX alloys.

Effect of RRA on Microstructure

Microstructural Changes in AA7075 with RRA

The microstructures produced by the RRA treatments on AA7075 were observed and analyzed through TEM, electron diffraction, and differential scanning calorimetry. RRA was applied to the material in T6 temper. The samples in T6 temper were subjected to the retrogression at 160°C, 180°C, 200°C, and 220°C for the time necessary for the minimum hardness to be obtained, i.e., 29, 9, 2, and 0.5 min, respectively. The precipitates found in the microstructure of this alloy were the equilibrium precipitate, η , with a hexagonal crystal structure and an incoherent interface with the matrix. The metastable precipitate, η' with a composition and crystal structure close to that of η but with a semi-coherent interface with Aluminum was also observed.^[23] The high density of fine precipitates are responsible for the greater strength obtained by this treatment. Retrogression alone and RRA treatment are done on the alloy. Retrogression is done at temperatures 160°C, 180°C, 200°C, and 220°C and RRA treatment is also done at the same temperatures. On the basis of the results reported, it can be inferred that, the microstructure after the retrogression is similar in the cases of the four temperatures tested as observed in Fig. 2a,b. The precipitation inside the grains is same as that of the T6 temper, while the grain boundaries show coarse precipitates, which are similar to the T7 temper. It is clear that dissolution of the less-stable precipitates, GP zones, and the smaller η' precipitates occurred at all retrogression temperatures, and this dissolution is controlled by the retrogression temperature. Similar results were obtained by other authors during retrogression at higher temperatures.^[35]

Re-aging promotes a very dense precipitation inside the grains while GBPs continue to grow during retrogression. The RRA microstructure is similar but a little coarser and denser

Fig. 2 TEM image of AA7075 (a) after retrogression at 200°C and (b) after RRA (retrogression at 180°C)^[23]

within the grains. The GB precipitation in RRA-treated sample is quite different and very similar to the T7 temper.

According to Park and Ardell,^[19] during re-aging a precipitation of η' occurs, but the coarser precipitates transform to η . Rajan et al.^[36] made observations that, the RRA microstructures are similar to those for the T6 temper inside the grains and are similar to those for the T7 temper in the grain boundaries.

Microstructural Changes in AA7050 with RRA

The microstructure of rolled AA7050 plate passed through a sequence of operations like hot rolled, solution treated, quenched in water at ambient temperature, and heat treated to RRA conditions and was compared with that of T6 and T7451 treatments.^[24] Transmission electron microscopy (TEM) was done to characterize the microstructure of the samples of AA7050, and it was concluded by the investigators that the η' precipitates are responsible for the majority of the precipitation, whereas the η precipitates and GP zones are present in smaller amounts.^[24]

From the TEM images shown in Fig. 3c,d of RRA heat-treated samples, it is observed that the microstructure

Fig. 3 TEM micrographs and corresponding SAED patterns of AA7050 in various conditions. (a and b) T6, (c and d) RRA, and (e and f) T7451^[24]

shows a very fine distribution of η' in the Aluminum matrix, which is similar to T6 condition as shown in Fig. 3a,b, and η precipitates on the grain boundaries are distributed similarly to that in the T7451 as shown in Fig. 3e,f condition. The yield strength and ultimate strength for the RRA-treated alloy obtained was 510 and 566 MPa, respectively, and corresponding values of T6 and T7451 were less than that of the RRA-treated alloy. These data reveal that the RRA-treated samples possess strength that is closely comparable to those of the T6 heat-treated samples.

The GP zones and the η' phases are the main strengthening precipitates, and the GBPs separated with large spacing in T6 temper condition are associated with great susceptibility to corrosion. Therefore, it indicates, RRA heat treatment can improve SCC resistance of the alloy without the significant loss in strength. The microstructure of sample subjected to RRA is similar to that of T6 sample within the grains. However, the GBPs keep growing during the retrogression stage. The final GBPs are much finer compared to that of the T7451 overaged sample. The precipitate-free zone (PFZ) in the RRA sample is narrower when compared to that in the T7451-tempered sample.

Microstructural Changes in AA7150 with RRA

The microstructures of the RRA-treated AA7150 were studied. AA7150 was retrogressed at different temperatures (175°C, 185°C, and 195°C) for different intervals of time. It was found that as the hardness of the retrogressed AA7150 approaches the near-peak condition, the corresponding RRA-treated AA7150 possesses good EC resistance without loss in strength. By retrogressing at 175°C, the retrogression time can be extended to 3 h, and the RRA-treated AA7150 possesses high strength as that of conventional AA7150-T6.^[27] According to Gu et al.,^[39] AA7050-T6 is strengthened by GP zones. However, Wu et al.^[40] studied the microstructures of Al-Zn-Mg-Cu alloy C912, and found that in addition to GP zones, there also existed some fine η' precipitates.

Figure 4 shows TEM bright field intra-grain (i.e., grain interior) images and corresponding diffraction patterns of the AA7150 with the T6 (Fig. 4a) and T73 (Fig. 4b) tempers. Very fine intra-grain features were observed in the 7150-T6 Al alloy. This image reveals that no diffraction spots from η' precipitates exist. Therefore, AA7150-T6 is mainly strengthened by fine GP zones with high number density. Compared to AA7150-T6, precipitate size in T73 is increased. And it was inferred that the η' precipitates contribute to the strengthening of the AA7150-T73. Figure 4c and d show the TEM bright field intra-grain images of AA7150 RRA retrogressed at 175°C for 3 h. It is evident that its intra-grain precipitate structure is coarser than that of the AA7150-T6, and the particle density is also decreased. This RRA-treated AA7150 (at 175°C for 3 h) possesses a strength as high as that of AA7150-T6.

Fig. 4 TEM bright field intra-grain images and corresponding diffraction patterns of AA7150 after (a) T6, (b) T73; RRA at (c) 175°C for 3 h, (d) 195°C for 1 h^[27]

However, compared to AA7150-T73, it is populated by smaller precipitates in higher number density.

The TEM images of the GB region of AA7150 are shown in Fig. 5a–d. Figure 5a shows that the η precipitates are continuous, and therefore the T6-tempered alloy is very susceptible to EC. As seen in Fig. 5b, η precipitates are distributed discontinuously at the grain boundaries; AA7150-T73 is not susceptible to EC. The TEM images of the GB regions of AA7150-RRA (175°C for 3 h) and AA7150-RRA (195°C for 1 h) are shown in Fig. 5c,d,

Fig. 5 TEM images of the GB region of the T6, T73, and RRA-treated AA7150: (a) T6, (b) T73, retrogressed at (c) 175°C for 3 h, (d) 195°C for 1 h.^[27]

respectively. The GB η precipitates are coarser than those in the AA7150-T6. The discontinuous distribution of the η precipitates at the GB is a feature of the retrogression process. As retrogression temperature is lower than the solution temperature of η precipitates, but higher than the re-aging temperature, η precipitates congregate and coarsen. As a result, GB η morphology similar to that of AA7150-T73 is formed possessing both strength and corrosion resistance.

Microstructural Changes in AA7049 with RRA

RRA study was carried out on AA7049 alloy extrusion of 65 mm diameter $\times$ 160 mm length. Heat treatment was carried out to three different tempers T6, T73, and T77.^[28] All specimens were initially heat treated to T6 temper and then subjected to RRA heat treatment at 180°C–240°C, for duration varying from 2 to 60 min followed by water quenching. Subsequently, re-aging was done at 120°C for 24 h followed by air cooling to room temperature.

TEM micrograph of the alloy in peak aged T6 temper condition revealed a very fine precipitation of GP zones distributed homogeneously inside the grains with the coarser and less spaced η' GBPs as shown in Fig. 6a. The micrograph of the alloy in overaged T73 temper condition

is shown in Fig. 6b, where uniformly distributed coarser precipitates are present inside the grains. Comparing TEM images of T6 temper with RRA (Fig. 6c, d), a fine distribution of η' precipitates is seen in the interior of the Aluminum alloy matrix. The coarser η precipitates, which are distributed in the matrix, are similar but bigger in size in T73 temper as compared to RRA. The observations are in close agreement with those in the literature.^[37,38] Therefore, in RRA the precipitates η' and η are dispersed in the alloy matrix along with the coexistent coarser and sparsely distributed η precipitates with decorated grain boundaries together with PFZs.

Summary of the Effect of RRA on the Microstructure Changes

1. The GBPs keep growing during the retrogression stage of RRA heat treatment.
2. The final GBPs in RRA samples are much finer compared to overaged condition.
3. The PFZ is much narrower compared to overaged samples.
4. The precipitates η' and η are dispersed in the alloy matrix along with the coexistent coarser and sparsely distributed η precipitates with decorated grain boundaries.

Effect of RRA on Mechanical Properties

Changes in Mechanical Properties of AA7050 with RRA

The effect of the RRA heat treatment on the mechanical properties of Aluminum alloy, AA7050, is investigated by means of hardness measurement and tensile testing.^[19] Hot-rolled Aluminum alloy AA7050 plate of 18-mm thickness was used in this work. After preheating at 420°C for 90 min, the plates were rolled to 2 mm by multi-pass. Before the RRA treatment, the sheets were solution treated at 473°C for 60 min followed by water quenching at room temperature. The RRA treatment carried out is shown in Table 2.

The treatment was done at three retrogression heating rates of 340°C·min⁻¹, 57°C·min⁻¹, and 4.3°C·min⁻¹. They were denoted by R-340 and RRA-340, R-57 and RRA-57, and R-4.3 and RRA-4.3, respectively. The hardness was tested at five random locations on each specimen to obtain a reliable average value. The relationships between

Fig. 6 Bright field TEM image of AA7049 alloy in (a) T6 temper, (b) T73 temper, after RRA at (c) 180°C for 10 min, (d) 240°C for 60 min^[28]

Table 2 RRA with different retrogression heating rates employed in AA7050^[25]

RRA state	Pre-aging (temperature, time)	Retrogression heating rate (°C·min ⁻¹)	Retrogression (temperature, time)	Re-aging (temperature, time)
RRA-340	120°C, 20h	340	190°C, 0.5–120 min	120°C, 24h
RRA-57	120°C, 20h	57	190°C, 0.5–120 min	120°C, 24h
RRA-4.3	120°C, 20h	4.3	190°C, 0.5–120 min	120°C, 24h

Fig. 7 Relationships between hardness and retrogression time at different retrogression heating rates in AA7050: (a) Retrogression; (b) RRA^[25]

hardness and the retrogression time of the alloys are shown in Fig. 7a for retrogression and Fig. 7b for RRA treatment at different heating rates. Hardness curves of R-340 and R-57 are having similar characteristics, i.e., the hardness value decreases first and then increases to a peak value and thereafter decreases monotonically. Hardness values show two different kinds of variations as the retrogression time increases. For RRA-340 and RRA-57, the curves are similar. It increases to a peak value in the beginning and then decreases monotonically. For R-4.3, the curve starts decreasing slowly and then the rate of decrease increases.

RRA-57 has the highest value of peak hardness and R-4.3 has the lowest hardness peak value.

It can be seen from Fig. 8a that R-340 and R-57 show similar characteristics, and the ultimate strength value increases first and then starts decreasing. The curve for R-4.3 shows that the curve goes downwards more steeply, then increases slightly and finally decreases monotonically. Figure 8b shows similar characteristics between yield strength and ultimate strength curves. Figure 8c shows similar characteristics shown by R-340 and R-57. R-4.3 increases to the peak value gradually and decreases

Fig. 8 Relationship between tensile properties and retrogression time at different retrogression heating rates in AA7050: (a) Ultimate tensile strength, (b) yield strength, (c) % elongation^[25]

with the retrogression time. The elongation values were almost the same when the yield strength reaches the peak value under the three state conditions. Hence, the results show that the retrogression heating rate significantly affects GBPs, which in turn affect the mechanical properties of the alloys treated by RRA process. It is found that the medium heating rate ($57^{\circ}\text{C}\cdot\text{min}^{-1}$) leads to the highest mechanical properties.

Changes in Mechanical Properties of AA7150 with RRA

The tensile property of RRA-treated Aluminum alloy AA7150 was studied.^[2] Rolled AA7150 sheet with a thickness of 2 mm was used in this study. AA7150 was retrogressed at different temperatures (175°C , 185°C , and 195°C) for various times. Retrogressed samples were re-aged at 120°C for 24 h for tensile testing. The tensile specimens were machined from the AA7150 samples subjected to the different aging treatments. The microhardness of some retrogressed samples was measured. The measurements were taken on a HXD-1000T microhardness tester with a load of 200 g applied for 15 s.

Figure 9a–c gives a comparison of the strength and elongation of the AA7150 RRA retrogressed for various times at 195°C , 185°C , and 175°C , respectively, with T6 and T73 tempers. It can be concluded that AA7150-T6 possesses a tensile strength of 610 MPa and yield strength of 530 MPa approximately. The AA7150-T73 Al alloy possesses the lowest strength ($\sim 10\%$ lower than that of AA7150-T6). The strength of the AA7150-RRA depends on both the retrogression temperature and retrogression time. From Fig. 10a–c, microhardness of the retrogressed AA7150, it is noted that the similar behavior is observed in the case of three retrogression temperatures. Following retrogression, the microhardness is initially lowered to a “valley” and then increases towards an apex value. As the retrogression time is further extended, the hardness is decreased monotonously. The hardness decreases more rapidly during the initial retrogression stage at higher retrogression temperature. As the hardness of the retrogressed AA7150 reaches the near-apex during the retrogression, the AA7150-RRA possesses better resistance to EC, without appreciable strength loss when compared to AA7150-T6.

Danh et al.^[42] discussed the hardness modification during the retrogression and proposed that the drop in

Fig. 9 AA7150 alloy: Aging treatments; strength and % elongation in RRA retrogressed for various times at retrogression temperatures followed by re-aging at (a) 195°C , (b) 185°C , and (c) 175°C ^[27]

Fig. 10 Microhardness of AA7150 as a function of retrogression time at retrogression temperatures of (a) 195°C, (b) 175°C, and (c) 185°C^[27]

hardness during the initial retrogression stage was mainly due to the partial retrogression of GP zones. The precipitation and growth of the semi-coherent η' precipitates were responsible for the recovery in hardness. Then, the coarsening of the η' precipitate caused the further decrease in the hardness.

Changes in Mechanical Properties of AA7075 with RRA

AA7075 was investigated to evaluate the effect of RRA on mechanical properties.^[21] Tensile specimens taken from as-received condition were solution treated by heating to 470°C for 30 min, water quenched, and then artificially aged at 100°C, 120°C, and at 140°C for 24 h. This was retrogressed at different temperatures, namely 160°C, 180°C, and 200°C. All specimens were finally re-aged at 120°C for 24 h.^[21] The hardness values are shown in Table 3. Hardness values were reported as HB 116, 124, and 116 for preaging at 100°C, 120°C, and 140°C, respectively. Increasing the preaging temperature at 120°C and 140°C did not yield a significant change in hardness. Considering the tensile strength, preaging at 120°C gave the

highest tensile properties among all the preaging conditions. Higher retrogression temperatures led to higher values of tensile strength.

Table 3 Effect of RRA on mechanical properties of alloy AA7075^[21]

Condition	Hardness (HB5)	Tensile strength (MPa)
Preage T6: 100°C	116	546.19
T7: 160°C	102	469.3
T7: 180°C	128	531.19
T7: 200°C	114	622.43
Preage T6: 120°C	95	558.26
T7: 160°C	124	672.89
T7: 180°C	128	688.84
T7: 200°C	130	698
Preage T6: 140°C	116	468.06
T7: 160°C	126	431.02
T7: 180°C	124	526.25
T7: 200°C	126	547.65

Changes in Mechanical Properties of AA7010 with RRA

The influence of RRA treatment on short transverse tensile properties of AA7010 extrusions was studied using 7010 Aluminum alloy extrusions in the form of slabs of size $2000 \times 200 \times 70 \text{ mm}^3$.^[29] The slabs were solutionized at 480°C for 4h, control stretched, and aged in two stages, 120°C for 24h followed by 170°C for 18h. Coupons of size $200 \times 25 \times 15 \text{ mm}^3$ and $15 \times 200 \times 70 \text{ mm}^3$ were cut from the slabs to study mechanical properties along longitudinal (L) and short transverse (ST) directions, respectively. These coupons were re-solutionized at 480°C for 90 min followed by aging at 120°C for 24h (T6 temper). Retrogression of these coupons was carried out at 200°C using a salt bath furnace for 5 min and 10–70 min at every 10 min interval. This was followed by re-aging at 120°C for 24h. Tensile properties in short transverse direction were evaluated for various tempers.

The variations in 0.2% YS and % elongation with retrogression time for RRA-200 condition for extrusions in

longitudinal and short transverse directions were plotted in Fig. 11a,b and compared with that of T6 temper. The hardness and 0.2% YS in ST direction attains a peak after 10 min of retrogression and starts to decrease with a further increase in retrogression time. The maximum in 0.2% YS achieved for RRA200-10 (retrogression at 200°C for 10 min followed by re-aging) is 15% more than that for T6, with ductility equaling 1% in both cases. The short transverse ductility of extrusions, which was much lower in the T6 condition, was improved to the optimum level after RRA treatment.

Summary of the Effect of RRA on Mechanical Properties

1. The heating rate during the retrogression plays a key role in the resultant mechanical properties after re-aging. Optimum retrogression heating rate needs to be selected for attaining the desired mechanical properties.
2. Ductility in short transverse direction significantly improved with RRA compared to the T6 temper in AA7010.

Fig. 11 Variations in 0.2% YS and % elongation of AA7010 along (a) L direction with retrogression time, retrogressed at 200°C , (b) ST direction with retrogression time, retrogressed at 200°C ^[29]

3. Mechanical properties comparable to T6 temper can be achieved with optimum combination of RRA parameters like temperature and time and prior aging treatment before RRA.
4. The drop occurs in hardness/strength during the initial retrogression stage due to the dissolution or the partial retrogression of GP zones. The growth of the semi-coherent η' precipitates during re-aging, results in an increase in hardness thereafter. The coarsening of the η' precipitate causes further decrease in the hardness during the later regime of re-aging.

Effect of RRA on Corrosion Resistance

Effect of RRA on General Corrosion Resistance of AA7075

The types of corrosion taking place in AA7075 are intergranular corrosion, EC, and SCC. The influence of RRA heat treatment on the corrosion properties of AA7075 were studied.^[20] The corrosion test is carried out using the salt spray corrosion test machine. The experiment was carried out in the salt spray chamber using the rectangular specimens as per standards. Initial weight of the specimen is noted and then tied to a hanging bar in the salt chamber.

The chamber is cleaned and filled with 5% NaCl solution until the level covers the heater coil in the chamber and is maintained at 35°C. The lid of the chamber is closed and made sure it is air tight. The compressor is also switched on to help the uniform distribution of fumes. The specimens are removed after every 3 h and are cleaned in 70% concentrated nitric acid. The final weights of the specimens were taken and tabulated as shown in Table 4. The test is continued for 30 h.

From Table 4, it can be seen that RRA treatment results in decreased weight loss compared to the as-cast specimen, increasing the corrosion resistance. Corrosion rate of as-cast specimen is 0.0426 mm·y⁻¹ and that of RRA is 0.009377 mm·y⁻¹. Comparing the values of the three samples, it is clear that the weight loss in the as-cast specimen is more, which shows that the corrosion rate is more for as-cast specimen when compared to that of the RRA specimens. The decrease in corrosion loss is 78.01% for the 5 min retrogressed specimen and it is 77.31% for the 10 min retrogressed specimen.^[20]

Table 4 Corrosion rate of AA7075 specimens^[20]

Specimen	Weight loss (g) after 30 h	Corrosion rate
		(mm·y ⁻¹) 86.7 × (W/d A t)
As-cast	0.0141	0.04265
RRA 475/130(24)/220(5)	0.0031	0.009377
RRA 475/130(24)/220(10)	0.0032	0.009679

Effect of RRA on EC Resistance of AA7150

The EC behavior of the RRA-treated Aluminum alloy AA7150 was studied. The alloy was retrogressed at different temperatures (175°C, 185°C, and 195°C) for various time periods.^[27] The accelerated EC test was performed at room temperature according to the “EXCO” test as described in ASTM G34.^[45] The EXCO solution of 4M NaCl + 0.5M KNO₃ + 0.1 M HNO₃ (pH-0.4) was used. After 48 h of continuous immersion in the EXCO solution, the corrosion morphologies were recorded, and their corrosion ratings were judged via inspection according to ASTM G34.

The EC morphologies and the corresponding corrosion ratings of the AA7150 with various tempers are shown in Fig. 12. Severe EC occurs on the AA7150-T6 alloy surface and AA7150-RRA specimen retrogressed for 1 h. As the retrogression time is extended to 2 h, EC of less corrosion rating is observed. When retrogression is done for 3 h, its corrosion rating is similar to that of the AA7150-T73.

For retrogression at 195°C and 185°C, it is also found the EC susceptibility diminishes with the retrogression time. When retrogressed for 3 h, the corrosion rating is similar to that of the AA7150-T73. For retrogression at 195°C and 185°C, the EC susceptibility diminishes with the retrogression time. Hence, for retrogression at any temperature, as the retrogression time increases, the corrosion susceptibility decreases.

Effect of RRA on SCC Resistance of AA7050

The effect of RRA on the SCC performance was studied on AA7050 Aluminum alloy.^[26] After the RRA treatment, samples were prepared for SCC test by milling up to 2.0 mm thickness in one surface. And during the test, the samples were placed into the salt-spray chamber for 60 days.

Figure 13 shows the surface of the specimen after SCC testing. At original condition, there is corrosion as small pits in the T76511 sample. For RRA-20, there are extensive cracks present, which are aligned along the long transverse direction. Similar characteristics were shown in RRA-40 + T6 as that of T7, since there is no sign of corrosion in the image. The alloy became susceptible to SCC after retrogression for 20 min and re-aging. Therefore, for the alloy AA7050, the strength and SCC resistance was at its peak when it was RRA treated for 40 min. The strength was close to that of T6 temper, and SCC performance was similar to the T7 temper. The T77511 temper is the designation for overaged condition protected by patent law,^[30–33] which is the optimized combination of strength and SCC resistance.

Effect of RRA on SCC Resistance of AA7085

The influence of RRA on SCC of AA7085 Aluminum alloy was investigated by slow strain rate testing and is shown in

Fig. 12 EC morphologies of AA7150: (a) T73, retrogressed at (b) 175°C for 1 h, (c) 175°C for 2 h, (d) 175°C for 3 h, (e) 185°C for 1 h, (f) 185°C for 2 h, (g) 195°C for 0.5 h, (h) 195°C for 1 h^[27]

Fig. 13 Superficial aspect of AA7050 samples after SCC testing (scale markers correspond to 1 mm)^[26]

Table 5. The SCC testing was done using the slow strain rate test (SSRT) at a strain rate of $3.3 \times 10^{-7} \text{ s}^{-1}$ in air and in 3% NaCl (mass fraction) + 0.5% H_2O_2 (volume fraction) aqueous solution, respectively. Rectangular tensile specimens with a gauge length of 30 mm and a width of 6 mm were used for SSRT.

The susceptibility to SCC was calculated using the following expression:

Table 5 Heat treatment variants of AA7085 studied ^[18]	
Temper	Heat treatment
T6	120°C, 24 h
T74	(110°C, 6 h) + (160°C, 10 h)
RRA	(120°C, 24 h) + (180°C, 0.5 h) + (120°C, 24 h)
DRRA	(120°C, 24 h) + (180°C, 0.5 h) + (120°C, 12 h) + (180°C, 0.5 h) + (120°C, 24 h)

$$I_{\text{SSRT}} = I_{\text{Corr}} / I_{\text{Air}},$$

where I_{Corr} is the elongation in air, I_{Air} is the elongation in corrosion solution. Calculating I_{SSRT} is an efficient method to evaluate the SCC resistance of Aluminum alloy and to understand the relationship between heat treatment and SCC.^[30–33] The higher the value of I_{SSRT} , it shows the better SCC resistance.

Figure 14a,b shows the results of slow strain rate testing, and it is clear that both tensile strength and elongation of the samples in the 3% NaCl + 0.5% H_2O_2 solution are lower than those in atmosphere, indicating the alloy has the SCC susceptibility. From Fig. 14c, the T6 temper shows the maximum susceptibility to SCC. The SCC resistance of dual retrogression and re-aging (DRRA) temper is higher than that of T6, and it is similar to that of T74. Therefore, SCC resistance can be improved by doing DRRA treatment and can attain a condition similar to that of T74.

Fig. 14 SSRT curves of AA7085 with different heat treatment: (a) in air, (b) in 3% NaCl + 0.5% H₂O₂, and (c) I_{SSRT} [18]

Effect of DRRA on SCC Resistance of 7B50 Aluminum Alloy

Influence of DRRA temper on EC behavior of Al–Zn–Mg–Cu alloy was investigated by EC tests. The study of EC morphologies of the 7B50 alloy using various aging tempers was carried out. [44] The accelerated EC test was performed at room temperature according to the EC (EXCO) test as described in ASTM G34. [45] The EXCO solution of 4.0 ml·L⁻¹ NaCl + 0.5 ml·L⁻¹ KNO₃ + 0.1 ml·L⁻¹ HNO₃ (pH = 0.4) was used. After 48 h of continuous immersion in the EXCO solution, the sample corrosion morphology was recorded by a digital camera and an optical micrograph.

EC rate has been summarized by the EXCO rate standard. “ED” (severe exfoliation) > “EC” > “EB” > “EA” > P (=slight amount of incipient exfoliation), where “P” represents pitting corrosion and “EA”–“ED” describe a range from superficial to severe exfoliation. Figure 15a shows the EC morphology of the RRA specimen; there it can be seen that peeled off multisurface layers and deeper etch pits with corrosion rating “EC”. Comparing Fig. 15a with b, DRRA shows part separation of metal with rating “EA”. Figure 15c exhibits the corrosion morphology of alloy in T76 temper. Only a small number of tiny blisters are observed, which is rated by “EB.” Therefore, the EC resistance is in the order

Fig. 15 EC morphologies of 7B50 alloy by different aging tempers: (a), (a') RRA; (b), (b') Dual RRA; (c), (c') T76 (EC surfaces (c) and cross section (c')) [44]

of $RRA < T76 < \text{dual } RRA$. It means in the case of 7B50 alloy, DRRA treatment enhances its resistance toward EC.

Effect of RRA on Corrosion Resistance of Al–Zn–Mg–Cu Alloys

Influence of RRA treatment on the EC, intergranular corrosion, and SCC of an Al–Zn–Mg–Cu alloy was investigated by means of optical microscope (OM) and TEM.^[22] Sample preparation includes stepped solution heat treatment, which was performed at 465°C for 40 min and subsequently at 490°C for 30 min. Then the samples were water quenched at room temperature. Sample 1 was then artificially aged at 120°C for 24 h, named as T6 treatment, while sample 2 was aged at 120°C for 24 h, followed by retrogression process at 180°C for 0.5 h, then artificially aged at 120°C for 24 h, named as RRA treatment.

The accelerated EXCO test was done according to the standard EXCO test as in ASTM G34.^[45] The EXCO test solution was prepared as follows: 4.0 ml·L⁻¹ NaCl + 0.5 ml·L⁻¹ KNO₃ + 0.1 ml·L⁻¹ HNO₃.

It can be seen from Table 6 that the surface appearance of sample 1 does not change until it is exposed for 12 h in the testing solution. When exposed for 12–72 h, the corrosion pattern on the surface of sample 1 changes from the superficial pitting to the severe exfoliation state. While for sample 2, even superficial pitting cannot be observed until it is exposed for 15 h in the EXCO solution, and the corrosion pattern changes from P to EA (superficial pitting) when exposed for 15–72 h. Therefore, it can be concluded that the RRA process can affect the exfoliation susceptibility and improve EXCO resistance with a rating of EA.

Summary of the Effect of RRA on Corrosion Resistance

1. General corrosion resistance, pitting corrosion resistance, and EC resistance is improved with RRA.
2. By carrying out retrogression at any temperature, as the retrogression time increases, the general as well as EC susceptibility of the alloy decreases.
3. DRRA treatment enhanced the resistance toward EC as well as SCC. However, the exact mechanism responsible for this improvement needs further investigation.
4. The GBPs in RRA samples are much finer, PFZs are much narrower compared to overaged condition. This results in better corrosion resistance.
5. η' and η precipitates in the alloy matrix are dispersed along with the coexistent coarser and

sparsely distributed η precipitates with decorated grain boundaries, which leads to better SCC and EC resistance.

Effect of RRA on Fatigue Crack Growth

Effect of RRA on Fatigue Crack Growth in AA7075

Effect of RRA treatment on the fatigue crack growth behavior of AA7075 Aluminum alloy was investigated.^[46] The variation of crack propagation rate (da/dN) with stress intensity factor range (ΔK) of the alloy in T761 and RRA conditions at $R = 0.1$ and 10 Hz is revealed in Fig. 16, and three regimes of FCP can be identified. RRA-treated sample exhibits high-FCP threshold value, as arrowed in Fig. 16. In Paris regime some deviation between the two curves was observed, where the T761-treated sample showed high crack propagation rate, whereas the higher resistance against slow crack propagation was observed for the RRA-treated sample. The fatigue fracture of RRA-treated sample occurred ultimately at about ΔK of 28 MPa·m^{1/2}, which is much greater than that in T761-treated sample (about 15 MPa·m^{1/2}). Apparently, the FCP resistance of the RRA-treated sample is higher than that of the T761-treated ones.

Although the specimen subjected to RRA exhibited superior fatigue strength compared to overaged condition in AA7075, other variants of RRA treatment may result in comparable fatigue resistance with T6 temper condition. The same needs to be established before coming to a conclusion

on the effect of RRA on the FCGR of the alloy. Wang et al.^[24] have also reported enhanced FCGR in AA7050 alloy after subjecting it to RRA heat treatment. Misorientation distributions of grains in T761 and RRA conditions near crack tip at high ΔK regime are illustrated in Fig 17. Intergranular crack propagation at crack tip along with crack branching are observed in T761-treated sample, as shown in Fig 17a. It can be clearly seen that the propagation direction of the crack branching is vertical to the loading direction, whereas main crack tends to propagate along GB. In the RRA-treated sample, transgranular crack propagation is observed at crack tip, as circled in Fig 17b. Apparently, the intergranular crack propagation exhibits less resistance compared with the transgranular crack propagation arising from the fact that GB is weaker than matrix due to the presence of PFZs. Crack branching is usually recognized as an acceptable method of retarding crack propagation, since it results in a lowering effective stress intensity at crack tip.^[47] At high ΔK levels approaching rapid unstable crack growth regime, however, the crack propagates at an even faster rate and the retarding role of crack branching appears to be relatively less significant. Therefore, microstructure in RRA condition is less prone to FCG.

Summary of Effect of RRA on FCGR

1. RRA-treated sample exhibited higher fatigue crack propagation threshold.
2. Sample subjected to RRA showed higher resistance against slow crack propagation.
3. Microstructure consisting of finer precipitates in RRA-treated samples results in more crack branching, which is usually recognized as an acceptable method of retarding crack propagation.

CONCLUSIONS

1. The effect of RRA on microstructure in AA7XXX alloys has been studied and found that microstructure

shows a very fine distribution of η' in the Aluminum matrix, which is similar to T6 condition, and η precipitates distributed on the grain boundaries are distributed similar to that in the overaged tempers.

2. Mechanical properties like hardness and tensile properties were not affected significantly with few combinations of RRA parameters like temperature and time, heating rate, prior aging treatment before RRA for almost all AA7XXX alloys. The optimum combination of RRA for various alloys has been fairly established. Ductility in short transverse direction significantly improved with RRA compared to the T6 temper in AA7010. Other alloys can be investigated to study their response to RRA.
3. The effect of RRA on general corrosion resistance, EC, and stress corrosion resistance has been studied and found that RRA heat treatment results in better corrosion resistance in selected combinations for various alloys. The retrogression time rather than temperature plays a vital role in improving the EC resistance of the alloys. As the time increased, the resistance to EC increased. Dual RRA treatment was found to enhance the resistance toward EC as well as SCC.
4. The effect of RRA heat treatment on FCGR in AA7075 has been studied and it has been reported that the fatigue strength in T761 conditions is better than that for RRA condition. Further investigation on the AA7XXX alloys is required to study the mechanisms responsible for the improvements mentioned earlier.

ACKNOWLEDGMENT

The authors are grateful to Director, VSSC for his kind permission to publish this review article. The authors are also grateful to the editors for the invitation to write a chapter on this topic and bringing it out in the current form.

Abstract

A semisolid metal processing technique is one of the newest metal casting technologies (less than 40 years). However, it has already proved itself as a commercially workable technology for the production of complex shape metallic components with improved mechanical properties and dimensional tolerances. The review of the commercially significant aluminum alloys and the specifics of their rheology are presented in this article.

Keywords: Aluminum alloys; Rheology; Rheoprocessing; Semisolids.

INTRODUCTION

Semisolid metal (SSM) processing (also known as *semisolid forming [SSF]* or *semisolid metallurgy*) is a relatively new metal casting technology. The conventional metal-forming processes use either (1) metals in solid state (solid state forming) or (2) metals in liquid state (casting). The process was discovered in 1971 by David Spencer who was measuring the viscosity of partially solidified Sn-15wt%Pb alloy. He noted that a vigorously agitated semisolid alloy specimen (sheared dendritic structure) has a very low viscosity. The same year, industrial trials showed the viability of the new metal-forming technique. There were many attempts to substitute mechanical stirring in order to achieve a required microstructure. The techniques include electromagnetic stirring, electric discharge through a semisolid dendritic material, mixing of powders, and isothermal coarsening. On a commercial scale, only electromagnetic stirring became a commonly accepted technique for generating non-dendritic materials. The SSM processing has the following benefits:

- It has a potential for better control of flow, final porosity, and microstructure of cast products.
- It can produce castings with near-net-shape complex geometries.

- It consumes less energy due to lower temperature processing of billets.
- Productivity is increased due to shorter solidification times, reduced shrinkage, and longer die life.
- Ductility and dimensional repeatability are improved compared to conventional cast products.

It is demonstrated that the SSM processing can be used on all nonferrous and ferrous metals, and metal matrix composites (MMCs) with improved casting properties and quality. Since these slurries have lower temperatures than liquid metals, the SSM processing is an effective method to reduce the casting temperature, to improve a die life, and to reduce production times.

Recently, a comprehensive review of the SSM processing has been done by Fan.^[21] The objectives of this article are to classify the achievements concerning the SSM processing of commercially significant metals and alloys, and to review the specifics of their rheology.

RHEOCASTING AND THIXOCASTING

Since the invention of the SSM processing, industrial trials demonstrated the feasibility of two casting techniques: rheocasting and thixocasting. Thixocasting is the

manufacture of billets of the desired microstructure, and the consequent reheating and forming of the billets in the semisolid state.^[51] The desired SSM structure is obtained mostly by electromagnetic stirring. The main advantage of the thixocasting is that it does not deal with liquid metal, and the process can be automated. Disadvantages of this process are as follows: (1) there is material loss during reheating the billets, and (2) risers and gates cannot be recycled within the foundry. In the rheocasting technique, the parts are produced by the SSM process directly from the liquid metal. The process has two versions. In the first version, liquid metal is poured into a container of the billet size, and then provided to the shot chamber of the forming machine. A desired structure is obtained in the billet by manipulation of cooling, grain refinement, and convection. This approach is used in the new rheocasting process invented by UBE Industries Ltd. (Tokyo, Japan) in 1999. This process combines the conventional vertical indirect squeeze casting technology with an innovative method for preparing the globular precursor material (slurry). The key of the success is in the preparation of a semisolid precursor material with a globular alpha aluminum phase.^[42] This process allows up to 20% cost reduction.

In the second version, the desired slurry structure is obtained within a large bath by a combination of cooling, grain refinement, and stirring. Some amount of the SSM is then removed from the bath and formed by the process. A difference between the common thixocasting process and the rheocasting UBE process is shown in Fig. 1.^[51] The UBE process consists of five steps: (1) preheating and coating the container, (2) pouring the molten metal into the container, (3) cooling down the alloy to the molding temperature to generate fine and spheroid primary crystals, (4) reheating the metal to remelt the chilled edge zone to form a homogeneous microstructure throughout the entire container, and (5) providing the metal slurry to the mold under pressure. The UBE process has all the advantages

of the thixocasting process and eliminates the main disadvantages such as billet and furnace reheating costs, and scrap recycling.

Schematics of the typical rheo-die casting (RDC) equipment for manufacturing Al alloy components is shown in Fig. 2.^[34] It consists of two basic functional units: a twin-screw slurry maker and a standard cold chamber high-pressure die casting (HPDC) machine. The twin-screw slurry maker has a pair of screws rotating inside a barrel. The screws have especially designed profiles, which are corotating, fully intermeshing, and self-wiping. The screws and barrel are manufactured from special materials in order to avoid reaction with molten aluminum. The fluid flow inside the slurry maker is characterized by high shear rate and high intensity of turbulence. The basic function of the twin-screw slurry maker is to convert the liquid alloy into high-quality semisolid slurry through solidification under high shear rate and high intensity of turbulence. During the slurry-making process, there is an enormous amount of ever-changing interfacial area between the solidifying alloy, the screws, and the barrel.^[34]

Hypereutectic A390 alloys (Al–17Si–4CuMg) have generated a significant interest in the recent years, due to their attractive properties, such as low coefficient of thermal expansion, high wear resistance, high strength, and high hardness,^[75] and are widely used in the automotive and aerospace industries. However, the semisolid processing of A390 alloys presents considerable difficulties due to the segregation of large primary silicon particles, the wide range of solidification, and a large proportion of eutectic, resulting in poor processability of the semisolid slurry. Tebib et al.^[75] proposed a novel rheoprocessing of A390 alloy by the separation of α (Al) and Si eutectic phases and an increase of the volume fraction of the non-dendritic α (Al) phase. The resulting slurry can easily be demolded, is self-supporting, and can be easily sliced (Fig. 3), which is an indication of the good processability of the alloy using this method.^[75]

Fig. 1 Difference between thixocasting and UBE rheocasting^[51]

Fig. 2 Schematic illustration of the RDC process^[34]

Fig. 3 Semisolid slurries self-supported (a) and easy to cut (b) using the novel method^[75]

The SSM forming requires a fine-grained feedstock with a special non-dendritic, spheroidal primary solid microstructure. Usually, fine-grained equiaxed dendritic cylindrical bars provide the feedstock. Brown et al.^[13] described two techniques for obtaining this structure: (1) using mechanically stirred aluminum alloys that are then continuously cast and (2) using electromagnetic stirring. They concluded that the production of the mechanically stirred bars is less expensive.

An SSM processing technology differs fundamentally from other methods of metal casting in material preparation before the process. This process operates between the solidus and liquidus temperatures, and the solid fraction in the formed metal is defined by the temperature. A precise

setting of the temperature is necessary for the high quality of the cast product. SSM casting technique can be applied to both heat-treatable premium alloys with high strength and ductility, and secondary alloys that do not require heat treatment. The advantages of the SSM process are as follows:^[37]

- Product complexity, close dimensional tolerance, near net shape, thin wall, and excellent surface finish, comparable to conventional die castings.
- Lower porosity ($< 0.1\%$) compared to other casting processes.
- Good strength and ductility comparable to squeeze and permanent mold castings.
- Suitability for alloys that considered difficult to cast from 100% liquid metal.
- Low-processing temperature and therefore short cycle time and low stress on tooling.
- Ability to undergo a T-5 heat treatment without losing ductility.
- Ability to form hypereutectic Al–Si alloys while retaining the desirable size and distribution of primary or second phases in the case of billet version of SSM.
- Product consistency when using precast billet.
- Minimized material usage and machining.

Baran and Bastian^[6] stated that squeeze and semisolid castings are porosity-free castings with enhanced mechanical properties. These die castings have an excellent surface finish, and they are heat treatable because they are produced with minimum turbulence. The processes allow achieving an elongation of 12%.

In order to produce an excellent surface quality and parts capable of developing high strength and good plasticity by utilizing the semisolid-forming process, the composition of the alloy must be closely controlled in order to optimize the process. Kazakov^[44] determined advanced alloy compositions through the use of analysis of the fraction liquid/temperature curve. The data were obtained through the use of differential scanning calorimetry aided by thermodynamic modeling. It is shown that an optimum composition results in a slurry containing 50% liquid at a temperature of 585°C or lower.

According to Young and Eisen,^[84] semisolid processing is broken down into three main categories: semisolid processing, semiliquid processing, and slurry on demand process. The authors briefly described and analyzed each process. Practical examples are given for each process, and the issues of the recycling of the runners, casting scrap, and so on are discussed.

THT Presses, Inc. (Dayton, Ohio) developed sub-liquidus casting (SLC) process, which uses normal foundry alloys and thus is considered as a low-cost slurry process.^[37] An explanation of concept fundamentals and mechanisms is given by Jorstad et al.^[38] The authors determined the mechanical

properties of two SLC cast parts and alloys, and compared them to similar products manufactured by a traditional billet SSM, by squeeze casting and by permanent mold.

Decker^[19] describes the activity of Thixomat Inc. (Livonia, MI, USA) in the development, application, and commercialization of a semisolid injection molding process (thixomolding). Thixomolding is based on the principle that metal alloys become semisolid at temperatures between the liquidus and solidus temperatures. Parts are made by heating metallic feedstock into the machine where it is heated to a semisolid state at a temperature just below the melting point and injected at high speed into a closed die. Parts with linear tolerances of 0.013 mm per linear inch and wall thickness of less than 1 mm were produced by this process.

Rice et al.^[68] developed a new process for the direct solid freeform fabrication (SFF) of metallic components. The process does not use powders, thus minimizing porosity and shrinkage distortion. The SFF process utilizes the rheological and thermophysical properties of SSM slurries to build a near-net-shape metallic component in one step. A stream of semisolid is deposited over a moving substrate that follows a 3D pattern. The high viscosity of the semisolid slurries allows the stream to be deposited over previous layers in a controlled fashion.

Rice and Mendez^[67] describe the direct slurry forming (DSF) process, which consists of forming stirred semisolid slurry and moving that slurry directly to the die casting machine. The process has been used at Gibbs Die Casting (Henderson, Kentucky) to produce automotive parts. The DSF process eliminates capital cost expenditures, reduces the number of steps required, and thus reduces the cost of semisolid formed components compared to other SSF processes.

IdraPrince, Inc. (Holland, Michigan) has recently developed a new semisolid rheoprocessing, which uses a rotating, cool, graphite rod that rapidly removes heat to begin solidification in a shot of molten alloy. The rapid application of controlled cooling and convection creates enough solid nuclei within the melt that the metal is ready for semisolid casting within seconds. Stirring and cooling are unnecessary after solidification begins because they have no effect on the final microstructure (Modern Casting, 2004).

A prediction of the shape and motion of the solid/liquid interface front is the most important problem of the process. A front tracking on a moving mesh and a front tracking on the fixed grid are the two numerical techniques for numerical modeling of the solidification process. The technique using the front tracking on a moving mesh involves a moving boundary condition, and therefore, it is restricted to simple problems such as one-dimensional (1D) problems or when the interface is well defined. In the front tracking on the fixed grid method, the evolution of latent heat is accounted for enthalpy definition. The simulations conducted on a fixed space grid are based on the (1) enthalpy, (2)

heat capacitance, (3) fictitious heat flow, or (4) temperature recovery techniques. The effective heat capacity method is the most popular, and it depends on the determination of the temperature gradient of the enthalpy (dh/dT) on the solidification front. This method can be applied to both the Stefan problems (isothermal solidification) and mushy zone problems. In the Stefan problems, a small solidification interval must be introduced. The Del Giudice's method (the effective heat capacity equation is referred to the oriented direction of the temperature gradient) and the Lemmon's method (the temperature gradient is normal to the phase change front) are recommended by Dalhuijsen and Segal.^[17] Sharma et al.^[71] proposed to apply the Sheil equation or the equilibrium relationship to determine the phase change rate by the specific heat method. Yoon et al.^[81] proposed an equivalent specific heat method for a single-phase semisolid material. Swaminathan and Voller^[74] proposed an enthalpy approach for determining the heat transfer during the phase change process. The evolution of the latent heat is explained by a temperature–enthalpy relationship. This model works well for pure metals. For alloy systems, this model requires many empirical constants, which must be determined for each alloy composition individually. Moreover, a nonlinear enthalpy–temperature relationship requires adjustments via iterations. A solidification model, which includes a formation of both aligned and equiaxed dendrites, was proposed by Basu and Sekhar.^[7] It is suggested that a liquid fraction–temperature relationship in the mushy zone is linear, and it is described by the linearized Sheil equation. Therefore, the model does not work for alloys with low solute contents.

In order to make easy the production of components made by the SSM process, computer models were developed to simulate the mold filling and solidification. Backer^[5] describes a software program entitled WRAFTS, which has the capability to precisely model the filling of the die with a two-phase (liquid and solid) material.

Kang et al.^[40] presented an overview of the development of a new finite-element program (SEMI-FORM S/W) to predict the solid-phase deformation of semisolid materials, filling defects, and liquid segregation. The developed model is recognized as an efficient and economical tool for designing and optimizing thixoformed products with arbitrary shaped dies.

Petera and Kotynia^[63] proposed a model that considers the thixoforming process in combination with the finite-element algorithm. The model involves both thermal phenomena and rheological properties of alloys in the semisolid state. Non-isothermal rheological equations determine the flow behavior of each phase.

SEMISOLID RHEOLOGY

Metal alloys in the semisolid state exhibit specific rheological properties such as thixotropy and pseudo-plasticity between the solidus and liquidus temperatures.^[63] The constitutive

behavior of alloys in the semisolid state is complicated due to its dependence on the solid fraction, morphology of the solid phase, and thermomechanical history. Most of the models developed on thixoforming assumed that the semisolid materials are homogeneous.^[81] Some models consider a two-phase flow, but again neglect the thixotropy.^[86]

Alexandrou et al.^[2,3] developed more sophisticated models on thixoforming, but they neglected the heat transfer phenomena during the process. In their commercial simulation package, Alexandrou et al.^[4] considered the heat transfer and phase change with thixotropic behavior, but they ignored the phase segregation.

Hegbusi and Mat^[30,31,54] developed the models assuming that at low solid fractions, the mushy zone behaves like a semisolid slurry, but a porous medium at high solid fractions.

The application of semisolids is affected by different types of flow instabilities and problems related to the flow-solidification process (Brown et al., 1993). Solid fraction is considered as a most dominant factor that controls the flow resistance and is controlled by the temperature. At solid fractions between 0.05 and 0.1, the slurry behaves as a non-Newtonian and history-dependent fluid. At concentrations between 0.5 and 0.6, the slurry behaves like a non-linear viscoplastic solid, and the flow resistance increases significantly. The critical fraction solid is less than 0.2 for dendritic particles, and it is above 0.5 for rounded particles. According to Joly,^[35] this critical value is shear rate dependent. It occurs at lower fractions solid with lower shear rates. Joly and Mehrabian^[36] experimentally studied the thixotropy of a Sn-15%Pb alloy. The flow resistance of rounded particles, after some transient time, continues to decrease with an increase in shear rate. It is assumed that higher shear rates break up agglomerates of particles and increase flowability.

The history dependence of semisolids is necessary to understand the different kinetic processes. It can be characterized by hysteresis experiments. Based on the hysteresis analyses, Joly^[35] concluded that slurries are highly thixotropic, and under steady-state and isothermal conditions, the flow behavior is pseudoplastic. The history dependence of semisolids is more pronounced at high values of the fraction solid. It is shown that semisolids change flow resistance more rapidly after a shear rate increase than after a shear rate decrease.^[10,52] This may be related to the accepted fact that the rate of particle agglomeration is considerably slower than the rate of disagglomeration. Martin et al.^[53] presented the model using the agglomeration/disagglomeration mechanisms based on the definition of a structural parameter.

Joly^[35] has demonstrated that the particle size is mainly controlled by the cooling rate. At higher cooling rates, the finer dendrites (hence, smaller particles) will be developed. Increased cooling rates also result in higher apparent viscosities for a given fraction solid.^[41] It is assumed that this phenomenon is related either to a hydrodynamic effect

of smaller particles or to the more irregular geometry of the smaller particles.

A particle shape (dendritic or rounded) is another main factor affecting the flow behavior. Laxmanan and Flemings^[49] compared the dendritic and rheocast structures. The dendritic structure at the same fraction solid exhibited about 2 orders of magnitude higher resistance than the rheocast structure. Particles of irregular shapes accelerate the transition to high flow resistance due to more hydrodynamic interaction.

Due to particle deformation and agglomeration, the liquid phase can be entrapped between the particles. Consequently, the apparent volume fraction solid and the flow resistance will increase. At lower shear rates, a greater agglomeration and hence more entrapped liquid will occur. It will significantly increase the flow resistance. A liquid entrainment and the apparent fraction solid will also be increased if the particles have irregular shape. An effective volume fraction is a major determinant of flow resistance. Im et al.^[32] studied the mold filling quality, the residual flow, and the effect of the natural convection on the solidification process.

Flemings et al.^[25] reviewed the fundamental studies on the rheology of SSMs and the application of the findings to the development of improved metal-forming (rheocasting) processes. It is shown that a vigorous agitation during solidification produces a highly fluid semisolid slurry with a non-dendritic structure including solid spheroids dispersed in liquid. The authors also describe a high-temperature die casting (thixocasting) process, which utilizes the thixotropic nature of the slurries.

Bhutani et al.^[9] examined the fundamental concepts of rheology and reviewed the work on the rheology of semisolid alloys. Based on the findings on the rheology of semisolid alloys, the authors concluded that new processing techniques are to be developed and some of the existing techniques could be modified. The authors describe other developments such as compocasting, rheorefining, rheoforging, and production of high-strength alloys by fractional melting/solidification, which have emerged as a result of fundamental studies on the rheology of semisolid alloys.

Hirai et al.^[29] studied the effect of composition on viscosity by means of stirring experiments on Al-, Cu-, and Fe-based seven semisolid alloy compositions. The authors proposed an equation to express the apparent viscosities as a function of solidification rates of metals in the composition and their shear rates.

Yang and Tsao^[80] reviewed a semisolid processing of aluminum alloy A356. The effects of metal temperatures on the process were studied experimentally on a specially built furnace and a high-temperature viscometer. The viscosity of the aluminum alloy in the semisolid state is shown as a function of the metal temperature and holding time.

Most of the casting defects in the conventional die casting processes are caused by the flow behavior of the liquid

metal within the die cavity. Gas entrapment often occurs during the filling of the die under violent flow conditions, which results in gas porosity. Vinarcik^[76] discussed the advantages of producing die casting in using the semisolid die casting process and the associated planar metal flow. The conditions for lamellar flow and turbulent flow of liquids are described, and the concept is extended to metal flow into a die casting mold cavity.

Koke and Modigell^[48] experimentally analyzed how the microstructure of globular grains develops with respect to the shear rate and cooling rate during the solidification. It is observed that the average particle size increased with increasing shear rate and decreasing cooling rate. In order to account for those phenomena, the rate of crystal growth and the relationship between the average particle size and the viscosity was modeled by applying the Sherwood two-film model for the mass transport. The dependence of the viscosity from the particle size was modeled with a modified Krieger–Dougherty model. The isothermal experiments were conducted to characterize the rheological behavior of tin–lead alloys. The system demonstrated a shear thinning rheological behavior at the steady-state flow. The yield stress strongly depends on the microstructure and the degree of agglomeration of the solid phase. The Herschel–Bulkley model was used to describe both the thixotropic and the yield–stress behavior of the test alloys.

RHEOPROCESSING OF ALUMINUM ALLOYS

An SSF has developed into a high-volume production method for lightweight aluminum parts.^[78] The development of the SSF process depended upon the resolution of a number of critical technical issues, such as (1) a reliable source of feedstock, (2) a robust forming technology capable of producing parts that are meeting automotive specifications, (3) alloys that permit rapid cycling of the forming machine, and (4) designs that utilize the outstanding mechanical properties obtained when using the SSF process.^[78]

Cheikh et al.^[15] described the equipment, procedures, and methods used in preparing the graphitic AlSi alloy and die casting it in a cold chamber die casting machine. AlSi alloy is prepared by vigorously stirring the graphite into a partially solidified, compocast alloy and then using this metal in the die casting unit. The authors presented the metallographic structure, properties, and possible applications of this alloy.

Pathak and Tiwari^[62] analyzed the properties and structures of aluminum–copper–lead alloys (1.2 wt% copper and 10–30 wt% lead) rheocast and poured into iron molds with continuous stirring. It was determined that lead is homogeneously distributed in the interdendritic regions of broken primary aluminum-rich dendrites. The mechanical properties including frictional resistance and wear resistance are decreased due to the lead.

Robert^[69] discussed the possibility of the production of metallic rheocast slurries by heat-treating as-cast or cold-deformed structures at temperatures just above the solidus. The method was applied to hypoeutectic Al–Cu and Al–Si alloys, C–Zn alloys, and high alloy steels M-2 and 304. It is shown that roundness and globular solid-phase diameters increase as the treatment time increases, and high previous deformation leads to more perfect rheocast structures. Concepts of the transition from dendritic to globular structures and the growth mechanisms of the globular solid phase with holding time are discussed.

Kang and Kang^[39] investigated the fabrication of a fiber-reinforced aluminum alloy containing Al_2O_3 short fibers by means of semisolid extrusion into a billet. The fibers were introduced into the semisolid (mushy state) melt under the vigorous agitation at different stirring times and temperatures. Extrusion forces and surface defects with and without lubrication are analyzed. The mechanical properties of the resulting aluminum composites are measured. It is shown that these properties are improved after the secondary working of hot extrusion.

Kitamura et al.^[46] investigated the soundness, structures, properties, and dimensional accuracies of semisolid aluminum alloys produced in horizontal and vertical die casting machines. It is shown that the properties of semisolid metals up to 0.6 fraction solid (100 MPa pressure) are almost the same as liquid metal samples. However, there is a reduction of macrosegregation and an enhancement of dimensional accuracy with the semisolid samples.

Quaak et al.^[64] reported an investigation of the manufacture of aluminum-based MMCs using semisolid state forming. Several aluminum MMCs were investigated with an emphasis on A356 alloy and Duralcan F3A20S composite (A356 + 18 vol% SiC particles). The microstructure of slurries and the behavior of reinforcing particles during melting, remelting, and forming were described. It is defined that matrix and composite slurries exhibit strong pseudoplastic behavior. Extrusion before partial remelting accelerates the decrease of flow stress during isothermal holding.

Quaak et al.^[65] performed laboratory experiments during partial solidification with low-pressure die casting and with partial remelting in forging. The experiments were conducted at near isothermal conditions using A356 alloy and Duralcan F3A20S MMC. Porosity levels were 0.4% in semisolid casting and even less in semisolid forging. Composites were more easily formed than alloys. Partial remelting was more adequate than partial solidification.

Kiuchi and Sugiyama^[47] described a new process to manufacture semisolid alloys. To validate the process, they carried out the experiments on Pb–Sn, aluminum alloys, and cast irons. Mechanical properties of the test alloys were measured. It is shown that these properties are significantly improved by the semisolid processing.

Young^[82,83] describes many advantages of the Buhler semisolid metal casting process over conventional die

casting. The advantages are lower metal temperatures, reduced solidification shrinkage, gas-free, weldable, heat-treatable, and almost net-shape dimensionally castings. In this process, induction-heated billets are automatically loaded into the shot sleeve and cast when about 60% solid.

Christiansen^[16] describes the thixoforming process as a simple procedure that involves the stirring of an aluminum alloy as it is solidifying, thus breaking up the dendrite arms. Subsequent remelting of a thixoformed billet only requires it be heated to the semisolid state prior molding. It is stated that the resultant component is stronger and denser compared to the conventionally cast part.

Wallace^[77] states that weight reduction with safety and pressure tightness are the major driving forces toward the use of squeeze casting and semisolid casting. According to the author, solidification shrinkage and internal gas porosity are often encountered in conventional die castings. The squeeze casting and semisolid castings are associated with thicker gates, slower fill times, and longer periods of high-pressure application during filling of the dies. The slower fill times allow lower iron content in the molten aluminum alloy, without leading to soldering of the die. Sound parts can be produced if the proper process features are applied.

Midson and Brissing^[57] discusses the application of SSM process in a number of commercial castings, including 7 kg automotive suspension components. The authors state that the process produces components with better mechanical properties and higher internal integrity than the conventional HPDCs. It utilizes a 40% liquid and a 60% solid slug, which comes from a specially prepared billet. The feedstock was made by continuously casting aluminum that is electromagnetically stirred during solidification.

Midson and Young^[60] provided some process guidelines for the production of semisolid aluminum castings. The authors studied the impact of the casting temperature on the die filling behavior and the quality of semisolid aluminum castings. The results showed that a plate die could not be filled with semisolid VF319A when the temperature of the semisolid alloy was below 565°C. It was necessary to heat the semisolid alloy to a temperature between 564°C and 570°C to completely melt the blocky silicon particles, which have a negative impact on tensile elongation.

Im et al.^[32] specified the problem of the aluminum alloy solidification. However, in this article, the composition of the alloy and the experimental results are not presented.

Petera and Kotynia^[63] presented the qualitative comparison of the numerical simulations with those reported by Im et al.^[32] for the phase change phenomena occurring in a range of temperatures. The square cavity of the dimensions of 0.05×0.05 m was used as the computational domain. The authors demonstrated that the flow patterns as well as the temperature fields are consistent with the data known from the literature. In order to validate their numerical model in terms of assessing the operating conditions

for the thixoforming process in a more complex geometry, Petera and Kotynia^[63] analyzed a real die casting. A bracket of a car engine support made of aluminum alloy AlSi7Mg was chosen for verification. The different stages of thixoforming in terms of free surface progress and the corresponding solid fraction field evolution are obtained as a result of the simulations.

Figueredo et al.^[23] modified a parallel-plate rheometer for measuring the viscosity of semisolid slurries under isothermal or continuous cooling conditions at shear rates up to 2000 s^{-1} and under transient conditions. The technique was used for measuring the viscosity of aluminum alloy A357. It is shown that the shear rate rapidly changes by varying either the rotation speed of the plate or the gap between the plates. It was possible to obtain the shear rate changes up to 1500 s^{-2} . The semisolid slurries were prepared by reheating the alloy into the semisolid range. Viscosity measurements on A357 alloy under conditions of constant and abruptly changing shear rates are presented and related to the structure changes.

Midson et al.^[58] provide a brief overview of the induction heating process used to preheat the aluminum alloy slugs from special billets before introducing these slugs into the die casting machine. The slugs are heated to a temperature where they are about 50% liquid and 50% solid. The temperature control of this process is very sensitive to the location of the slug in the induction coil and the chemistry of the alloy, which affects the electrical conductivity of the slug. After preheating, the slug is introduced into the injection chamber of the die casting machine.

Replacement of iron and steel components with lighter weight aluminum is associated with demanding functional specifications and safety-critical issues. Midson^[56] describes the Buhler squeeze casting and SSM processes. The SSM process uses a specially prepared material, which is cast at a temperature where it is only 50% liquid and 50% solid. The squeeze casting process uses fully liquid metal. The author presents a number of case studies and fatigue data.

Wyss et al.^[79] developed a technology to produce thin-walled aluminum automotive components having greater than 15% ductility. The technology used a die casting process based on SSM forming of aluminum alloys that is cost-competitive with conventional pressure die casting. Sound semisolid parts were cast using aluminum alloy granules as feedstock.

Aikin and Ramachandran^[1] determined the mechanical properties of the variety of commercial squeeze and semisolid aluminum alloys. The tensile yield strengths are expected and measured for 356 and 357 alloys with fine secondary dendritic arm spacing. The measured elongations were quite high, with a few samples exhibiting extremely high values of elongation to failure. In some samples, the presence of oxides produced premature failure in the 3%–5% elongation range. Higher iron contents yield

a larger volume fraction of Fe-containing intermetallics, which unfavorably affected tensile ductility.

Davidson et al.^[18] defined the room-temperature fatigue properties of a semisolid cast A356 alloy by determining a Wisler curve for lives between 104 and 107 cycles. The tests were conducted in axial tension/compression cycling at zero mean stress. It was observed that fatigue cracks initiated from shrinkage pores or oxide films at the surface of the specimens. The fatigue properties of the semisolid castings were compared with casting made by other processes. It is shown that semisolid castings performed slightly better than squeeze castings made on the same machine and from the same die. Both semisolid and squeeze castings had significantly better fatigue life than those produced by the gravity die casting process.

Bergsma et al.^[8] reported the results of studies of the mechanical properties of 357 and modified 319 semisolid formed aluminum alloys. In their study, some alloys were electromagnetically stirred, whereas other alloys were formed from ingot that was not stirred during solidification but had undergone a semisolid thermal transformation (SSTT) during heating to produce a spherical microstructure suitable for semisolid forming. The T4, T5, and T6 tensile properties were optimized for both SSTT alloys using various aging studies of formed parts. The T6 fatigue properties of both SSTT alloys were investigated. It is shown that the SSM tensile and fatigue properties were superior to conventional cast alloys, and the properties of SSTT are comparable to SSM prepared by electromagnetic stirring.

RDC is a new technology developed for manufacturing near-net-shape components of high integrity directly from liquid aluminum alloys.^[22] The process combines the high-shear dispersive mixing by the twin-screw extruder with the cold chamber die casting process. This process is successfully applied to process cast, wrought, bearing, and immiscible aluminum alloys. The RDC specimens demonstrate near-to-zero porosity, fine and uniform microstructure, and improved tensile strength and ductility.

Recently, a commercial rheocasting process called SSRTM has been developed based on the fact that rapid heat removal and convection at only very near the liquidus temperature are critical for forming a non-dendritic microstructure.^[85] The SSR is proved itself operationally friendly process operating with conventional vertical or horizontal die casting machines, and sand and permanent mold casting processes.

THIXOMOLDING OF ALLOYS

A modification of the thixocasting process called thixomolding has been used for forming light metal alloys.^[27] This process feeds fine chips to a machine that has much in common with a plastic injection molding machine. Sannes

Fig. 4 Schematic drawing of a four-bladed vane rheometer

et al.^[70] cast alloys AZ91 and ZE52 under conditions, which result in different microstructures. A Physica MC10 Reolab viscometer equipped with a four-bladed vane of 20 mm in diameter and 20 mm in length (Fig. 4). The samples of 40 mm in height were mounted in a steel crucible with a diameter of 37 mm. To prevent slip between the samples and the crucible, the samples were fixed to the wall. Prior to reheating, two slits (30 mm in depth) were machined for the vane in the solid samples. The rotation speed of the vane was set to 1 rpm during the experiments.

The vane method for rheological measurements was described by Kenntok^[45] and Dzuy and Boger.^[20] To calculate the shear stress from a measured torque and known vane dimensions, the vane was replaced by a cylinder whose dimensions are equal to those of the vane (Fig. 1b). The torque balance is given by

$$T = 2\pi R_v^3 H_v \tau_w + 4 \int_0^{R_v} \tau_e(r) r^2 dr. \quad (1)$$

The shear stress at the end surface is a function of the radial position r and can be approximated as follows:

$$\tau_e(r) = \left(\frac{r}{R_v} \right)^p \tau_w. \quad (2)$$

A solution of Eqs. 1 and 2 gives

$$\tau_w = \frac{2T \left(\frac{H_v}{D_v} + \frac{1}{p+3} \right)}{\pi D_v^3}. \quad (3)$$

Sannes et al.^[70] chose $p = 2$ and calculated the shear stress by Eq. 3 from the measured torque T and from the known vane dimensions. It was shown that the rheological behavior of magnesium alloys is dependent on the microstructure. A structure of a small equiaxed grain

demonstrates a thixotropic behavior at a lower fraction of liquid than a ripened and coarse grained structure. The authors concluded that the rheological and thermal measurements could be used to establish casting parameters.

Miwa et al.^[61] reviewed the processing problems in a new form of injection molding, which produces near-net-shape casting of magnesium alloys and composites. AZ91D alloy was processed using the new semisolid extrusion system in which a metal wire net was used instead of a die.

Thin-walled (< 0.1 mm) components produced by thixomolding is considered as an alternative option to the injection molded plastic (LeBeau and Maffia^[50]). The process consists of heating magnesium alloy pellets in a heated screw. From the heated screw, the semisolid material is forced into the die at 322°C . The authors provide the design information on the process, such as fatigue strength, thermal conductivity, and the normal mechanical properties.

The new rheocasting process is a novel approach for semisolid casting of light metals, in which the slurry is prepared from normal casting alloys directly at the foundry machine (Kaufmann and Uggowitzer^[43]). The process tested on the magnesium alloy AZ71 proved to be superior in strength and ductility. The mechanical properties are compared with data from HPDC parts. The authors proposed the ideas for increasing ductility and process stability with slight alloy modifications and proper heat treatment.

A twin-screw rheomolding process used in injection molding of polymers was adapted for near-shape production of metallic components.^[33] The experimental results of rheomolded light alloys showed that the new process produces fine and near mono-sized solid particles distributed uniformly in a fine eutectic matrix.

A non-isothermal rheological model of metal alloys in the thixoforming processes developed by Petera and Kotynia^[63] was verified by comparing the simulation results with the Stefan–Neumann analytical solution of the 1D steel solidification problem by conduction. It is assumed that the solidification process occurred at a constant temperature, and the metal properties of both phases are constant and independent of the temperature. The problem itself is in fact unidirectional, but, for the simulation purpose, an equivalent 3D problem has been designed, thus enabling a consistent use of the same 3D code as in more complex real casting. A steel solidification in a cavity of the dimensions of $40 \times 1 \times 1$ cm was analyzed. The equivalent specific heat method and the enthalpy method of solving the solidification problems were used. The analytical solution was compared with the simulation results for both methods. The authors demonstrated an advantage of the enthalpy method in terms of accuracy. Due to better numerical stability, the time step for the new method could be increased without losing the phase-change front.

Petera and Kotynia^[63] verified their numerical algorithm for the melting problem of light metals. The computational domain was a rectangular cavity of the dimensions of 8.89×6.35 cm. The computational domain was extended to the third dimension. The obtained results were compared with previous experimental and numerical works available in the literature. The results appeared to be sensitive to the upwinding parameter α , which has been adjusted by a trial-and-error method. The authors assume that a modification of the upwinding techniques together with corrected conductivity property will yield better agreement with the experimental data.

Koke and Modigell^[48] investigated low-melting alloys with a concentric cylinder rheometer. It was analyzed how the microstructure developed with respect to the shear rate, the isothermal shearing time, and the type of measuring procedure. Besides the steady-state flow behavior, the dynamic, isostructural, and yield behavior were examined for different solid fractions and microstructures.

CONCLUSIONS

In this article, various aspects related to the rheological behavior of semisolid aluminum alloys have been illustrated and discussed. An extensive review of the available literature has been presented for the SSM processing. An obvious progress in the SSM processing of aluminum alloys during the past three decades has been demonstrated.

Rolling of Aluminum

Kai F. Karhausen

VAW Aluminium AG, Bonn, Germany

Antti S. Korhonen

Helsinki University of Technology, Espoo, Finland

Abstract

Because of its lightweight and strength, aluminum alloys are used increasingly for the production of lightweight construction. In addition to applications in the expanding transportation market, aluminum sheet and foil materials are traditionally used for food and medical packaging, thin foil, and fin stock for air conditioners and heat exchangers, decorative panels and lithographic sheet. Rolling is a process used for the production of strip or sheet. In this article, rolling processing of aluminum and aluminum alloys is discussed in detail and specific processes include: hot-rolling, cold-rolling, and rolling of aluminum foils.

Keywords: Cold-rolling; Foil; Hot-rolling; Mechanics; Plate; Sheet.

INTRODUCTION

Rolling is a basic process for producing strip and sheet. Due to small product thickness, the demanded tight tolerance and quality requirements such shapes are difficult to produce directly by casting. In addition to producing the required shape, deformation by rolling ensures that the microstructure of the product is adjusted for further processing. The typical dendritic or coarse cellular as cast microstructure is effectively modified by hot rolling. Recrystallization processes lead to a complete re-organization of microstructure. This improvement of micro-structure and mechanical properties is also important for manufacturing thicker products such as plates. Compressive deformation by rolling may even close existing pores or voids. In addition, the development of texture during hot and cold rolling plays a significant role in establishing the final properties of aluminum sheet. These processes will be discussed in detail in this chapter.

The use of aluminum has increased in many applications.^[1,2] Its lightweight is an obvious advantage and it has gained interest, e.g. in attempts to save energy by developing lightweight constructions. Aluminum alloys offer adaptable tensile strength levels between 60 and 530 MPa, good castability and formability, good chemical resistance, versatile possibilities of surface treatments and high electrical as well as thermal conductivity. Optimum alloys can be found for a variety of applications in transportation, structural components, packaging, electronics and for machine components. In addition to the supply for various applications in the expanding transportation market, the traditional usage of rolled aluminum sheet and plate

material is in can body and can top stock, food and medical packaging, closure caps, thin foil, fin stock for air conditioners, brazing sheet for heat exchangers, decorative panels and lithographic sheet.

From a historical perspective the dominant material in rolling is steel, which accounts for the largest quantity in the world's metal rolling production. The advances in the rolling of steel strip and sheet^[3,4] therefore often found their way into the rolling of aluminum as well. In the case of aluminum one difference is that thinner sheets and foils make up a more significant portion of the product palette. The rolling of thin gauges presents some basic difficulties, which will be discussed in detail. Excluding the striking metallurgical differences between aluminum and steel, lower hot rolling temperatures for aluminum, which are about one half of that for steel, and differing frictional conditions, the basic rolling technology for both steel and aluminum is based on the same general mechanical principles. Some features of modern aluminum rolling mills are first briefly reviewed and the basic mechanics of rolling are discussed.

HOT ROLLING OF ALUMINUM

Figure 1 shows some basic casting and hot rolling mill configurations for aluminum strip production. The basic difference in the type of production method depends on the required production capacity. Due to the lighter weight of aluminum, the production capacities of aluminum mills are usually lower than those for steel. The choice of mill depends on the product spectrum and the capacity

Fig. 1 Hot strip casting and rolling mills for aluminum alloys^[5]

requirements. Single stand mills, where multi-pass rolling is performed in reversing manner is usually used for roughing passes as well as for finish rolling. Tandem mills, where several stands are in line, are used for the finish hot rolling passes. An alternative to the tandem mill can be the Steckel-type mill, in which reversing rolling is performed from coil to coil. A traditional hot reversing roughing mill and hot tandem finishing mill production system becomes economical for steel if the annual production

exceeds 0.5 million tons; and with an increased number of furnaces, roughing mill and finishing mill stands annual production can easily be extended up to several millions of tons. An alternative in the case of steel is thin slab casting technology, which can be employed to replace the traditional reversing roughing mill, if the surface quality is not critical and the production spectrum is not wide.

One producer of rolling mills for both steel and aluminum^[5] recommends that more than 600,000 tons per year

(see Fig. 1.5) can be obtained with the classical hot reversing roughing and tandem finishing mill concept for rolling aluminium strip. A single stand reversing hot mill alone is capable of a production of up to 160,000 tons per year.

The reversing roughing mill combined with a Steckel-type reversing hot or warm finishing mill is recommended for smaller amounts of production. It offers the advantage of producing small batches on a “just-in-time” basis, which is not economical in tandem mills. It should be mentioned, however, that for some products this concept may lead to severe problems in mechanical properties due to the longitudinal variation of texture and microstructure.

For still smaller amounts of production thin slab casting or thin strip casting may be considered. The twin roll caster may be used in low-capacity plants for casting mainly soft alloys down to a nominal minimum strip thickness of 6 mm.

A belt-type caster followed by tandem hot rolling can be employed for a full range of alloys including the 1100, 3000 and 5000 series. The caster produces alloys in the thickness region of 16–20 mm and after the tandem finishing mill, a thickness down to 2 mm or 3 mm is obtained.

In aluminum rolling the requirements for dimensional accuracy and flatness have been increasing steadily. For this reason various control techniques have been developed where the shape of the roll gap is influenced by the geometrical and thermal crown of the rolls as well as by the application of torques to influence bending. Systems which deserve special attention are those based on variable crowns and lateral shifting of work rolls, such as CVC (Continuously Variable Crown), UPC (Universal Profile Control) or HVC (Horizontal Vertical Crown), usually applied with additional roll bending.^[6–8] For an even finer adjustment of shape, selective spray cooling is applied to the work rolls. Combinations of these methods offer shape control within a broad range. The CVC concept has become popular both in new mills and in revamping older installations. The world’s largest aluminum-processing plant of Alunorf, Germany (a joint venture of VAW and Alcan), with an annual production capacity of 1.4 million tons of hot strip and 900,000 tons of cold strip has been reported to employ CVC in its newest hot and cold strip mills.^[9]

Hot working is defined as a forming operation in the range above 0.6 times the melting temperature of the metal, which in the case of aluminum is above 300°C. As compared to cold working, forming in this region is assisted by dislocation climb, cross slip and activation of additional slip systems. Strain hardening, which in cold working causes high pressures, is reduced considerably by dynamic recovery, resulting in the formation of polygonized dislocation arrays of lower energy. Further softening is induced by static recovery (annihilation and rearrangement of dislocations) and recrystallization (nucleation and growth of new grains) during inter-stand times or upon subsequent annealing. These factors lead to considerably lower flow stresses which, apart from lowering the necessary energy

for rolling and lowering the pressure on the roll-set, enhance the formability of the material by reducing stress concentrations which initiate failure. Thus, high reductions above 50% can be accomplished. A compact overview on the current understanding of the structural influences in hot rolling is given by McQueen.^[10]

During hot rolling, aluminum alloys undergo significant changes in microstructure and texture, which determine the product quality. Thus, tight control of metallurgical changes is required in order to ensure a cost-efficient production of high-quality sheet material. All major aluminum rolling mills employ thermo-mechanical processing-routes in which the rolling operation is not only employed to achieve the desired reduction, but to accomplish well-defined metallurgical properties. Consequently, hot rolling procedures for aluminum alloys differ considerably from the steel rolling practice.

The development of the most important metallurgical features during a typical processing route of Al-Mg-Mn alloys is depicted in Fig. 2.^[26] The conventional processing route of hot rolled sheet today starts with a DC (Direct Chill) casting operation.^[1] As the overall efficiency of the processing route is to a large degree determined by batch size, it is usual to aim for the largest ingots that can be processed in the hot mill. Modern machines can handle drop weights exceeding 100 tons. The resulting low cooling rates lead to coarse precipitates and segregations. The most dominant features of the cast ingot are the cell size, as well as type, size and distribution of constituent particles and eutectic precipitates.

Furthermore, the highly heterogeneous cooling rates from the DC casting impose variations in microstructure throughout the slab. Due to grain refinement, a close to random texture is usually observed (Fig. 2a). Surface segregations may be removed by a subsequent scalping operation. Even 100% of the production may be scalped before rolling to ensure good quality of the products. Subsequently follows an ingot homogenization treatment, during which internal stresses are relieved, elements in supersaturated solid solution (Fe, Mn, Si, Cr, etc.) are precipitated, microsegregations are leveled to some extent by long range diffusion and primary phases are transformed. When the alloy is held at high temperature for a sufficient time, precipitates coarsen. It has been shown for alloy AA3003,^[11] that the mean dispersoid size can be varied between 0.03 and 0.17 μm with a concurrent variation in dispersoid density between 740 and 11 μm^{-3} for low and high temperature annealing respectively. As the dispersoid size strongly affects recrystallization during and after hot rolling, it needs to be controlled by optimum heat treatment conditions. From homogenization the slab is usually cooled down to hot rolling temperature. This leads to a further reduction of elements in solid solution and a growth of coarser secondary particles. The microstructural state of the slab before hot rolling significantly influences most final properties of a number of product groups.

Fig. 2 Evolution of grain structure, precipitation structure and texture in sheet production of Al-Mg-Mn alloys^[26]

The hot rolling operation is performed at the highest possible temperature to lower flow stress in order to reduce loads and to achieve high reductions. An upper temperature limit is imposed by the need for controlling recrystallization and precipitation, dependent on the alloy, as well as by the occurrence of pick-up. During conventional rolling, the coarse as cast structure changes to a deformed and recrystallized structure having considerably finer grain size. Coarse primary precipitates are crushed and become distributed more evenly. Decreasing temperatures during rolling and an increase in vacancy concentration in the lattice due to deformation lead to a further precipitation of secondary phases.

With regard to microstructure, hot rolling can be seen as a succession of deformation and annealing steps. The most dominant metallurgical features are recrystallization and the development of preferred crystal orientations (texture). Both processes are interrelated and influenced by ongoing precipitation. Recrystallization is particularly determined by the alloy system and the processing conditions. In high-purity aluminum, the grain boundary mobility is high and the material already shows rapid recrystallization during processing (dynamic recrystallization). However, in customary industrial alloys, dynamic recrystallization may be observed only at extremely high temperatures, where the effect is mainly caused by local bulging of grain boundaries and not by nucleation and growth. For these materials, recrystallization typically takes place during inter-stand times or after rolling at elevated temperatures (post-dynamic or static recrystallization). In commercially pure alloys such as AA1050, typically used for packaging foil or lithographic sheet, elements with low solubility, like Fe and Si, interact with the grain boundaries and efficiently obstruct recrystallization when present as finely dispersed precipitates.

The presence of Mn and Cr causes the same effect unless the elements are already bound in coarse particles. Within the Al-Mg-Mn alloy system, used in considerable amounts for beverage cans or automotive components, recrystallization covers a broad range within the scope of industrial conditions and thus can be influenced to a large degree by the choice of rolling parameters. Figure 3 gives an example of the recrystallization spectrum of alloy AA5182.^[12] In industrial practice, the recrystallized structure can be obtained in a separate annealing treatment, but more sophisticated technologies utilize self-annealing on the coil from the rolling heat.

Grain size and especially texture development are determined by recrystallization, which in turn govern the properties of products delivered in hot rolled condition as well as those of subsequently cold rolled sheets. Cold rolled products particularly, such as can body stock, require a distinctive cube texture in the hot rolled condition in order to reduce earing upon the drawing operations of the can manufacturer. The formation and evolution of cube components has received much attention of researchers and industry.^[13–15] During hot rolling with little inter-stand recrystallization, the cube nuclei are formed at the expense of rolling texture components, and they can grow upon subsequent annealing. A coarse size and large inter-particle spacing are desired to enhance recrystallization during coiling. On the other hand, this may cause inter-stand recrystallization leading to the formation of large cube bands which deform unfavorably in subsequent passes. To restrain inter-stand recrystallization, the rolling temperature can be lowered, or the rolling speed can be increased. In this situation another restriction is introduced by the occurrence of particle-stimulated nucleation (PSN). The transition range from cube texture to the random PSN texture is depicted in Fig. 4 for alloy AA3104

Fig. 3 Spectrum of recrystallization for alloy AA5182^[12]

Fig. 4 Cube vs PSN texture dependent on forming conditions for alloy AA3104^[16]

with a given constitution before rolling.^[16] In addition, the importance of size and distribution of coarse constituent particles (Fig. 5) emphasizes the need for understanding the development of microstructure throughout the whole process chain.^[18]

Hot rolling is the dominant process in the production chain of aluminum strips and sheets inducing microstructural heterogeneities in the end product. It is obvious, that discontinuous rolling on a reversing mill causes heterogeneities along the rolling direction. The delay time between head and tail continuously increases, so that for some passes the slab may partially recrystallize if no precautions are taken. Furthermore, especially in the roughing passes, the deformation is characterized by large gradients in strain rate and temperature in strip thickness. Heterogeneities in width may become severe, when operating at low speeds and if the mill is not equipped with selective cooling systems.

From the above it can be deduced that tight metallurgical constraints are imposed on the hot rolling schedule and processing parameters have to be controlled within narrow windows. The discussed mechanisms are governed by the initial state of the ingot (alloy composition, state of microstructure, constitution-size- and distribution of precipitates and elements in solid solution) in combination with the applied hot rolling and annealing conditions (temperature-time history, strain path, strain rates and tooling boundary conditions). The layout and optimization of such complex interacting systems can only be performed if the microstructure can be quantified at all processing stages. Thus, predictive models are essential for this task and are subject of major research efforts in the aluminum industry.

Figure 6 documents an application in which the computed fraction of inter-stand recrystallization in a tandem hot finishing mill and the percentage of cube texture and earing are correlated,^[12] the results of which are used for pass optimization in order to reduce earing in the end-user-product.

In comparison to steel industry, where modeling techniques for multi-pass hot rolling have a long tradition and are well advanced [e.g. 19–22], the modeling of aluminum alloys is at a considerably earlier stage. In steel, the influence of texture on recrystallization is usually neglected, and the only material parameters that need to be considered in the austenitic regime are grain size and work-hardening and -softening kinetics. The kinetics of static recrystallization are usually assumed to follow an Avrami equation of the following form:

$$X = 1 - \exp \left(-C \left(\frac{t}{t_{0.5}} \right)^k \right) \quad (1)$$

X is the recrystallised volume fraction after an annealing time t , and C and k are constants. The characteristic time

Fig. 5 Cube vs PSN texture dependent on the state of precipitation for alloy AA3104^[17]

Fig. 6 0/90° earing and cube intensity vs computed fraction of interstand recrystallization after the first pass of a three stand hot mill for alloy AA5182^[12]

needed for 50% recrystallisation $t_{0.5}$ is usually expressed in terms of an empirical formulation such as

$$t_{0.5} = a \times \varepsilon^{-b} \times d_0^c \times Z^{-d} \exp\left(\frac{Q_{\text{res}}}{RT}\right), \quad (2)$$

where a – d are constants, Q_{res} is the activation energy for recrystallization, d_0 is the initial grain size and R is the universal gas constant. Z is the Zener–Hollomon-Parameter which can be understood as a temperature compensated strain rate which characterizes the forming conditions during rolling. It is calculated as

$$Z = \varepsilon \times \exp\left(\frac{Q_{\text{def}}}{RT}\right), \quad (3)$$

where Q_{def} is the apparent activation energy for deformation. In a similar manner empirical formulations for the recrystallized grain size d_{rex} have been developed in forms such as

$$d_{\text{rex}} = e \times d_0^f \times \varepsilon^{-g} \quad (4)$$

Again, e – g are empirical constants.

Attempts to apply similar sets of equations to Al alloys may be successful in limited cases, but generally turn out to be difficult. For example, Sellars^[23] reported that microstructures calculated by these equations appear unrealistic, as too large grain sizes were predicted. It is concluded, that in modeling multi-pass hot rolling of Al alloys some unresolved questions exist, and it appears, that more fundamental descriptions of the evolution of microstructure are required than for steels. It is of particular importance to account for particle precipitation and dissolution and to identify the nature of different possible nucleation sites for recrystallization.

The development of such models is subject to current research and advances have been made to incorporate physically based characterization of potential nucleation sites for recrystallization and their respective efficiency under

various deformation conditions.^[24,25] In such way also the evolution of recrystallization texture is incorporated.

COLD ROLLING OF ALUMINUM

The applications of cold rolled aluminum strip have traditionally been in the beverage can, food packaging, building construction and automobile industries. Trends include rolling of wider strips up to 2000 mm and reducing the gage from 0.35 mm and 0.30 mm down to 0.25 mm. Reduced thickness gage and shape tolerances have also

been predicted.^[5] Figure 7 represents various types of cold rolling mills offered by one producer.^[5] The selection of mill depends on the required throughput, alloy, temper and material finish requirements.

The most conventional approach would be to start with either 6-high or 4-high heavy-gage cold strip mills (2.1 or 2.2 in Fig. 7). They are said to offer the flexibility to cover the complete range of alloys over a wide gage range from 14 to 0.3 mm. The capacities of these mills can reach up to 100,000 tons per year.

If still higher throughput is required, a continuous cold rolling line that utilizes a two- or three-stand tandem mill

Fig. 7 Cold rolling mills for aluminum alloys^[5]

is recommended. They can be used for large-scale production of a limited range of products. The capacity of such a line would be about 300,000 tons per year. Tandem mills for the rolling of steel strip usually contain more stands depending on the amount of production. Often the cold rolling mills for steel strip may contain up to six stands. The last stand may even be a 6-high mill.

Light-gage strip mills are used for further processing after the heavy-gage mill. They may be either 6-high or 4-high design. They may be used to roll gages down to 0.02 mm. In particular, the 6-high type mill with shifting of intermediate rolls can be utilized for foil-roughing applications. The capacities are of the order of 30,000 tons per year. Finally for special applications such as polish rolling of bright-finish material, a two-high mill (2.4) with limited reductions at low throughput speeds may be used.

Further processing to aluminum foil may finally be done in special 4-high mills. The trend in industry has been towards thinner gages and their market share has been increasing. High-quality process control is required for rolling speeds exceeding 1000 m/min. Up to speeds of 1500 m/min, 4-row cylindrical roller bearings and 2-row axial roller bearings are being used. If the rolling speeds exceed 1500 m/min, oil film bearings are used instead.^[5]

As the specific rolling pressure increases towards thin gages, roll flattening and roll bending increase. Special attention has to be paid to the strip edges, as roll flattening decreases gradually from the loaded centre of the roll towards the lesser loaded segments of the roll outside the strip. In addition, an unfavorable thermal crown develops, which gains significance with thinner gages. Counter bending of the rolls proves to be ineffective since the strip is embedded in the rolls. As a consequence the so-called "edge drop" problem is frequently encountered, leading to tight edges, which in turn may cause quarter buckles or edge tearing. Accordingly, a major concern in cold rolling is to relieve the local pressure on the edges without affecting general flatness or shape. Various advanced control technologies have been developed for this purpose, such as zone cooling of the rolls, inflatable backup rolls or utilization of 6-high mills with lateral shifting of intermediate rolls.

In the cold working regime (below 100°C), dislocation climb and cross slip are very much restricted. The material undergoes considerable strain hardening where fracture usually occurs before a steady state is reached. A defined strain is applied during cold rolling to achieve the desired product strength by strain hardening, and to produce a plane sheet with well-defined and sometimes structured surfaces. An additional change in microstructure is caused by further crushing and alignment of constituent particles.

The strength of non-heat-treatable Al-Mg (Mn, Cu) alloys of the AA3xxx or AA5xxx groups is based on solid solution hardening and, to a lesser degree, on dispersoids. For these alloys, strain hardening during cold rolling may increase the strength to above 400 MPa. However, the

strong interaction of Mg with dislocations may lead to problems with peak stress and serrated flow curves (Portevin–Le Châtelier effect) and resulting Lüders line formation. Measures can be taken to avoid this effect, but they generally result in a loss in strength. For this reason, age-hardenable alloys (AA2xxx, AA6xxx) are often utilized for panel applications, such as car bodies, where homogeneous surfaces are dominant product characteristics. The strength of these alloys is based on precipitation hardening, which is obtained after a solution treatment and subsequent ageing. In any case, the microstructural and textural characteristics of the hot rolled band determine the achievable product quality after cold rolling and heat treatments to a large extent.^[26]

The control of preferred grain orientations (texture) deserves special attention during the cold rolling of all alloy groups. The texture determines the anisotropy of various sheet properties that are of crucial importance to most subsequent processing operations. For can body applications, anisotropy is usually expressed by the percentage earing level of a drawn cup. Another quality measure is the *r*-value, which defines the ratio of strain in sheet width to sheet thickness in uniaxial deformation. Strong texture variations result in *r*-value differences that cause thickness irregularities in any deep drawing operation.

For non-heat-treatable alloys, the cold rolling passes and annealing conditions need to be designed in order to meet the requirements on both strength and texture. The texture development during cold rolling is shown in Fig. 8 for alloys AA3104 and AA5182.^[27] The partially recrystallized hot rolled band will show the typical rolling texture (β -fibre) that leads to 0/45° earing. The dominant cube texture components, as present in the fully recrystallized hot rolled band, will result in 0/90° earing, while the RD-rotated cube texture component produces additional ears at 0/180°. Six-ear or eight-ear cup profiles reflect the intensity of different texture components. Subsequent cold rolling and eventual intermediate annealing procedures, which are adjusted to the condition of the hot rolled band, can be performed in such a way, that anisotropy is balanced, while at the same time work-hardening attains the desired strength level. The development of earing from the correspondent different initial textures and for varying cold reductions is shown in the lower part of Fig. 8.

BASIC MECHANICS OF ROLLING

Although fast modern computers now allow even three-dimensional numerical simulation of forming processes such as rolling, the simple slab method is still exploited by industry, e.g. for rolling load calculation.

The equilibrium of forces in the horizontal direction requires that

$$(\sigma + d\sigma)(h + dh) - \sigma h = 2pRd\phi \sin\phi \pm 2\mu pRd\phi \cos\phi. \quad (5)$$

Fig. 8 Evolution of texture and earing in sheet production of Al-Mg-Mn alloys^[27]

The sign before the last term depends on the position of the slab within the roll bite. From entry up to the neutral plane the rolled material flows slower than the rolls rotate and the material is therefore drawn in by the frictional forces. After the neutral plane the velocity of the material exceeds the rotational speed of the rolls and the direction of the frictional forces therefore changes.

The classical theories of rolling have been discussed in numerous books^[3,4,28–33] and a detailed discussion is therefore not necessary here.

Considering the forces acting on a cross-hatched slab of rolled material, as shown in Fig. 9, leads to the so-called von Kármán–Siebel equation, which forms the basis of the calculation of the rolling load.

Fig. 9 Stresses and forces acting on a slab of rolled material

The zones from entry to the neutral plane and from the neutral plane to exit are called backward and forward slip zones, respectively.

Omitting the second order differentials in Eq. 5 and rearranging leads to the von Kármán–Siebel equation

$$\frac{d(\sigma h)}{d\phi} = 2pR(\sin\phi \pm \cos\phi). \quad (6)$$

This equation is, however, rather difficult to solve and various simplifications have been proposed since the 1920s to facilitate its solution both in hot and cold rolling. Today, due to the increased use of computers, these solutions lose their importance, since the differential Eq. 5 can now be solved numerically without any further simplifications.

Hot Rolling

There are some characteristic features of hot rolling, that may be used to derive a simplified equation for rolling load calculation. It should be noted that what is presented here, is done only to illustrate the principle. For the actual calculations the original references given in previously mentioned works^[3,4,28–31] should be consulted.

The friction in hot rolling is usually high. Even the adherence of the material to the rolls may take place. This is called sticking friction. There is very little generally available information on the coefficient of friction in hot rolling of aluminium.

Generally the coefficients in hot rolling are considered to be high. Often the values cited are about $\mu = 0.3$ or 0.4 or even more.

Pietrzyk and Leonard^[29] discuss some previous work on friction in hot rolling of aluminum. They report the values given by Geleji.^[34,35]

$$\mu = 1.05 - 0.0005T - 0.056v, \text{ for steel rolls}$$

$$\mu = 0.94 - 0.0005T - 0.056v, \text{ for cast iron rolls}$$

$$\mu = 0.82 - 0.0005T - 0.056v, \text{ for ground steel or cast iron rolls.}$$

In applying Geleji's formulae, temperature should be in °C and v is the rolling speed in m/sec. Actually these type of temperature corrected empirical formulae were originally developed for steel by Eklund and Siebel.^[28] Geleji later added the correction factor for rolling speed.

Geleji^[35] also gives some numerical values for the coefficient of friction in hot rolling of aluminum. According to him in hot rolling of 99.5% Al alloy with slight oil lubrication μ varies from 0.47 to 0.60 depending on the reduction and thickness. For hot rolling of Duralumin with emulsion based lubricant he gives three values for $\mu = 0.3, 0.43$ and 0.6 depending on thickness and reduction.

If no lubricant is used severe sticking of the aluminum to the rolls may result.^[29,32] Local breaking of the oxide film on the surface may expose islands, where metal adheres to the rolls. Suitable coolants such as fortified mineral oil emulsions may be used to prevent further problems, even if a coating of aluminum on the rolls tends to form. Detached fragments may become embedded in the rolled product and cause problems. Insufficient lubrication may even cause the slab to wrap around the rolls into a tightly adherent band.^[29,32] Ensuring effective contaminant-free lubrication in hot rolling of aluminum is very important. Filtration and prevention of contamination, e.g. with bearing oils is required to prevent premature change of the coolant emulsions.^[32]

Since rolling loads in hot rolling are usually lower than in cold rolling, flattening of the rolls may be disregarded in simplified load calculation.

When rolling thicker slabs, spreading may cause problems. For relatively thin and wide strip the assumption of plane strain, i.e. no spreading, may be used for simplicity.

Various solutions have been derived, e.g. by Orowan (1946), Sims (1954) and Alexander and Ford (1955).

Since the contact length is usually small, it may be assumed in Fig. 10 that $\sin\varphi \approx \varphi$ and $\cos\varphi \approx 1$. If sticking friction is assumed, it means that

$$\mu p = k, \quad (7)$$

where k is the shear strength of the rolled material. After making these simplifications into Eq. 6 it takes the form

$$\frac{d(\sigma h)}{d\varphi} = 2R(p\varphi \pm k). \quad (8)$$

Fig. 10 Frictional forces within the roll gap

The roll pressure distribution $p = p(\varphi)$ may then be solved from this equation by assuming that the normal stresses σ and p are bound by the condition

$$p - \sigma = \frac{\pi}{4} \times 2k, \quad (9)$$

After substituting p to replace σ , Eq. 8 may be solved for p . Rolling load is then obtained by integrating

$$P = R \int_0^{\varphi_1} p d\varphi, \quad (10)$$

where p is the rolling load per unit width. A simplified formula to calculate the load was developed by Sims (see, e.g. Ref. [31] for details). According to Sims, the load is obtained from

$$P = 2k\sqrt{R\Delta h} \times Q, \quad (11)$$

where Q can be obtained from the nomogram developed by Sims. The nomogram is shown in Fig. 11. The correction coefficient Q is a function of the relation of roll radius to exit thickness and percentage reduction defined by

$$r = \frac{\Delta h}{h_1} \times 100\% = \frac{h_1 - h_2}{h_1} \times 100\%. \quad (12)$$

It may be noted that $\sqrt{R\Delta h}$ represents approximately the contact length in rolling. Q includes the extra load due to friction. If compared to frictionless compression between flat plates, which would correspond to $Q=1$, the loads in actual hot rolling may be considerably higher—up to even four times.

Cold Rolling of Aluminium

Cold rolling differs from hot rolling in that the rolling loads are usually higher, which may lead to considerable roll flattening. With smaller reductions and thinner strip, the elastic deformation of the strip may no longer be ignored. Elastic zones both at exit and entry may have to be considered.

Fig. 11 Larke's values of the Sims function Q ^[31]

Generally, lubrication can be considered as a key factor for cold rolling of aluminum. The coefficient of friction in cold rolling is usually much lower than in hot rolling. The magnitude depends of course on the type of lubrication that is used. The lowest values may be less than 20% of those in hot rolling. The successful cold rolling of aluminum requires a carefully balanced amount of friction. On the one hand, low friction levels reduce loads, prevent welding, and secure a more homogeneous deformation, which increases workability and minimizes residual stresses. Furthermore, a continuous lubricant film acts as a protective shield to reduce wear. On the other hand, a certain amount of friction is required to ensure a stable controllable rolling situation and to avoid surface defects related to skidding. A well-known defect,

directly related to unstable friction, is the so-called “herringbone defect.”

Lubrication is to a large degree governed by lubricant viscosity ν , rolling speed v and surface pressure p . The dependencies are represented by the well-known Stribeck curve (Fig. 12). Usually, a mixed lubrication regime is aimed at, in which hydrodynamic pockets are interspersed with boundary lubricated zones. This is important for rolling efficiency and especially for the surface finish. The extent of lubricant pockets and areas of boundary lubrication determine the surface appearance.^[36]

The most common lubricants in cold rolling of aluminum are mineral oils of low viscosity, in which the oil film is strengthened by boundary additives. Emulsions are increasingly being used for sheet rolling.^[32] Heating during rolling or subsequent annealing may result in brown or black stains, which is a major problem associated with lubricants. For foil rolling, paraffin (kerosene) is used in purified form, but staining during subsequent annealing can still be a serious problem.^[32]

In conventional cold rolling theories, it is usually assumed that the coefficient of friction is small and constant and that the bite angle is small, which leads to assumptions $\sin\varphi = \varphi$ and $\cos\varphi = 1$. After making these assumptions, the von Kármán–Siebel equation (Eq. 6) takes the form

$$\frac{d(\sigma h)}{d\varphi} = 2p R' (\varphi \pm \mu), \quad (13)$$

where R' is the deformed roll radius. To solve this equation σ may be eliminated from the yield condition by assuming that both σ and p are principal stresses. Thus

$$p - \sigma = 2k = \frac{2}{\sqrt{3}} \bar{\sigma}, \quad (14)$$

Fig. 12 Characteristics of friction in cold rolling

where $\bar{\sigma}$ is the effective stress or yield stress in uniaxial tension.

After eliminating σ in Eq. 13 by using Eq. 14, rearranging, ignoring a small term $[(s/2k)-1]$, putting $h = h_2 + R' \varphi^2$ and integrating one obtains

$$p = C \times 2k \frac{h}{R'} e^{\pm \mu H}, \quad (15)$$

where $H = 2\sqrt{R'/h_2} \arctan [\sqrt{R'/h_2} \cdot \varphi]$ and C is an integration constant which can be solved from the boundary conditions.

If there are front or back tensions affecting, the yield condition (14) gives as boundary conditions

$$\begin{cases} p = p_1 = 2k_1 - t_1, & \text{when } \varphi = \varphi \text{ (entry)} \\ p = p_2 = 2k_1 - t_2, & \text{when } \varphi = 0 \text{ (exit)} \end{cases} \quad (16)$$

where t_1 and t_2 are back and front tension, respectively and k_1 and k_2 are the corresponding yield stresses in pure shear.

By substituting the boundary condition from Eqs. 16–15 and solving C one finally obtains at the exit side

$$p^+ = \frac{2kh}{h_2} \left(1 - \frac{t_2}{2k_2} \right) e^{\mu H} \quad (17a)$$

and on the entry side

$$\bar{p} = \frac{2kh}{h_1} \left(1 - \frac{t_1}{2k_1} \right) e^{\mu(H_1 - H)}. \quad (17b)$$

Rolling force per unit width can now be solved by integrating

$$P = R' \left(\int_0^{\varphi'} p + d\varphi + \int_{\varphi_n}^{\varphi_1} p - d\varphi \right), \quad (18)$$

where φ_n is the angle at the neutral point.

Various modifications of the solution of the von Kármán–Siebel equation for cold rolling have been presented by different authors. Some of the pressure distributions obtained from various solutions have been compared in Fig. 13.

The deformed roll radius R' is usually solved from the equation by Hitchcock^[38]

$$R' = R \left[1 + \frac{16(1 - \nu^2)}{\pi E} \times \frac{P}{b \Delta h} \right], \quad (19)$$

where R is the undeformed roll radius, E and ν are Hooke's modulus and the Poisson ratio for the rolls, P is the roll force, b is the width of the strip and Δh is the draft (change of thickness).

Fig. 13 Roll pressure as a function of roll angle calculated by four different methods. From the dissertation of Teusch^[37]

In Hitchcock's formula the pressure on the rolls is assumed to be elliptically distributed along the arc of contact. The contour of the deformed rolls then remains circular. This assumption only holds for passes of sufficient strip thickness and reduction. When the entry strip thickness decreases, rolling loads increase and consequently roll flattening increases. A theoretical limit is reached, when both the rolls and the strip deform only elastically and no further plastic reduction can be attained. Thereby, a minimum accessible gage is defined under the assumption of roll flattening as described above. Nevertheless, rolling practice shows, that passes well below this limit can still be rolled, and measured loads appear to be considerably lower than the calculated ones. Löffler and Kramer^[28] state that with a roll diameter of, e.g. 300 mm, exit thicknesses of below 13 μm can be processed.

Rolling of Aluminium Foils

The application of conventional rolling theories, as described above, fails when the exit thickness falls below 100–70 μm .^[28] The reason for this is, that the contour of the deformed rolls is assumed to remain circular with an enlarged radius. As a consequence of the assumption, that plane cross sections remain plane, continuous plastic reduction occurs through the roll bite. Relative slip between work rolls and strip occurs along the entire arc of contact except for the neutral point, where the shear direction is reversed. In terms of the Coulomb friction law it follows, that limiting friction prevails throughout the roll gap, and predicted loads are unrealistically high.

It was already shown by Orowan in 1943 that the deformed roll contour does not remain circular when thin strips are rolled. The development of roll flattening with decreasing strip thickness is illustrated schematically in Fig. 14. This contour development could also be verified experimentally.^[39] To account for such effects, the

Fig. 14 Change of roll contour as strip thickness decreases^[28]

complexity of rolling models increases drastically as elastic strip deformation has to be considered and roll pressure and elastic roll deformation equations need to be solved simultaneously. Specific rolling models^[40–43] and finite element methods^[44] have been developed and successfully applied to foil rolling and temper rolling processes. The strip is generally divided into two elastic zones before and after the roll gap, and two distinct plastic zones that are separated by a central zone, where the material remains rigid and is transported without plastic reduction (Fig. 15).

Haeseling et al.^[40] calculated stress distributions and compared strip and foil rolling. Their results are shown in Fig. 16. It can be seen that, while in strip rolling a typical friction hill-type pressure distribution is obtained, in rolling of foils a Herzian distribution prevails. In addition to the Herzian distribution a peak on the exit side appears. This peak resembles the one observed in bearings operating under elastohydrodynamic lubrication conditions.

The tribological aspects gain importance with decreasing gages, as the ratio of contact surface to deformed volume increases. A brief overview on the importance of lubrication in foil rolling is given in Ref.[46]. The oils are exposed to high thermal loads, high pressures and high shear rates and the complex interactions in the roll gap, responsible for the shear stresses in foil rolling are not yet fully understood. Of utmost importance is the amount of oil being entrained into the roll gap, which determines the frictional conditions and thereby the possible reduction

of the pass as well as the surface quality of the product. Basically three mechanisms supply the roll bite with oil, which are depicted in (Fig. 17).

1. *Hydrodynamic entrainment*: In the wedge between roll and strip hydrostatic pressure builds up in the oil which is dependent on velocities, gap geometry and rheologic behaviour of the oil. The oil film thickness at the point, where the oil pressure reaches the yield point of the strip, is entrained into the roll gap.
2. *Surface roughness*: Additional oil is entrapped in valleys of the surface roughness of roll and strip, independently of speed.
3. *Adhesive layers*: Due to physisorption and chemisorption, boundary layers develop, which principally depend on temperature and the properties of oil, roll and strip.

In foil rolling, the combination of high speeds and the over-supply of oil leads to an hydrodynamics lubrication regime at the inlet of the roll gap. Here the aluminum is separated from the roll by a continuous oil layer. During deformation the oil film thickness is reduced and metallic contact occurs. Thereby, a mixed lubrication regime is usually reached. Due to its technological importance, especially for rolling in thin dimensions, a number of works are dedicated to formulate suitable friction models in the mixed lubrication regime [e.g. 47–50], but still a number of open questions remains.

CONTROL OF THICKNESS AND SHAPE

Customers of rolling mills require increasingly dimensionally accurate products. Great efforts have been spent on ensuring that flat rolled products possess the correct dimensions, flatness and shape. Sophisticated control systems have been developed for this purpose and it is an area where rolling mill operators and suppliers of the required technology compete. Although there exist standards describing dimensional tolerances of flat rolled products,

Fig. 15 Deformation zones in foil rolling^[45]

Fig. 16 (a) Calculated friction hill-type distribution of stresses in strip rolling; and (b) calculated distribution of stresses in foil rolling^[40]

Fig. 17 Mechanisms of oil entrainment during cold- and foil-rolling

these often lag behind the development of technology and customers may even specify the thickness as some fraction of what is defined in the standards. Modern unmanned production methods require consistently good dimensional accuracy and shape for flat rolled products in order to avoid disturbances or breaks in production. In addition, accurate dimensional control may give savings in product weight. This may produce further savings in, e.g. maximizing the pay load and reducing energy costs in transportation.

The elastic spring of the mill stand changes the exiting strip thickness from the value of the roll gap setting. Variations in friction, front and back tension, thickness,

Fig. 18 Schematic representation of changing (a) roll gap setting; (b) friction; (c) front or back tension; (d) strip thickness; (e) flow stress; and (f) temperature on the final thickness of the rolled strip^[30]

flow stress and temperature may all lead to changes in thickness as illustrated schematically in Fig. 18.

Due to coiling of the strip, some deviation in flatness results.^[51] However, more serious is a non-uniform deformation in the transverse direction and the resulting shape defects. An attempt to reduce the thickness of the rolled material results in bending of the rolls (Fig. 19). This leads to a thicker centre in relation to the edges.

Based on Fig. 20 strip profile or crown is defined as a thickness difference^[1]

$$C_r = h_m - h_t. \quad (20)$$

Too high reductions of the strip edges may result in buckling close to the edges. To describe the waviness a concept called percentage steepness is defined as^[3,51]

$$S_p = \frac{h}{l} \times 100[\%], \quad (21)$$

where l is the wavelength and h is the amplitude. Yet another measure of flatness is the I value, defined as relative elongation multiplied by 10^5

$$I = \frac{\Delta l}{l} \times 10^5. \quad (22)$$

Assuming that buckles are sinusoidal, it can be shown, that the I unit and steepness are interrelated. The I unit is also related to stress in the strip according to the equation

$$I = \frac{\Delta \sigma}{E} \times 10^5. \quad (23)$$

Fig. 19 Effects of various factors on roll crown (1. elastic deformation of the roll due uniformly distributed load; 2. ground roll barrel; 3. thermal expansion; 4. effect of non-zero crown of the entering strip; 5. real roll crown of a new roll; 6. effect of roll wear on crown)^[30]

Fig. 20 A sketch to illustrate the strip crown^[52]

Since controlling of the shape is important, great efforts have been put to developing various techniques. A more detailed review has been made, e.g. by Ginzburg.^[3] A brief summary is given in Fig. 21,^[53] which represents five techniques including continuously variable crown (CVC), double-chock bending, use of six-high mill, variable crown using internally pressurized rolls and axially crossed rolls. Yet another important technique is the selective cooling of rolls.

To improve productivity and product quality, automatic shape control (ASC) and gage control (AGC) systems are employed. Figure 22 represents an example of a six-high mill used for cold rolling of aluminum strip.^[5,54] In this example strip tension is measured and the required correction is provided by bending, shifting and cooling of the rolls.

To optimize the rolling process, various computer models are being used both on-line and off-line. Models are required for the elastic spring of the mill stand, rolling force and friction, thermal effects and roll wear in order to be able to predict the shape of the strip.

An effective mathematical model can determine the roll gap profiles of the individual stands and activate the adjusting systems to present them in real time as a function of individual operating parameters. The schematic principle of such an on-line model is shown in Fig. 23.

In addition to on-line models, off-time models can be used to calculate the strip profiles. The requirements for an effective process model are especially demanding for aluminum hot strip mills since the thermal crown of the work roll is subject to relatively large changes. The crown usually grows from strip to strip. In addition the varying

Fig. 21 Some crown and shape control techniques^[53]

rolling forces from strip to strip and from the head- to the tail-end causes additional variation in the roll gap profile. Figure 24 shows an assumed schedule that was used in an off-line model to simulate hot strip rolling.^[6]

As evident from the foregoing, the control of shape, tolerance and flatness is an critical issue in rolling mills.

Fig. 22 Schematic layout of automatic gage and shape control system for a six-high cold strip mill^[5]

Fig. 23 A schematic view of an on-line model for profile and flatness control^[6]

Fig. 24 An assumed schedule used for simulating hot strip rolling^[6]

Further development may be expected in new kinds of models and computational techniques that do not suffer from the limitations of traditional physical or mechanical models.

One such relatively new development when it comes to rolling is neural networks. They are especially suited to applications where there is a lot of data available, but the processes are not yet accessible to physical simulation. Rolling of metals is one such area. Provided that sufficient measurement data is available, an artificial neural network

can be taught and it can learn the dependencies hidden in the vast amount of data.

The application of neural networks is rather new in rolling and applications are just beginning to emerge. Despite this, there are already a number of rolling mills, where neural networks are being used for process control, as illustrated in Fig. 25.^[55]

The best results of artificial neural networks are probably obtained when they are combined with other existing physical or statistical models.^[56–58] Yet another areas

Residual Stress-
Strain Rate

Fig. 25 Rolling mills applying artificial neural networks for process control. Major neural mill automation systems by Siemens AG (implemented or under progress)^[55]

where artificial neural networks have been successfully applied is in the prediction of the mechanical properties and controlling of the annealing process.

A rather recent development in the application of neural networks in rolling is the self-organizing maps, or Kohonen maps. They have been successfully applied to control many other processes, e.g. in the paper industry, but results in rolling are just beginning to appear.

SEM Microstructures and Fractographs of Aluminum Alloys

S.V.S. Narayana Murty, Sushant K. Manwatkar, and P. Ramesh Narayanan

Material Characterization Division, Materials and Metallurgy Group, Vikram Sarabhai Space Center, Thumba P.O., Trivandrum, Kerala, 695 022, India

Scanning electron microscopy (SEM) provides microstructural information at improved resolution and magnification surpassing that of an optical microscope. Therefore, it is preferred at times wherein further information about the microstructure or chemical composition of the observed features is required. This demands an SEM fitted with an energy dispersive spectroscope (EDS). SEM-EDS is a powerful combination that can resolve many issues related to the microstructures of materials. This is widely used to determine the composition of eutectic phases, nature of dispersoids and constituent particles, and chemical composition of phase mixtures in welding. SEM-EDS is also widely used for the fractographic examination of fracture surfaces of tensile-tested specimens to understand the fracture morphology. It also provides vital information about the modes of failure such as ductile, brittle, or cleavage, though aluminum alloys show predominantly ductile behavior under a wide range of test conditions. Further, it is extensively used in analyzing failure of aluminum alloy cast/wrought components.

SEM observations can be conducted in both secondary electron mode and backscattered electron mode as desired based on the nature of investigation. In the secondary electron mode, topographical features are examined such as fracture surfaces. The mode of failure, namely, uniaxial tension, shear, and fatigue can be arrived by SEM examination. Fracture surfaces must be properly protected to obtain vital information and good quality photographs. If required, the specimens for fractographic observations can be cleaned with suitable acid solutions to improve

the quality by removing the surface oxides. The nature of products formed on the surfaces after testing in a corrosive medium can be analyzed in an SEM-EDS. A field emission SEM fitted with an EDS will have improved resolution over conventional SEM for metallographic and fractographic examinations. Electron probe microanalyzer (EPMA) will further help in the study of compositional gradients across micrometer scale in materials.

This atlas of SEM microstructures and fractographs provides photomicrographs and fractographs of various cast and wrought aluminum alloys. It is believed that the information provided will be useful for the readers to understand the microstructure/fractographic features under various loading conditions for different aluminium alloys.

Fig. 1 SEM micrograph of AA 2014 DC cast billet indicating the eutectic network of secondary phases along the cell boundaries

Fig. 2 High magnified image of specimen shown in Fig. 1

Fig. 3 High magnified image of specimen shown in Fig. 1. Precipitation can be seen at cell interior

Fig. 4 SEM micrograph AA 2014 cast and homogenized billet indicating thin network of secondary phases along the boundaries

Shielding Gas: Performance Improvement of MIG and TIG Welding of Aluminum Alloys

J.M. Fortain and S. Gadrey

Air Liquide, CTAS, Cergy-Pontoise, France

Abstract

Welded aluminium alloy products are widely used in the construction and packaging sectors: in this context, in order to be competitive, the welding processes must offer valid solutions from both the productivity and quality viewpoints in addition to health-related aspects with regard to welders and operators. In this context, the technological goals of *Air Liquide* have been focused on improving the quality of welded joints made using the MIG and TIG processes. The approach adopted here is to examine the various gas mixtures from the viewpoint of influence on electrical parameters (voltage), regularity of filler metal transfer, the surface tension of the melt bath and the convection patterns present in the latter.

Keywords: Aluminium alloys; Current; GTA welding; Influencing factors; Mechanical properties; Metal transfer; MIG welding; Mixtures; Molten pool; Penetration; Process conditions; Process parameters; Selection; Shielding gases; Spray transfer; Voltage; Weld shape.

In 2006, the main applications of aluminium products were in the transportation (27%), construction (20%), packaging (16%), electricity supply (10%), machinery and equipment (8%) sectors in addition to sustainable consumable products (7%). The main markets were China (22%), North America (24%), Western Europe (22%) and Asia (except for China) (21%). Predictions suggested that this extraordinary growth would continue, reaching 36 million tons in 2007, with a predicted usage of 60 million tons by 2020. Up until 1998, in the automobile industry, the quality of aluminium used increased by over 130%, and between 2000 and 2009, analysts predicted that crank-cases (+40%), wheels (+20%) and cylinder heads (+19%) would witness extensive growth in this direction.^[1] At the same time as substantial increases in fuel costs, consumers would demand vehicles that were increasingly lighter, economical and made using components that were easily recyclable (the increasing use of aluminium corresponds to a saving of millions of litres of fuel, with a corresponding reduction in greenhouse gas emissions).

The explosion in demographics would also lead to increasing demand for urban infrastructure and the market would require ever increasing production of aluminium products.

The transportation sector (automobile, aerospace, aeronautics and shipbuilding industries) and the energy sector demand continuous innovation and the introduction of novel technologies for the construction of welded structures or plans making use of sheeting, plates extruded and cast products.

Furthermore, in order to be more competitive, semi-automated, automated and robotic MIG and TIG welding processes require solutions that provide advantages in terms of productivity, quality and the health of welders and operators.

In this context, the technological goals of *Air Liquide* have been focused on improving the quality of welded joints from the productivity and quality viewpoints made using the MIG and TIG processes.

THE STATE OF THE ART OF WELDING ALUMINIUM AND ITS ALLOYS

Table 1 lists the majority of weldable aluminium alloys used globally.

The main physico-chemical characteristics of aluminium and their relative impact on weldability are reported in Table 2.

The difference between the melting point of aluminium (600°C) and its oxide Al_2O_3 (2060°C) – which is also an excellent electrical insulator – requires the complete elimination of the latter from the surface of the former prior to performing welding in order to avoid non-melting or inclusions in the melt zone.

The coefficient of thermal expansion (twice that of a carbon steel) results in significant distortions and deformations, which can be limited by correcting the power density of the arc on the piece and the specific heat input along the longitudinal progress of the weld.

Table 1 Aluminium alloys commonly used in welding

Designation	Composition
1xxx	Pure aluminium (.99%)
2xxx	Al + copper
3xxx	Al + manganese
4xxx	Al + silicon
5xxx	Al + magnesium
6xxx	Al + magnesium + silicon
7xxx	Al + zinc
8xxx	Al + Li

The coefficient of thermal conductivity is equal to six times that of steel, and this requires the adoption of measures analogous to those required for distortions.

When the high coefficient of linear expansion is combined with a narrow solidification range, shrinkage due to solidification occurs easily, and the various alloys are highly sensitive to cracking.

Another point related to Fig. 1 is the high solubility of hydrogen in liquid or molten phase aluminium: 20-fold more soluble in the liquid state (0.69 cm³/100g) (0.036 cm³/100g).

With the MIG process, the risk increases with the temperature reached by the droplets of metal in the melt bath on coming into contact with any contaminants dissociated in the arc path: hydrogen is dissolved in the metal droplets during transfer from the wire to the melt bath and inside the bath itself due to the overlying partial pressure. If the hydrogen content in the melt bath is at the limit of

Fig. 1 Solubility of hydrogen in aluminium

solubility for the solid phase, porosity will almost certainly form during solidification,^[2] which is a significant problem for welding.

Figure 2 reports the sources of hydrogen (hydrocarbons attributed to grease and oils and moisture on the edges and in the atmosphere) with the relevant solutions.

Indeed, the development of the continuous wire welding process under gas shielding has been mainly focused on reducing levels of porosity in the weld deposit, which is the most significant drawback and limitation for industrial performance. Several approaches have been adopted in order to resolve the problems associated with the presence of molecular hydrogen, such as the development of filler materials containing cobalt, which promotes the multiplication of nucleation points.^[3] However, these are not available on the market.

Table 2 Physico-chemical properties of certain materials

	Carbon steels	Stainless steels	Aluminium and alloys	Ratio	
Melting <i>T</i> (°C)	1536	1410	660	/2.5	Energy
Thermal conductivity 0°C (W/m K)	46	15	222	X5	
Coefficient of linear expansion (mm/m°C)	11.8	14–15	23.6	X2	Deformation and distortions
Density (kg/dm ³)	7.83	7.8-8	2.77	/3	Gravitational effects
Resistivity (×10 ⁻⁸ Ωm)	10–20	71–79	2.8-6.7	/2	Joule effect <i>R</i> × <i>I</i> (MIG)

Solubility of hydrogen in aluminium. Hydrogen trapping sources	Solutions: state of the art
Grease, oil and dirt on the edges	Degrease, brush
Moisture in the consumables	Store and use filler metal in sealed, inert and heated distributors
Moisture in the cylinders. Leaks, with entry of air into the gas feed lines	Check for leaks (entry of air and moisture) up to the current feed pipe. Select low water permeability materials for the pipes
Moisture on the welding torch nozzle (internal condensation)	Check the temperature of the cooling system
Turbulence in the gas flow allowing the entry of air	Use a short arc. Develop the welding procedure in terms of electrical parameters, speed, extended, melt bath position in order to favour degassing

Fig. 2 Contaminants and solutions

The processes and gases can cause vibrations in the melt bath which, thanks to the heating induced, causes changes in the surface tension of the molten droplets, and consequently convection currents, promoting the release of hydrogen. Other significant research studies have been aimed at trapping the hydrogen once more by adding halogens (chlorinated or fluorinated compounds).^[4]

In order to promote other solutions than those related to mechanical or electrical vibrations,^[5] alternative routes have been explored, based on the potential influence of gas mixtures on electrical parameters (arc voltage), the regularity of filler metal transfer, the surface tension of the droplets and the melt bath, in order to alter its wettability and hence convection currents inside it, in addition to an attempt to potentially develop the same gas for MIG and TIG processes.

This is clearly the scope of the present article.

OBJECTIVES BASED ON THE INFLUENCE OF THE MECHANISMS IN THE GASEOUS PHASE

How can performance, in terms of the transfer of filler metal, melt bath morphology and quality be improved through the use of gas?

Certain physical properties and the chemical effects on materials are reported in Table 3:

- the density of the gas has a direct effect on the efficacy of protection on the melt bath (especially for positional welding)
- thermal conductivity and specific heat capacity influence the energy density of the arc, which when increased, improves the stability of the arc itself
- viscosity influences droplet detachment, metal transfer stability and MIG welding speed

In Table 3, the properties in the white lines are independent of the material of which the piece is made while, on the other hand, the grey lines are influenced by chemical reactions with the piece (metal vapours, thermo-ionic elements, etc.). Besides the characteristics described above, there have been attempts to improve behaviour in terms of anode and cathode emissivity and stability.

Table 3 Physico-chemical properties of several materials

	N ₂	Ar	He	H ₂	O ₂	CO ₂	
Density (kg/m ³)	1.161	1.66	0.17	0.084	1.34	1.833	Shield gas efficiency Arc power density, transfer stability
Thermal conductivity at 0°C (×10 ⁵ W/cm ² C)	24	16.3	142.2	171.5	25	14.4	
Specific heat(J/kg K)	1041	521.3	5192	1490		846.9	Transfer stability/speed Arc ignition
Viscosity (Ns/m ²)	10 ⁻⁴	10 ⁻⁴	10 ⁻³	10 ⁻⁵	10 ⁻⁴	10 ⁻⁵	
Ionisation potential (eV)	15.58	15.7	24.6	15.43	13.62	13.77	
Chemical effect	Non-reactive	Inert	Inert	Active (reducing)	Active	Active	

In this paper, all tests have been conducted using standard filler materials, taking into consideration the fact that dilution of the base material with filler material significantly influences the finished properties of the welded joint (ultimate tensile strength, yield strength, elongation and resistance to corrosion).

SOME OF THE TRENDS EXAMINED

Mechanisms of interaction with aluminium

The interactions between CO₂, O₂ and aluminium to create aluminium oxide, improving electronic emission from the cathode, have been examined. In parallel, there have been attempts to introduce N₂ in order to improve the AlN combination, representing a valid alternative for increasing arc power density.

Movements of the melt bath and wettability

Increasing arc voltage

As may be deduced from the curves relating to argon and helium, shown in Fig. 3, for the same electrode/piece or wire/piece distance, the voltage depends highly on the nature of the gas or mixture used. By exploiting the progressive addition of helium, the corresponding increase in

Fig. 3 Arc characteristics as a function of gas

arc voltage results in increased energy, and consequently improved penetration and wettability.

Even more significant improvements are obtained by the addition of hydrogen (limited if compared to helium) in the case of welding austenitic stainless steels, but not recommended for aluminium alloys due to the tendency of the latter to produce porosity, as described earlier.

Thus, the addition of other elements is considered.

Effects on surface tension (γ) induced by the combination of elements contained in the alloy and in the gas

Small quantities of residual elements contained in the base material or in the wire significantly alter $d\gamma/dT$, altering movements in the melt bath. Information regarding this phenomenon is somewhat scarce: with the exception of several random tests, to date there has been no general study conducted for light alloys.

Quality of the welded joints

With reference to the various applications, testing has concentrated on:

- surface appearance: shape of the oversize and appearance of the bead, with reference to oxide inclusions and deposits (performed visually)
- quality: bead solidity, with the identification of two-dimensional (cracks) and three-dimensional (inclusions, micro-inclusions and porosity) faults

Evaluation criteria

The evaluation process is based on two types of criteria: operating criteria related to the applicability of the process under industrially relevant conditions and integrity evaluation criteria through the execution of mechanical tests, to be considered during product planning optimization.

Operating conditions: welding performance

The influences on the following have been considered:

- regularity of filler metal transfer
- weld speed or penetration
- melt bath behaviour

Metallurgical results

Mechanical and metallographic tests have been conducted:

- at ambient temperature
- mechanical strength (transverse test section) to assess the position of rupture and the corresponding ultimate tensile strength
- bending tests to assess the ductility of the deposit
- macrographic and micrographic inspections to confirm specific defects detected by X-ray or in order to show the bead shape and microstructure (micro segregations, micro-inclusions or porosity)

PRELIMINARY STUDIES AND RESULTS

The selection of base material and filler material, summarized in Table 4, has been conducted based on recommendations in terms of the quality and mechanical properties of the welded joint.

With regard to the selection of gas mixtures and limiting additions, the latter have been justified by the results obtained from previous Japanese studies (1967–1970),^[6] considering also the electronic developments in welding machines, giving a significant contribution to improvements in process stability and reliability.

Finally, it has been decided to examine the effects of these additions within the limited range reported in Table 5:

- $N_2 < 1$ in order to avoid the formation of brown flakes on the bead surface and an irregularly shaped bead
- CO_2 and $O_2 \ll 5\%$ in order to avoid bead rippling

Despite the significant improvements in bead appearance, the addition of hydrogen to the mixtures has not been considered due to the high risk of porosity.

Developments relating to bad shape, joint quality and appearance (shape and cleanliness) have been considered.

Estimation of the performance of Ar–He/O₂ mixtures

Operating conditions

In order to assess the influence on arc stability and penetration, it is sufficient to prepare head on plate samples, and depending on the results, turn attention to

Table 4 Selection of filler material according to base material

Material	MIG electrode wire	TIG electrode wire	Comments
5083–5086	5183–5356	5183–5356	5356 or 5183
6061	4043	4043	4043–4047
1050	1100	1100	

Table 5 Addition of gas to MIG and TIG welding mixtures

Base Ar–Ar/He	MIG	TIG
Addition of O ₂ , CO ₂ , N ₂	CO ₂ 1–2% O ₂ 1–2%	CO ₂ < 1%
Microaddition of N ₂	Microaddition of N ₂ 150–900 ppm	150–900 ppm

Peak current (A)		330
Baseline current (A)		110
Peak voltage (V)		28
Pulse frequency (Hz)		155
Pulse time (ms)		1.6

Notes: Material, 5086; thickness, 6 mm; electrode wire diameter d : 1.2 mm; 5356 DCTWP 13 mm position 1G; thrust technique.

Table 7 Changes in parameters with the addition of O₂ and CO₂ to Ar – case of bead on sheet, spray arc

Ar reference	Additions	Wire speed (m/min)	Current (A)	Voltage (V)
	Reference	12.5	210	22
	1% O ₂	12.5	224	24.6
	2% O ₂	12.5	228	25.6
	3% O ₂	12.5	232	28
	1% O ₂	12.5	230	23.8
	2% O ₂	12.5	234	25

speed of advancement (Ws) for full penetration joints (Tables 6 and 7).

The addition of O₂ and CO₂ results in a significant increase in current and voltage, therefore improved penetration with varying O₂ percentage, as shown in the macro examination reported in Fig. 4, and a significant increase in spray transfer when compared to pulsed mode.

To assess the quality of weld deposit, preliminary tests have been conducted on butt joints, with X-ray tests and fracture tests (with a small V-shaped notch by means of cross-sectioning of the traction test).

Fracture, reported in Fig. 5, shows a significant difference in the density of micro-inclusions in the weld deposit, performed with ArO₂ and ArCO₂: the quantity of inclusions using 1% CO₂ is greater than that with 2% O₂ (the nature of the inclusions has not been identified). Finally, the decision has been taken to continue testing with the addition of just up to 1.5% of O₂.

**Fig. 4** Results typical of beads on plates with the addition of O₂ in Ar**Fig. 5** Comparison of fracture test results as a function of gas composition**Fig. 6** Weld speed as a function of O₂ addition in the Ar or Ar–He base gas

Differences in performance

As reported in Fig. 6, spray and pulsed arc transfer can be achieved by wire addition speeds (Wfs) of 12.5 and 9

m/min, respectively, and the comparison has been made under full penetration conditions.

With 1.5% O₂, the weld speed is increased by approx. 30% in terms of spray transfer, and by 20% in pulsed arc transfer.

The weld speed with Ar–1% O₂ is approximately equal to that achieved with the mixture Ar–20% He, with the same advantages in terms of wettability in both cases. The most significant increase in weld speed in spray transfer is probably due to improved surface exchange with liquid droplets per unit time.

This also explains the greater consistency of black deposits (magnesium oxide, easily removed by brushing) on the weld bead with spray welding.

Estimation of performance in Ar–N₂ mixtures

Operating conditions

A 100-ppm increase in nitrogen in the argon produces a 9% increase in penetration and melt bath surface. This result has been obtained at equal voltage, wire advancement speed and weld speed. The current shows an increase (4 A) and a slight reduction (2%) in bead width (Table 8).

Figure 7 shows additional tests to evaluate the more significant addition of nitrogen (from 0 to 1000 ppm) to the argon shielding gas or in the argon–helium shielding mixture in order to present the upper acceptance limits of

nitrogen addition. As shown in the diagram in Fig. 7, the same result has been obtained with welding of 5086 alloy.

These welding tests confirm the increase in penetration with an increase in nitrogen content for both alloys selected (5083 and 6061 shown in Fig. 8). Figure 9 shows the increase in melt bath dimensions with an increase in nitrogen content in the shielding gas.

It may be claimed that the addition of 5% helium to the gas corresponds to an addition of 150 ppm nitrogen, in terms of increase in melt bath surface.

In the execution of these tests, the electrical parameters have been corrected as a function of nitrogen addition, and this has been described in Fig. 10.

In the graph, the size of the bubble represents weld bead penetration to sheet thickness in the case of gas with three different nitrogen contents (0, 300 and 900 ppm).

This comparison has been made for three different operational parameters, with an increase in arc current and voltage from the lower limit of the spray transfer field of existence to its upper limit: hence the increase in penetration due to the nitrogen content in the shielding gas is effective at all current values.

Mechanical properties observed using the Ar–O₂ mixture

Prior to execution of the tests relating to the use of mixtures containing Ar/I–1.595 O₂, reference tests have been conducted with gases containing Ar or Ar/He mixtures.

In parallel, it has been decided to assess the impact of purity between passes by determining ultimate tensile strength, yield strength and elongation in weld deposits in the case of multipass joints.

After having checked the good quality of the joint by radiography, tension tests (transverse and longitudinal) and transverse bending tests have been conducted.

All test pieces have passed the bending tests without showing any signs of rupture along the melt line. The values relating to the 3Ar/He mixture, with or without O₂, are concentrated within the range of 268–272 MPa, which is very close to the minimum required value of 275 MPa for the base material.

The design joint coefficient is equal to 0.97%: the effective value is equal to 0.85%, which means that the presence of up to 1.5% O₂ has no negative impact (in terms of micro-inclusions produced) on strength values at room temperature (Fig. 11).

Fig. 7 Comparison between penetration values as a function of micro-additions of nitrogen (bead on plate), continuous wire welding, material 1050, spray transfer

Table 8 Modification of parameters with the addition of N₂ in Ar – bead on plate, spray arc

Gas	100% Ar	Ar + 100 ppm N ₂	Ar + 300 ppm N ₂	Ar + 600 ppm N ₂	Ar + 900 ppm N ₂

Macrographic tests

Some test pieces taken from significant areas have simply shown the influence of the addition of the O_2 to the argon on weld bead shape morphology: for example, Fig. 12 shows the progressive flattening of the oversize and enlargement of the weld bead at equal levels of penetration.

Probably, the weld speed in the case of the use of Ar-1.5% O_2 may be increased. Good wettability is observed on both sides, with no internal defects observed (Fig. 12).

Only the surface shows surface blackening (magnesium oxide, simple to remove). Numerous simple methods for improving weld bead appearance have been tested, by directly inserting the gas (inert or active) into the current-carrying tube, thus drastically reducing the density of blackened deposit and its colour: furthermore, the introduction of active gas inside the current-carrying tube has been shown to be more efficient (Fig. 13).^[7]

Fig. 12 Macrographs of butt joints, spray transfer with the addition of O₂ to Ar

Welding International

Fig. 13 Influence of partitioning of the gas mixtures in the torch

Other extraneous contamination occurs during fabrication when it becomes necessary to clean the surfaces prior to welding, or, in the case of multilayer welding, when cloths or brushes are used. As shown in Table 9, this phenomenon has been assessed for all procedures for estimating weld deposition.

Aside from mixture 3 containing Ar–He, all the values reported in Fig. 14, with or without the addition of O₂, are very similar aside from the reduced recorded ultimate tensile strength value of 240MPa and elongation of 13%, probably due to direct contamination from cloth fibres. Industrial experience with TIG welding (automatic

ad orbital) with aluminium alloys has frequently shown that the use of cloths is very critical and brushing is more reliable.

Mechanical properties recorded using the Ar/O₂ mixture

The mechanical properties of full penetration weld beads: from Table 10, it may be observed that a nitrogen content of up to 900ppm has no effect on the mechanical properties of aluminium joints.

INTERPRETATIONS AND RECOMMENDATIONS

Observations on N₂ microadditions

Analysis of high-speed images (HSVR: high-speed recording) has been performed in order to explain the influence on electrical parameters and the weld bath.

Arc melt surfaces

High-speed imaging has made it possible to compare the external surfaces of the arc as a function of percentage of nitrogen in the shielding gas.

It has been observed that, at equal voltage values, an increased nitrogen percentage results in greater current values (the use of flat characteristic generators guarantees constant voltage).

In the same way, a reduction in arc length may be observed between the surface of the piece and the tip of the wire. In this configuration, due to the high luminescence of the arc, the melt bath surface is not visible. This makes it difficult to define the length of the arc (Table 11).

Complimentary observations of the melt bath

Further studies have been conducted with different video camera settings in order to show the influence of nitrogen content in the melt bath, with identical electrical parameters.

The observations show that with higher nitrogen contents, at the same voltage and wire advancement speed, the arc is deeper. In addition, a small coating of floating particles may be observed on the bath below the arc plasma, which shall be analysed later (Table 12).

Observations of cathodic spots

A comparison has been made between the gas Arcal I (100% argon) and the mixture containing 900ppm nitrogen in argon, in order to highlight the differences in terms of cathodic spots and cathodic drop. Testing has been conducted at constant wire advancement speed, arc length and voltage in order to exclude the influence of changes in stick-out (Fig. 15).

Under the same conditions, the increase in power density is due to the reduction in the area of cathodic spots, resulting from the addition of nitrogen to the shielding gas.

Scanning electron microscopic analysis of small particles present in the melt bath

In order to determine the nature of particles floating on the melt bath observed by high-speed video, a scanning electron microscopic analysis was carried out.

Figure 16 shows the surface of a joint made with the addition of 900ppm nitrogen in argon. Spectra 1 and 3, respectively, relate to the melt bath surface. Spectrum 2 corresponds to a coating particle present in the melt bath (Fig. 17).

Spectrum 2 indicates the presence of nitrogen on the surface of the joint. Since this is practically insoluble in aluminium in both the solid and liquid phases,^[8] its presence demonstrates that in the solid state, the compound forms on the surface of the melt zone during welding. The main substances present in the arc are aluminium, magnesium,

Fig. 16 Analysis of the weld bead surface

Fig. 17 Weld bead surface spectra

argon, nitrogen and oxygen. The nitrogen and aluminium compounds that can form in the solid state include aluminium nitrate and magnesium nitrate. In any case, tests conducted with different types of aluminium alloys (with or without magnesium) have shown the same level of penetration. This fact supports the hypothesis that the surface particles that form during welding consist of aluminium nitrides (AlN), the melting point of which is 2200°C, with high thermal conductivity.^[9]

Conclusions regarding the understanding of nitrogen microaddition

The results obtained from the micro-addition of nitrogen are mainly associated with the influence on the characteristics of the electric arc.

The dissociation of nitrogen near the anode results in the absorption of energy, and a reduction in the external temperature of the arc produces a constriction: at the same time, in contact with the reduced temperature near the melt bath, ions and atoms become molecules once more, releasing a consistent amount of energy.

If both effects contribute significantly to increasing arc power density, the limited additional amount does not justify the significant increase in penetration or weld speed.^[10] Most likely, another justification is based on the observation of the presence of aluminium nitrate on the melt bath: these highly emissive particles (twofold emissivity in comparison to aluminium) produce minor movements in the cathodic spots which, in combination with the previously described effects, lead to increased power density.

Influence of additions and micro-additions, respectively

It is interesting to note the analogous results obtained with MIG welding with the addition of 600ppm nitrogen to

argon and 1.5% O₂ to argon, respectively, in terms of weld speed (Ws) and relative weld bead shape.

As a general overview, the major advantages of the micro-addition of nitrogen are:

- improved weld bead appearance quality with reduced spray, with no black deposits compared to those obtained with the addition of O₂
- the possibility to use the same shielding gas for both MIG and TIG processes: for the latter, nitrogen contents in excess of 2% are not recommended in order to limit wear of the tungsten electrode; similarly, even the very limited addition of O₂ to the shielding gas is highly detrimental for TIG welding, promoting the formation of tungsten oxide WO₂ on the surface of the electrode, interrupting laminar flow on the electrode itself and on the melt bath (Fig. 18)

The increased penetration that can be obtained with the addition of nitrogen or oxygen depends on the heat of reaction in relation to the formation of aluminium nitrates (AlN) and aluminium oxides ((2/3)Al₂O₃) (the free energy of this reaction is -40 kcal/mol and -200 kcal/mol, respectively).

Again, as mentioned previously, the increased penetration is also influenced by the increased power density.

Recommendations and applications of mixtures

Following on the results of the various tests reported in Table 13, the final two lines should be considered:

- the addition of O₂ to argon or argon-helium mixtures has significant effects on weld speed or penetration. With the addition of 1.5% O₂ to argon, the weld speed is similar to that obtained with argon-helium mixtures, for all argon-helium percentages, with no change in

Fig. 18 Images of the formation of WO₂ around the electrode

Table 13 Comparison of the results of different additions to Ar and Ar–He mixtures

Gas	GMAW of aluminium alloys						
	Productivity			Quality			Aspect
	Penetration	Arc striking	Welding speed	Soundness	Mechanical properties	Shape profiles	Fumes, deposit
Argon (reference)							
Helium							
Argon+He (5 and 20%)							
Argon+CO ₂ (0.008 and 0.1%)							
Argon+O ₂ (0.008 and 2%)							
Argon+N ₂ (0.008 and 0.09%)							

mechanical properties: the drawback to the formation of black surface oxides around the bead (easily removable) is acceptable when bead appearance criteria are not a priority. These gas mixtures are not recommended for traditional TIG processes.

- Precisely as with O₂, the effects of the micro-addition of nitrogen must be compared with the addition of helium to argon–helium mixtures (with 20–70% helium). With the addition of up to 600ppm nitrogen to argon, the weld speed is analogous to that for the mixture containing 20% helium; furthermore, significant improvements in the operating conditions are obtained in terms of bead appearance and joint quality, if compared to the use of argon alone. It is also possible to use these mixtures for both MIG and TIG processes, with similar increases in performance.

In order to confirm the veracity of the conclusions, some clients in different manufacturing sectors (shipbuilding and cryogenics) are testing different nitrogen micro-additions compared to the addition of oxygen to argon: the preliminary conclusions are mainly centred on the selection of gases containing 600–900ppm nitrogen, where the flexibility of site supply is also appreciated.

Sintering Behavior: Al–SiC Compacts in Different Atmospheres

Tadeusz Pieczonka

AGH University of Science and Technology, Kraków, Poland

Abstract

The effect of sintering atmosphere on densification of Al–SiC compacts was investigated. Dimensional changes were monitored in situ in a dilatometer in flowing nitrogen, nitrogen/hydrogen mixture (95/5 by volume), and argon. Two grades of SiC powder were used—F240 characterized by large particles and FCN13 with very fine particles. Mixtures containing 10 and 30 vol.% of SiC reinforcement were prepared in a Turbula mixer. Green compacts of about 80% of theoretical density were made of each mixture. For comparison, compacts made of pure aluminum powder were also investigated. It was shown that nitrogen is the only sintering atmosphere producing shrinkage. This ceramic constituent lowers the sintering densification. Metallographic examinations of sintered composites revealed that sintering of compacts occurs in the presence of a liquid phase exclusively in nitrogen. The melt appearing in Al–SiC compacts is capable to wet the solid phases, which makes shrinkage possible and is beneficial for metal/ceramic bond formation.

Keywords: Al–SiC composites; Densification; Liquid phase sintering; Powder metallurgy; Sintering atmosphere.

INTRODUCTION

Aluminum-based metal matrix composites (MMCs) reinforced with ceramic particles (particularly with Al_2O_3 or SiC particles, platelets, or whiskers) are modern, light-weight materials that have a very attractive combination of material properties and price. Aluminum and silicon carbide have very different mechanical and physical properties. By combining these materials, MMCs suitable for a wide range of applications can be produced. They are characterized by low density, a relatively high strength even at elevated temperatures, good ductility, high wear and fatigue resistance, high friction coefficient, reduced thermal expansion, high thermal conductivity, and good corrosion resistance. The requirements of the transportation sector include components with almost three times lower densities than iron-based parts, including those manufactured by powder metallurgy (PM). The replacement of the sintered steel parts by the aluminum-based ones has additional economic benefits, because of the relatively low temperature of sintering in a cheap and safe nitrogen atmosphere. There are already several aluminum-based PM materials in use, including aluminum MMCs, of which those reinforced with SiC particles are the most significant.^[1–7]

Developed for aerospace and military applications, they have found, up to now, limited use in the automobile industry. However, these materials have already begun to

substitute conventional materials in household appliances, computers, and audio and video equipment, as well as in sport and leisure applications.

PM is thought to be the most common and the most economic production technique for MMCs. One of the advantages of PM compared to casting is having better control on the microstructure, where better distribution of the reinforcement is possible in PM compacts. The next advantage of PM concerns lower sintering temperatures than those required for casting. Therefore, the unwanted interfacial chemical reactions between the matrix and reinforcement can be avoided or become significantly limited, and thus, there is better control of the reinforcement–matrix interface. By carefully controlling the relative amount and distribution of the ingredients of a composite, as well as the PM processing conditions, Al–SiC MMCs with enhanced mechanical and tribological properties can be produced.

A review of the literature on Al–SiC sintered MMCs indicates that most research concentrated on raw materials, in terms of their quality, particles sizes, and metal–ceramic proportions, and on sintered properties.^[5–13] By contrast, a little attention has been made to the sintering process alone, in particular to the role of the sintering environment.^[13–16] Thus, the present investigation is an attempt to further evaluate the effect of the sintering atmosphere on densification of Al–SiC compacts during pressureless sintering.

It is well known that in industrial practice, it has been demonstrated unambiguously that nitrogen is the most suitable sintering atmosphere for aluminum.^[17–19] It could be supposed, therefore, that nitrogen may also be the best environment for sintering of Al–SiC powder mixtures, particularly at temperatures at which the reactions between metal matrix and reinforcement can be neglected.

EXPERIMENTAL PROCEDURE

The following starting materials were used:

- Air atomized AGC100 grade aluminum powder produced by ALPOCO, Skawina, Poland.
- Two grades of ball milled SiC powders supplied by Norton-Norway, F240 and FCP13.

Some properties of the powders are shown in Tables 1 (Al) and 2 (SiC).

FCP13 grade SiC powder was very fine (mean particle size below 1 μm); thus, its particle sizes were characterized by the specific surface, which was 13 m^2/g .

Before mixtures were prepared, the SiC powders were cleaned in acetone, then dried.

Mixtures containing 10 and 30 vol.% of SiC were prepared in a turbula mixer with a mixing time of 1 h. Additionally, for comparison, as-delivered aluminum powder was also used. No binders or lubricants were added. The following mixtures were prepared:

- Al + 10 vol% SiC (F240 grade)
- Al + 30 vol% SiC (F240 grade)
- Al + 10 vol% SiC (FCP 13 grade)
- Al + 30 vol% SiC (FCP 13 grade)

Rectangular (15 $\times$ 4 $\times$ 4 mm^3) green compacts of 78%–81% of theoretical density were produced by uniaxial cold pressing with glycerol die wall lubrication. To achieve green porosity of about 20%, several compacts

were produced from each powder mixture at different compaction pressures.

Sintering was performed in a horizontal NETZSCH 402E dilatometer in different atmospheres flowing through the furnace tube of 35 mm inner diameter at 100 mL/min. These sintering atmospheres used were as follows:

- Pure nitrogen (52).
- 5 vol.% hydrogen and 95 vol.% nitrogen.
- Pure argon.

All gases used were high purity with a dew point below -70°C (which was the lowest point on a dew point meter’s scale) and oxygen content below 5 ppm.

Dimensional changes were monitored during the whole temperature–time program: heating at $20^\circ\text{C}/\text{min}$ to the isothermal sintering temperature of 620°C , at which the samples were held for 2 h, and cooling at $20^\circ\text{C}/\text{min}$ to room temperature.

RESULTS

Figures 1–5 clearly demonstrate that sintering atmosphere (N_2 , Ar, or $\text{N}_2 + 5\% \text{H}_2$) exerts a strong influence on the sintering densification of materials investigated; that is, shrinkage occurs in pure nitrogen only. It should be noted that 5 vol.% of hydrogen in the mixture with nitrogen is a sufficiently high concentration to stop the densification.

Additionally, the dilatometry curves document that both an increase in the ceramic content in the mixture and the use of the very fine ceramic powder lower the sintering shrinkage.

Figures 6–9 show the representative optical micrographs of sintered compacts. The structural component that indicates the presence of a liquid phase during sintering (pointed in figures by arrows) appears in materials

sintered in a pure nitrogen only, independently of their composition. In contrast, sintering in argon and nitrogen/hydrogen mixture does not modify the aluminum matrix in any way.

Fig. 5 Dilatometry changes of Al-30 vol.% SiC (FCP grade) compacts during sintering in different atmospheres

The amount of the liquid phase formed in the nitrogen atmosphere was not estimated quantitatively. It is easy to recognize in micrographs, however, that the presence of ceramic phase decreases its amount, which correlates with dimensional changes shown on dilatometric curves.

DISCUSSION

Dilatometry curves shown in Figs. 1–5 document that sintering atmosphere (N_2 , Ar, or $N_2 + 5\%H_2$) influences not only the sintering densification but also the mechanism controlling this process. Two completely different types of dilatometric curves can be distinguished: for sintering in pure nitrogen resulting in isothermal shrinkage, and in other atmospheres, when no dimensional changes occur isothermally. This observation is valid for all compositions investigated; that is, the SiC added to Al, in contrast to the atmosphere, does not change the type of dimensional behavior during sintering. The amount of isothermal shrinkage, however, is influenced both by the SiC content and by its particles sizes. Generally, the larger the surface of direct Al–SiC contacts, the lower the isothermal shrinkage in nitrogen.

It has already been shown^[17–20] that densification occurring during sintering of pure aluminum in nitrogen is connected with Al nitriding, and even a small amount of hydrogen in a mixture with nitrogen will strongly impede the sintering shrinkage. The current results as well as the previous ones^[16] clearly show that only pure nitrogen is an active sintering atmosphere also for Al–SiC compacts, producing their densification. Similar to the sintering behavior of unalloyed aluminum, isothermal shrinkage developed in Al–SiC compacts in nitrogen at high shrinkage rate may suggest that a liquid phase contributes to densification. The appearance of the liquid phase in the system at 620°C is possible due to the highly exothermal aluminum nitriding reaction, which may result in a local increase of the temperature

Fig. 6 Microstructure of the interior of aluminum compacts sintered in (a) argon, (b) nitrogen/hydrogen (95/5) mixture, and (c) nitrogen. Isothermal sintering temperature: 620°C

above the melting point of Al. It is well known that the appearance of the liquid alloy is crucial for sintering of aluminum-based materials.

Fig. 7 Optical micrographs of sintered compacts made of Al + 30 vol.% SiC (F240 grade) powder mixture. Sintering atmosphere: (a) argon; (b) nitrogen. Isothermal sintering temperature: 620°C

Interfacial characteristics in MMCs reinforced with ceramic reinforcements play a significant role in determining the mechanical properties, such as strength, ductility, toughness, and fatigue. To achieve superior mechanical properties in MMCs, it is essential to form adequate interfaces, which not only do not degrade the reinforcement during fabrication but also retain structural stability, both for corrosive environments and at elevated temperatures. In general, a frequent problem encountered in fabricating Al-based composites reinforced with various carbides, in particular with SiC, can be the formation of Al_4C_3 at the matrix/reinforcement interface as a product of the interfacial reaction between both constituents. Al_4C_3 is known to be very brittle and unstable, resulting in the degradation of mechanical properties of composites. In addition, due to the hydrophilic nature of Al_4C_3 , composites containing Al_4C_3 are very sensitive to some corrosive environments. Therefore, formation of Al_4C_3 during composite fabrication has to be either avoided or minimized. From this viewpoint, PM is a very suitable route for fabrication of Al–SiC MMCs because sintering may be effective at lower temperatures than those at which synthesis of Al_4C_3 develops. Viala et al.^[21] have

Fig. 8 Optical micrographs of sintered compacts made of Al + 10 vol.% SiC (FCP grade) powder mixture. Sintering atmosphere: (a) argon; (b) nitrogen. Isothermal sintering temperature: 620°C

shown that solid Al and SiC remain in thermodynamical equilibrium at temperatures lower than 923K in vacuum at atmospheric pressure, which is nearly 10K below the melting point of Al. Above 923K, solid Al starts to react with SiC and Al_4C_3 is formed and, additionally, a ternary liquid phase with low carbon content, and with a silicon atomic percentage of about 1.5%, may appear. Liquid Al reacts with SiC more intensively, which results in the formation of some other phases.^[21]

Depending on the atmosphere, during current experiments, sintering process took place in the solid state, when argon or 95N₂/5H₂ was used, or in the presence of the transient liquid phase in case of pure nitrogen. Microstructure investigations carried out on sintered compacts confirm the presence of a liquid phase during sintering of Al and Al–SiC compacts in nitrogen (Figs. 6c, 7b, 8b, and 9b), which is responsible for shrinkage. It may also be noted that a liquid appears in sintered compacts at furnace temperature markedly below the melting point of aluminum. This is attributed to local heating, with the temperature there exceeding the furnace temperature, due to the exothermic reactions between aluminum

Fig. 9 Optical micrographs of sintered compacts made of Al + 30 vol.% SiC (FCP grade) powder mixture. Sintering atmosphere: (a) argon; (b) nitrogen. Isothermal sintering temperature: 620°C

and nitrogen. These reactions are responsible for local melting.^[18–20] The liquid phase that appears wets the aluminum surface and penetrates the aluminum grain boundaries. Similar interactions between aluminum and nitrogen take place when Al–SiC compacts are sintered in pure nitrogen. However, the presence of SiC limits the amount of liquid phase formed, and thus the sintering shrinkage.

Taking into account the isothermal sintering temperature of 893K, it can be stated that the interfacial reactions between Al and SiC cannot be expected. In fact, the photomicrographs of the samples in Fig. 7 show the SiC particles dispersed in a single aluminum matrix phase.

The SiC particles exhibit clear outlines and no reaction product can be seen at the Al–SiC interface. It has to be noted that optical micrographs do not show any products of the reaction between the liquid phase appearing in compacts sintered in nitrogen and SiC. It is easy to recognize, however, that there is good wettability of the SiC surface by this liquid (Fig. 10). As a result, the liquid readily spreads across the ceramic surface, which is well documented in Fig. 10 and indicated by arrows. In this way, nitrogen

Fig. 10 Microstructures of Al-30 vol.% SiC composite sintered isothermally at 620°C for 2 h in nitrogen. The arrows indicate the wettability of the ceramic surface by the liquid phase appearing during sintering

Fig. 11 Disintegration of SiC clusters and redistribution of fine SiC particles. Optical micrographs of sintered compacts made of Al + 10 vol.% SiC (FCP grade) powder mixtures. Sintering atmosphere: nitrogen. Isothermal sintering temperature: 620°C

atmosphere is not only beneficial for densification but also assists in the formation of bonding between Al and SiC.

Figures 8 and 9 show the strong tendency of very fine SiC particles to form clusters in sintered Al–SiC composites. The use of this SiC powder lowers the permeability of the compacts and decreases the available Al-free surface. Therefore, the reactions between Al and nitrogen atmosphere are limited, and less liquid can appear. It is seen in Fig. 11 that the fine SiC particles remain stable in contact with the liquid. The flow of the liquid toward the Al grain boundaries is associated with redistribution of the fine SiC particles. An additional function of the liquid is to penetrate the SiC clusters and disintegrate them. Both mechanisms are beneficial for Al–SiC interfacial bonding.

The above metallographic observations and interpretations correlate with the dilatometry results. Similarly, as for pure aluminum, hydrogen plays a detrimental role in

the sintering of Al–SiC composites: the reactions between aluminum and nitrogen are blocked at hydrogen content of 5 vol.% in the mixture with nitrogen. Therefore, a liquid phase does not appear in the sintered system. Sintering behavior of Al–SiC composites in argon is similar to that in the $N_2 + 5\% H_2$ atmosphere.

CONCLUSIONS

The sintering process of Al–SiC powder mixtures is strongly influenced by the sintering atmosphere. The results may be summarized as follows:

1. Among gases used, only nitrogen is a chemically active sintering atmosphere for pure aluminum and Al–SiC powder mixtures.
2. Nitriding of aluminum matrix, taking place only in a pure nitrogen atmosphere, is responsible for transient liquid-phase formation during isothermal sintering, despite the latter process being carried out at temperatures significantly lower than the melting point of aluminum.
3. The melt appearing in Al–SiC compacts is capable of wetting the solid phases, which results in sintering shrinkage, penetration of Al grain boundaries, spreading across the SiC surface, and thus the interfacial Al–SiC bond formation. Additionally, in the case of the very fine SiC particles, the liquid disintegrates to some extent SiC clusters and affects the redistribution of these particles.
4. The operation of nitrogen in the Al–SiC system is similar to that for sintering of pure aluminum. However, the reaction area between aluminum and nitrogen is decreased by the presence of a ceramic phase. Therefore, the amount of the liquid phase, and thus the amount of sintering shrinkage, is lowered.

ACKNOWLEDGMENTS

Special thanks are due to the Aluminium Powder Company Limited (ALPOCO) from Skawina in Poland for donating the high-purity aluminum powder.

Smelting of Aluminum

Michael M. Gasik

Helsinki University of Technology, Espoo, Finland

Michael I. Gasik

National Metallurgical Academy of Ukraine, Dnipropetrovsk, Ukraine

Abstract

In this article, an overview of aluminum reduction from oxides and other aluminum compounds is provided. Specific topical coverage addressed are: physical chemistry of aluminum reduction, smelting processes including: the Hall-Héroult Process, the ALCAN Process, the Alcoa process, the Elliot-Mitt Process, and others. In addition, direct reduction of aluminum alloys, and electrodes for aluminum production are discussed.

Keywords: Electrodes; Electrolysis; Master alloys; Reduction; Smelting.

INTRODUCTION

In this chapter, the basics of the aluminum reduction from oxides and other aluminum compounds are considered. The most important and practically tested processes are discussed together with their thermodynamics. The advantages and disadvantages of these processes are compared and new possibilities in aluminum production are presented. Because aluminum electrolysis is a well-documented process described in many handbooks since its invention, more attention is paid to the modern situation of the electrolysis, technological barriers and development opportunities.

In the second part of the chapter, direct reduction of aluminum-based compounds is discussed. This electro thermal process is cost effective, robust and widely used for aluminum alloys and master alloys with different elements (silicon, iron, manganese, calcium, chromium, zirconium, etc.).

Finally, electrode requirements, manufacturing and application are shown with respect to electrolysis (anodes in the Hall-Héroult process), electrometallurgy (self-baked and pre-baked) as well as for novel techniques (inert anodes). Energy issues of aluminum industry are also considered in this respect.

These three areas themselves are very wide and detailed description of the major topics in any of them would require its own book (or books) to be written. More specific details about the process of anode mass preparation or aluminum oxycarbides formation could be found in numerous articles and technical papers to which the reader is encouraged to refer for more details (only a few of them are listed in the references).

The objective of this chapter is to present a general outline of the basic issues of the aluminum reduction, smelting, and electrolysis, alloy formation as well as very important

issues about the electrodes used in these processes from the engineering point of view.

PHYSICAL CHEMISTRY OF ALUMINUM REDUCTION

Aluminum exists in nature in the various mineralogical forms of alumina, Al_2O_3 , either “pure” (bauxites, corundum) or bonded with silica, alkalis and other elements in alumina-silicates. Dissociation of alumina at high temperatures produces sub-oxides like AlO , Al_2O_2 , and Al_2O in the gas phase, although there are data about the existence of AlO and possibly “ Al_2O ” in the solid state as well.^[1] Figure 1 shows that all major aluminum oxides are rather stable at high temperatures (negative free energy of formation). This means that the reduction of aluminum from its oxides is difficult to realize.

It is not also possible to reduce aluminum (Al^{3+}) to its metallic state in an aqueous solution. Figure 2 demonstrates that at any reasonable pH (0–14) at room temperature, either hydrated alumina ($\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$) or aluminate-ion like $\text{Al}_3(\text{OH})_4^{5+}$ will exist. At very high reducing potentials, aluminum may be theoretically reduced to hydride AlH_3 but is already out of range of stability of water, so the aqueous media electrolysis cannot take place here (hydrogen generation due to water electrolysis will overcome aluminum reduction).

Alumina is known to form many forms, phases, and hydrates. The preparation of alumina from bauxites requires, thus, knowledge of reactions and processes associated with the decomposition of alumina hydrates. Holm and Lovi^[2] have studied dehydration processes of European and South African bauxites using DSC together with

Fig. 1 Ellingham-type diagram of aluminum oxides (Gibbs energy of formation, kJ/mol vs. temperature)

thermosonimetry (TS). This method is based on the registration of sound signals generated by the transformations in solids.^[3,4] Bauxites from South Africa contain mainly gibbsite $\text{Al}(\text{OH})_3$, but European bauxites contain mostly boehmite $\gamma\text{-AlO}(\text{OH})$ or diaspor $\alpha\text{-AlO}(\text{OH})$. It is known that dehydration of gibbsite in bauxites is likely to take place in two steps:

as well as directly on reaction:

Dehydration of boehmite and diaspor takes place as a rule by a single reaction:

Using thermosonimetry (TS), it has been possible to determine the peculiarities of the dehydration, which cannot be seen by other methods. As an example, it was shown^[2,5] that the first above-mentioned reaction has been fixed by DSC as a single-stage process, but using TS gives two distinct areas of reactions at $310\text{--}320^\circ\text{C}$ and $322\text{--}325^\circ\text{C}$. It has been explained by applying a two-stage mechanism as:

Fig. 2 Electrochemical phase stability areas vs. potential (V) and pH. Dashed lines are water stability ranges. Only stable compounds and ions are shown for 25°C and for molarity of 1 mol Al per 1 H_2O

Iron hydroxides that are also present in bauxites, dehydrate at relatively low temperatures. Goethite (FeOOH) transforms into hematite (Fe_2O_3), with an endo-thermic effect resulting at 340–350°C. Hydrohematite ($\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$) decomposes at 50–150°C. Hydrogoethite ($\text{FeOOH} \cdot \text{H}_2\text{O}$) has two endothermic stages: at 50–150°C and 340–350°C.

Dehydration of bauxite from Guinea (West Africa) has been studied by DTA.^[5] It has been shown that nearly 70% of constitutional water removes from bauxite at 280–330°C, nearly 25% water removes at 530–570°C and full dehydration takes place only at 800–900°C.

Many researchers have reported that the temperatures of phase transformations in Al_2O_3 – SiO_2 – H_2O system are strongly dependent on heating rate and water pressure.^[6] It is being considered that gibbsite transforms into boehmite (at ~453 K) or into χ -alumina (523–573 K), and then into κ - Al_2O_3 at 773–1073 K (Fig. 3). Bayerite α - $\text{Al}(\text{OH})_3$ also transforms into boehmite at ~453 K, but also may decompose into γ - and η -aluminas at 503–533 K. γ - Al_2O_3 transforms in its turn into the δ -phase (>1123 K), and then into Θ - Al_2O_3 (~1323 K). Alternatively, η -alumina also transforms into Θ -phase directly at ~1123 K. All these phases finally give alpha-phase, but at different temperatures: ~1473 K (Θ -, κ -phases), and 663–813 K (diaspore). Mizuno and Saito^[6] have shown by TG and DTA that thermal decomposition of aluminum nitrate and sulfate mixtures with fumed silica gives different products at various temperatures of heat treatment.

Gasik and Sale^[7] have used simultaneous thermal analysis (TG, DTA, and DTG) to determine the thermal decomposition of fine alumina hydrate made of aluminum nitrate precursor. Figure 4 represents the results of STA run in air at a heating rate of 10 K/min. It is seen that water removes out of the specimen in two steps,

Fig. 3 Temperatures (K) of phase transformations of aluminas and alumina hydrates (gathered from data of different sources)

which have their DTG-peaks at 393–423 K and 693–723 K, respectively. The results were compared with the ones obtained by other studies,^[6,8–10] and these processes were considered to be diffusion controlled. The first of them represents a transformation of $\text{Al}(\text{OH})_3$ to $\text{AlO}(\text{OH})$, and the second stage is possibly related with the formation of γ - Al_2O_3 from $\text{AlO}(\text{OH})$. The formal kinetic analysis for both the stages shows that these reactions are likely to be described by Avrami–Erofeev’s equation.^[11,12] This is in an agreement with the hypotheses about nucleation, growth of nuclei, and retardation due to overlap of growing nuclei. The formation of different products (aluminas and alumina hydrates) depends strongly on water partial pressure. The authors^[13] have reported about such gibbsite transformation, which may be treated as a continuous sequence of structures – from boehmite to α - Al_2O_3 . It can be described by the formula, $\text{Al}_2\Box\text{O}_{3-\nu/2}(\text{OH})_{\nu}\blacktriangle_{1-\nu/2}$, where $\Box$ means cationic and $\blacktriangle$ means anionic vacancies, respectively. They have found that the scheme as in Fig. 3 depends on the

Fig. 4 Simultaneous thermal analysis (STA) of alumina hydrate (after Gasik and Sale^[7])

initial crystallinity of the gibbsite specimen. With TG/DTA and following x-ray analysis, it was shown that high-amorphous gibbsite dehydrates into χ , κ -, and α -aluminas, eliminating the stage of boehmite. However, in the core of a well-crystallized sample, boehmite forms at 573 K and further transforms to γ -, Θ -, and finally, to α - Al_2O_3 .^[13] It was also observed that the temperature range and temperature of the DTA peak is proportional to the degree of crystallinity.

The above data of the alumina transformations are very important to understand not only for the bauxite processing, but for the aluminum smelting reduction as well. Alumina processed by different methods may have different phases and, thus, reaction ability. This could significantly affect the reduction reaction kinetics.^[5,11] No full thermodynamic data are still known for all alumina phases. Using the data available, some phase stability diagrams may be, however, constructed (Fig. 5). This picture shows phase stability areas in the Al–O system heated up in argon (normal pressure 1 bar). Here, one may recognize that at $\sim 1650^\circ\text{C}$, oxygen partial pressure under alumina will be $\sim 10^{-20}$ bar.

The reduction of alumina directly to pure aluminum is actually only possible by electrolysis (like the Hall–Héroult process). Using carbon leads to the formation of carbide and oxycarbides, which affect thermodynamics and kinetics of the process, as shown below. These compounds do not form in the presence of other elements like silicon and iron.

It is known that during co-reduction of several elements, their chemical potentials and, therefore, activities may be significantly lowered and, thus, thermo-dynamic conditions for the reduction may be improved.

THE HALL–HÉROULT PROCESS

The Process Basics

The smelting process that is still used today was discovered almost simultaneously but independently in the United States and France. Working in Ohio, Charles Martin Hall made the same discovery that metallurgist Paul Lois Toussaint Héroult made in a laboratory in Gentilly: both men dissolved alumina in molten cryolite and then extracted the aluminum by electrolysis. In the Hall–Héroult process, alumina (Al_2O_3) is dissolved in an electrolyte that consists of molten fluoride salts kept at about 950 – 970°C . The alumina itself is separated from bauxite, a natural ore, by the Bayer process. The process takes place in electrolytic cells (or “pots”), where carbon cathodes form the bottom of the pot and act as the negative electrode. Anodes (positive electrodes) are held at the top of the pot and are consumed during the process when they react with the oxygen coming from the alumina. When direct current is passed through this melt, the alumina is decomposed into molten aluminum, deposited at the cathode, and oxygen, which reacts with the carbon anode to form CO_2 .

The cells today are of two types: those with pre-baked anodes and those with baked-in-place anodes (Soderberg). All the pot-lines built since the early 1970s use the pre-baked anodes, where the anodes, manufactured from a mixture of petroleum coke and coal tar pitch (acting as a binder), are “pre-baked” in separate electrode plants (see “Electrodes for Aluminium Production” section for more details about electrode production). In the Soderberg technology, the carbonaceous mixture is fed directly into the top part of the pot, where “self-baking” anodes

Fig. 5 Phase stability diagram for the Al–O system in argon (1 bar)

are produced using the heat released by the electrolytic process.

The electrolyte used is based on cryolite (Na_3AlF_6), which is the best solvent for alumina. To improve the performance of the cells, various other compounds are added including aluminum fluoride (AlF_3) and calcium fluoride (CaF_2), to lower the electrolyte's freezing point. The electrolyte ensures that a physical separation is maintained between the liquid aluminum (at the cathode) and the carbon dioxide/carbon monoxide (at the anode).

Although the mechanism of electrolysis is still imperfectly understood, most investigators agree that cryolite ionizes to form hexafluoroaluminate (AlF_6^{3-}), which dissociates to form tetrafluoroaluminate (AlF_4^-), sodium (Na^+), and fluoride (F^-) ions:

Alumina dissolves by forming oxyfluoride ions $\text{Al}_2\text{OF}_{2n}^{4-2n}$, at low concentrations and oxyfluoride ions AlOF_n^{1-n} , at higher alumina concentrations:

Cells are generally operated with 2–6% Al_2O_3 in the electrolyte. Measurements indicate that Na^+ ions carry most of the current and, most probably, a charge transfer occurs at the cathode interface. Here, hexafluoroaluminate ions are discharged, forming aluminum and F^- ions to neutralize the charge of the current carrying Na^+ ions:

Oxyfluoride ions discharge on the anode, forming carbon dioxide and AlF_6^{3-} ions:

In operation, cryolite freezes on the sidewalls of the cells forming a “ledge” which protects the sideling from severe attack by aluminum and molten cryolite. It also freezes over the top of the bath and forms a “crust” to support a top layer of alumina thermal insulation. Alumina is fed to the bath through holes punched in the crust. The carbon dioxide exits through holes in the crust and is collected under the hoods. The carbon dioxide and air leaking in is now ducted to dry scrubbers which remove fluorides from the gas stream. Fresh alumina contacting the gases removes the hydrogen fluoride and the evaporated fluoride particulate. This alumina, fed to the cells, returns the fluoride to the cells. The hydrogen fluoride comes from the residual

hydrocarbons in the anodes and trace water in the alumina and air humidity reacting with the fluoride bath.

Control of alumina concentration in the cells is accomplished by a slight underfeeding. When the alumina reaches a critical level, the cell goes on anode effect, caused by a limiting rate of diffusion of alumina to the anode surfaces. The cell voltage then rises and some fluorocarbons are generated. The ratio of sodium fluoride to aluminum fluoride in the cryolite bath changes over time and corrective additions are added based on laboratory analyses.

Molten aluminum is deposited at the bottom of the pot and is siphoned off periodically, taken to a holding furnace, often but not always blended to an alloy specification, cleaned and then generally cast. A typical aluminum smelter consists of around 300 pots. These will produce some 125,000 t Al annually. However, some of the latest generation of smelters are in the 350,000–400,000 t range. The smelting process is continuous. A smelter cannot easily be stopped and restarted. If production is interrupted by a power supply failure of more than four hours, the metal in the pots will solidify, often requiring an expensive rebuilding process.

A modern alumina smelting cell consists of a rectangular steel shell typically 9–12 m long, 3–4 m wide, and 1–1.2 m high. It is lined with refractory insulation that surrounds an inner lining of baked carbon. Thermal insulation is adjusted to provide sufficient heat loss to freeze a protective coating of electrolyte on the inner walls but not on the bottom, which must remain substantially bare for electrical contact to the molten aluminum cathode. Steel (collector) bars are joined to the carbon cathode at the bottom to conduct electrical current from the cell.

Although the principles of electrolysis process have remained unchanged for more than 100 years, the performance of the electrolytic cells has been vastly improved. Today's best cells operate with energy efficiencies about 50%, which is above average for electrolytic processes in molten salts. One of the keys to further improvements in energy efficiency and productivity is a better understanding of the chemical and physical conditions prevailing in the cells. In Fig. 6, there is a schematic of the process and the main research activities for the process improvement (SINTEF, Norway).

Energy and Environment Issues of the Electrolysis

The energy consumption for aluminum reduction is estimated to be 15–16 kWh/kg of aluminum at current levels of 60–70 kA^[14,15] without taking into account the energy necessary for alumina fabrication from bauxites. The lowest energy consumption that can be achieved today is about 13 kWh/kg of aluminum for a line of modern, high-amperage (up to 325 kA) reduction cells.^[15,16] It was recently estimated that at an average annual production of 20 million tons of aluminum in ~200 plants worldwide, the

Fig. 6 The schematic of the electrolysis cell and the main research directions in the process improvement (based on the data from SINTEF, Trondheim, Norway)

average energy consumption was about 14.7 kWh/kg.^[17] Despite a substantial decrease (~2.5 times) in energy consumption for electrolysis over the last 100 years, there is still enough to do – to reduce alumina electrochemically, only 6.365 kWh/kg is needed.^[16]

The theoretical reversible potential for the reduction of alumina by carbon is 1.22 V and various additional over voltages including polarization, raise this value up to 1.76 V.^[18] If other energy sinks are added (heating up the electrolyte, the anode, etc.), then the voltage would be around 2.02 V. Additional losses occupy another ~2.18 V: electrolyte drop 1.35 V, anode and cathode voltage drops 0.35 V, bubble-induced voltage drop 0.25 V external voltage drop ~0.15 V.^[18] Production cells normally have current (electrical) efficiencies ranging from 85% to 95%. Large, modern reduction cells operate with current efficiencies from 94% to 96%.^[15] Some part of the anode voltage drop compensates by carbon consumption for alumina reduction reaction, making carbon use efficiency about 80%.^[18]

Major energy savings are achieved through the recycling of scrap aluminum, which requires only about 5% of the energy required to produce primary aluminum (see Chapter 4). On the other hand, secondary (recycled) aluminum cannot sometimes be used due to its high level of contaminants. Further increase of current over

350–400 kA does not seem to be a realistic approach either, so alternative solutions for both electrolysis process and other reduction method are being intensively studied worldwide.^[15,16]

Emissions from aluminum reduction processes are primarily gaseous hydrogen fluoride (HF) and particulate fluorides, alumina, carbon monoxide, carbon dioxide (CO₂), volatile organics, and sulfur dioxide (SO₂) from the reduction cells. The source of fluoride emissions from reduction cells is the fluoride electrolyte. The dissociation of the molten cryolite is the source of the perfluorinated carbons (PFCs) – tetrafluoromethane (CF₄) and hexafluoroethane (C₂F₆), which are formed during anode effects. The factors related to the formation of PFCs are not currently well understood, but they can be formed either by the direct reaction of the fluorine with the carbon anode or electrochemically.^[18,30]

In the past, the main environmental concern of the industry was emissions of perfluorocarbons from the reduction cells. The industry has made significant achievements in reducing these emissions, and the focus of concern has shifted to carbon dioxide (CO₂) emissions. It is the main component of the anode gas during the electrolysis process. It is also generated during the production of the electricity used in electrolysis, and is, thus, strongly dependent on the source of electrical power.

The total process air emissions (excluding power plant combustion emissions) for smelting and ancillary processes for representative industry processes are estimated to be 1.56 kg/kg of aluminum, of which about 90% (1.4 kg) is CO.^[15] Total CO releases from the processes of bauxite mining through the production of molten aluminum have been estimated at 11.7 kg/kg of aluminum.^[15,18] Combustion emissions account for approximately 70% of this total.

A variety of control devices has been used to abate the emissions from reduction cells and anode baking furnaces. To control gaseous and particulate fluorides and particulate emissions, one or more types of wet scrubbers (spray tower and chambers, quench towers, floating beds, packed beds, Venturi tubes) have been applied to all types of reduction cells and to anode baking furnaces. In addition, particulate control methods such as wet and dry electrostatic precipitators (ESPs), multiple cyclones, and dry alumina scrubbers (fluid bed, injected, and coated filter types) are used now on all the cell types and with the anode baking furnaces.

Developments and Opportunities in the Electrolysis Process

The general targets of aluminum electrolysis have been outlined by the Aluminum Association as follows:^[15]

- Improve the performance of the Hall–Héroult cell to:
 - achieve an average cell efficiency of 97% on an annual basis
 - reduce the energy intensity to 13 kWh/kg Al (near to mid term) and to 11 kWh/kg Al (long term)
 - reduce the capital cost of aluminum production to \$2500 per annual metric ton of capacity
 - cost effectively minimize the generation of perfluorocarbons (PFCs)
- Reduce/eliminate CO emissions during smelting.
- Reduce the cost of aluminum reduction by 25% using alternative technologies
- Develop new uses for wastes and byproducts from aluminum processes.

As one may see, besides traditional ways of the electrolysis process and cell construction improvement, new technologies and material solutions are also being sought. The achievement of these targets greatly depends on the ability to overcome existing technology barriers, Table 1.^[15]

One of the key factors in achieving a Hall–Héroult cell average energy use of 13 kWh/kg (identified as a mid-term goal) is to optimize materials for the management of the internal control of the cell. Even if the energy requirements of the cell are lowered by reducing the anode–cathode space (or by other means), some method of conserving the energy in the cell is still needed. However, cell insulation is degraded by the corrosion of the sidewall and of the bottom

which creates a material-related R&D need. Related needs are a better understanding of the best design, the development of low-cost materials, and the development of wetted cathodes.^[15,18]

The analysis of the cell bath^[17] shows that excess energy is not only related to natural heat losses, but also to the higher electrode distance (bath depth) and ohmic losses at cathode side (between carbon blocks and steel current collectors). The distribution of the current in cathode is not uniform; in particular, for cathodes with side current leads: ~80% of the whole current is released through 1/3 of the cathode block, 15% at the next 1/3 and only 5% at the last third part.^[17] The higher is the current, the larger is the gradient of the current and, thus, magnetic–hydrodynamic effect (horizontal current density up to 3 A/cm²), leading to a curvature of the molten aluminum surface. To avoid shortcuts, the electrode distance should be increased – the higher the current is, the larger is the curvature and, thus, the ohmic losses (proportional to the square of the current).

Despite the current non-uniformity problems are known and respective solutions have been patented over 30 years ago, the costs of the reconstruction of existing electrolyzers were considered too high to be accepted. One of the reasons for high losses (15–16% of total losses) is poor electrical contact between steel leads and carbon blocks in cathode. Traditionally, this contact is made by the casting of pig iron between the steel and carbon.^[17,19] Pig iron melt wets perfectly carbon steel but does not wet carbon surface, resulting in mostly mechanical contact only. Such contacts have very weak strength, low resistance to corrosion and destruction and high electrical resistance (real contact surface is only 5–10% of their visible or geometric surface). In metal/metal contacts, such a surface may achieve 30% of total possible contact surface.

To solve the problem, it was suggested to make special contact jams (cubic blocks) of 100–200 mm, where a hole of 30 mm diameter and of the same depth is drilled first.^[19] In this hole, a special alloy is arc welded. The alloy wets perfectly porous carbon block and, thus, creates contact surface higher than 100% due to the porosity of graphite material (25–28%). The alloy infiltrates the block up to 15 mm depth, decreasing the contact resistance to a few micro-ohms. The tests conducted with industrial electrolyzer have demonstrated that, at working temperatures, the resistance of new contacts is 40–50% lower than traditional ones (pig iron), and stays nearly constant with time (normally, the contact resistance for pig iron joints increases up to 3% annually). New construction of the contacts has allowed decreasing energy consumption of 0.2 kWh/kg of aluminum.^[17]

It was also measured that new contacts have given 3–5% higher output of liquid aluminum and have decreased heat losses of ~3%. Calculation shows that energy savings of 0.6–0.7 kWh/kg of aluminum are possible with new current lead design.^[17]

Table 1 Technology barriers in the aluminum production (The Aluminum Association)

Environmental technological	• Hydrocarbons capture ineffective • Inability to raise thermal efficiency of reduction • Lack of robust understanding of bath chemistry • Too high voltage losses • Lack of basic material knowledge on dimensionally stable anodes • Need for improved cathode/wetted cathode research • Lack of new and feasible cell design concepts • Low efficiency of petroleum coke calcination
Economical	• High costs of equipment • Older cell improvement and reconstruction are not cost effective • No economical methods to remove impurities

Shortly, the following issues have been identified for primary aluminum production:^[15,18]

- conduct R&D of anode and cathode technologies (materials, their processing, experimental design for material selection, wetted cathode, inert anodes)
- R&D in alternative cell concepts (and processes)
- alternative carbon sources for new anode materials (higher ash and sulfur)
- improved control of electrical regime of the cell;
- robust bath chemistry
- low-resistance external conductors (leads)
- higher cell efficiency with power modulations
- new refractories and linings for the cell

The Aluminum Association has stated that one of the most critical needs of primary aluminum production is for a variety of near-, mid-, and long-term R&D activities on anode and cathode technologies.^[15] These activities should focus on the development of new materials (e.g. for inert anodes/cathodes), processing methods for these materials, experimental design for material selection, and wetted cathode technology. Using a systems approach to design dimensionally stable cells and optimize material use for the internal control of the cell could yield cell efficiency improvements within the next 10 years. In addition, the performance of signal analyses on the cell voltage in pot-lines could yield information that could be used to understand better and control the cell.^[15,18]

ALTERNATIVE PROCESSING OF ALUMINUM

Another of the most critical needs is for long-term R&D on alternative reduction and refining processes. This includes entirely new ideas for producing aluminum – e.g. direct reduction type processes or processes that totally eliminate electrolytic reduction.^[15] A coordinated effort covering both refining and reduction is recommended to optimize the cost/benefit of using current or alternative raw materials. Cost-benefit analyses of kaolin and other

alternative sources of alumina could contribute toward the ultimate goal of reducing production costs, as shown in “ALCAN Process” section.

Besides electrolytic process (reduction of alumina dissolved in cryolite), many alternative processes are being studied worldwide. Although some of the processes have been tested decades ago, there is still very little industrial implementation of these methods. The main obstacles for alternative process realization are the lack of combined units (integrating reduction and refining), lack of system approach, and for metal quality improvement, absence of new methods of low-temperature electrolysis of solid aluminum, existing needs to maximize the use of chemical energy, besides, only electrical.^[15]

The methods may be described as chemical (reduction by carbon or other agents) and electrolytic (electrolysis of compounds other than alumina). Some of these methods are discussed below (methods names are shown in the alphabetical order).

ALCAN Process

In the ALCAN process, bauxite and coke mixture are being heated in an electric arc furnace at temperatures above 2000°C. Because pure aluminum cannot be thermodynamically obtained by carbothermal reduction, the product is in a form of aluminum-rich alloy with ~30% Fe, ~10% Si, ~5% C, and Ti (primary alloy). The alloy is being put into a reactor with aluminum trichloride (AlCl₃) vapor preheated to 1300°C. The chloride vapor reacts with aluminum in primary alloy to produce aluminum monochloride, AlCl:

In the next reactor, aluminum monochloride vapor is contacted with aluminum droplet at 700°C; when the above reaction is reversed, aluminum is extracted into a liquid melt and aluminum trichloride is recycled.

ALCAN process has claimed substantial capital and operational benefits in comparison with the Hall–Héroult process. The main reason, which limits the application

of this process, is the very aggressive stress corrosion associated with the handling of gaseous AlCl_3 .

Alcoa Process

In this process, alumina manufactured by the Bayer process, reacts with chlorine in the presence of carbon (coke) at 700–900°C. The products of this reaction are gaseous AlCl_3 , CO, and CO_2 :

The gas mixture is directed into a condenser, where aluminum trichloride is separated at about ~70°C. Solid salt is added into a chloride bath, forming an electrolyte solution of ~5% AlCl_3 , ~45% LiCl , and ~50% NaCl . The electrolysis is carried out at 700°C in a special double-sided (bipolar) electrode cell with 2.7 V and anode current density 0.8–2.3 A/cm². Chlorine is collected at the anode side and recycled into the beginning of the process (chlorination reaction). Liquid aluminum is collected at the bottom of the cell.

The advantages of the Alcoa process are higher conductivity of the electrolyte (~4 Sm/cm vs. ~2.5–3.0 Sm/cm in the Hall–Héroult process), and lower distance between the electrodes. Thus, energy consumption in the Alcoa process (8.9 kWh/kg Al) is significantly lower and efficiency is higher than in the Hall–Héroult process. The problems of Alcoa process are mainly related to chlorine handling, corrosion, and environmental issues (side formation of chlorated hydrocarbons, residual deposits, etc.).

Carbon Reduction Process

The use of carbon reduction to produce aluminum from alumina or directly from bauxites may look the most straightforward approach to be realized. As shown above, theoretical reduction reactions like:

seem to be practically attractive. However, the reduction of alumina by carbon proceeds through the formation of gaseous sub-oxides (Al_2O , AlO , Al_2O_2), carbides (Al_4C_3) and oxycarbides (Al_2OC , $\text{Al}_4\text{O}_4\text{C}$).^[14] It was experimentally determined that alumina is being reduced by carbon in the following sequence:

The carbide, Al_4C_3 , is stable up to very high temperatures (2200–2500°C), higher than melting point of the alumina, so carbide formation in the furnace means “solidification” of the bath and the ceasing of the reaction by simple kinetic reasons.

Porada and Gasik^[5] have presented the following sequence of carbothermal reduction of alumina with the stoichiometric mixture ($\text{Al}_2\text{O}_3 + 3\text{C}$):

The quaternary equilibrium point, Al_2O_3 – Al_4C_3 – C – $\text{Al}_{(\text{liq})}$, in the Al–O–C system is achieved at about 2380–2390°C.^[5] Therefore, aluminum may be reduced by carbon from alumina, if necessary conditions for carbide and oxycarbides decomposition will be achieved. As shown below, this is practically possible in the case of low aluminum activity (aluminum solutions with other elements).

Theoretical calculations show that during the reduction of the stoichiometric mixture ($\text{Al}_2\text{O}_3 + 3\text{C}$) at 1 bar pressure in argon, some amount of gaseous aluminum may be produced (Fig. 7) but only when over 2050°C and only when accompanied by the carbide. If the pressure is lowered, the temperature may be lowered too. Figure 8 shows a similar picture for 1900°C, where a pressure of ~0.4 bar is needed for aluminum to reduce. However, the theoretical yield of aluminum may be reached only at very low pressures, yet accompanied by the carbide. Carbide formation makes the reduction process practically unsuitable to realize using “traditional” electrical or shaft furnaces. However, there are no theoretical limitations about alumina to be reduced by carbon in some kind of “novel”, non-equilibrium processes (sub-micron particles with low diffusion paths, plasma, microwave or laser-assisted processes, etc.). This area is yet very little studied.

Elliot-Mitt Process

This process uses a carbothermal reduction of alumina when the resulting aluminum dissolves in molten tin to prevent the formation of carbide and oxycarbides. To assist the reaction, higher temperatures (~1800°C) and lower pressures (~0.1 atm) are desired. Due to the presence of tin, aluminum activity is low enough to make necessary thermodynamic prerequisites for its reduction.

However, the practical realization of the process has resulted in the alloy of ~9% Al only. Although separation of aluminum from tin is possible by several methods, the product cannot yet satisfy requirements for pure aluminum.

Fig. 7 Thermodynamic equilibrium of the stoichiometric mixture ($\text{Al}_2\text{O}_3+3\text{C}$) reduction at 1 bar pressure in argon for different temperatures

Monochloride Process

The monochloride process chemically unites the Alcoa and the ALCAN processes. Here, alumina or bauxite is directly being reduced by coke in the presence of AlCl_3 vapor (not with chlorine, like in Alcoa process). Thus, both reactions of these processes are taking place simultaneously:

This reaction, however, requires much higher temperatures (1750–1850°C) than those of Alcoa process. Additives (silicon, iron) present in bauxites also react in these conditions to form lower chlorides (SiCl_2 , FeCl_2). The mixture

of these chlorides is submitted into a reactor, where liquid lead is sprayed from the top to rinse the gases. Lower chlorides then dismutate to elements and higher chlorides:

Lead-metal liquid drops are collected at the bottom of the reactor and aluminum is separated from lead by soaking the mixture at 700°C. Higher chlorides are recycled back to the process. The liquid aluminum obtained contains some silicon and lead.

Fig. 8 Thermodynamic equilibrium of the stoichiometric mixture ($\text{Al}_2\text{O}_3+3\text{C}$) reduction at 1900°C in argon for different pressures

This process has been successfully tested in laboratory conditions, but so far has not yet been realized in large-scale plants. It is expected that gross economic benefits of this process may be significant in comparison with the chain “Bayer+Hall–Héroult”, if a cost-efficient plant can be constructed.

Reynolds Process

This process also uses carbon reduction but as a multi-stage procedure, similar to those processes that occur in a blast furnace. Alumina is being reduced by carbon (coke) first to oxycarbides ($\text{Al}_4\text{O}_4\text{C}$) and then to carbide Al_4C_3 . Adding more alumina results in slag formation that reacts with carbide and oxycarbides to form aluminum metal. At these high temperatures, aluminum vaporizes and reacts with residual alumina to form sub-oxides:

Sub-oxides may then dismutate to produce aluminum and slag at lower temperatures. After several following stages, metal melt is being cleaned from carbon by alumina-oxycarbide slag and, finally, by gas.

The capital costs of Reynolds process were reported to be about 2/3 of the Hall–Héroult plant, but its practical realization has faced some difficulties, mostly with the construction of the furnaces and problems with material stability at these operational conditions.

Toth Aluminum Process

The shortage of high-quality bauxite supply has initiated studies of the processes that may use alumina–silicate raw materials instead of pure alumina. Toth Aluminum process uses, in the beginning, the same alumina reaction with chlorine in the presence of carbon (coke) at 700–900°C like in the Alcoa process:

Reduction of liquid aluminum trichloride is carried out by manganese at 300°C and at 15 atm (200 psi) in a special pressure reactor to make aluminum powder:

and liquid salt melt is separated into aluminum trichloride (recyclable into the process) and manganese dichloride. The latter is oxidized to Mn_2O_3 , which is used to recover manganese metal by a carbothermal reduction. There are some variations in the Toth Aluminum process, but the main limitation is its complicity and costs, related to the recovery of manganese and the low yield of aluminum. Even stoichiometric reaction needs 2 mol of alumina to produce 1 mol of aluminum. Fabrication of metal

manganese is not possible by a carbon reduction method, so only high-carbon ferromanganese (75% Mn, 7% C) can be received with the recovery of 65–70% of manganese only.^[14] Ferromanganese itself is not a very good reducing agent in comparison with pure manganese. According to the existing literature data, this process is not recently cost effective to be realized, taking into account that manganese mixes well with aluminum and the resulting alloy has little applications.

Electrolysis of Other Aluminum Compounds

Among alumina, other aluminum compounds are being considered for electrolysis process. One possible candidate is aluminum nitride, AlN. If aluminum nitride will be available commercially in industrial quantities, it may be a good alternative for electrolysis because the reaction:

will need only 0.72 V at 1000°C. Nitrogen would prevent anode from oxidation and this process would be an energy-saving one. The problem, however, still exists in finding a suitable electrolyte or solvent which may dissolve substantial amounts of AlN at medium temperatures.

Another potential candidate is aluminum sulfide, Al_2S_3 , which may be made by the reduction–sulfidation reaction:

This reaction is thermodynamically possible at over 1200°C, but process temperature should be over 1400°C to keep aluminum sulfide in the liquid state. The electrolysis of aluminum sulfide requires about 1.2 V, but released sulfur may dissolve in the electrolyte and form aluminum subsulfides. In the experiments, the yield was found to be about 70%, with the energy consumption close to that in the electrolysis of AlCl_3 . The process may be competitive to chloride electrolysis if an efficient method of sulfide production will be developed and sulfur utilization enhanced.

Reduction of Alumina Using Hydrogen

This case is unlikely to be used for aluminum production, but it has an interest with respect to the reaction of alumina with molecular or atom hydrogen and the dissolution of hydrogen in liquid aluminum alloys. In work,^[20] a brief thermo-dynamic assessment has been made to demonstrate the possibility of forming gaseous aluminum by the reaction of H_2 or H with alumina.

The phase stability areas in the Al–O–H system are shown in Fig. 9. If alumina is heated up at 1 bar hydrogen at ~1300°C, the reduction may proceed when water partial pressure is less than 10^{-8} (i.e. water vapor concentration is less than ~ 10^{-5} mg/l H_2). Such humidity of hydrogen is

Fig. 9 The Al–O–H phase stability diagram at 1 bar H_2

very difficult to maintain at high temperatures continuously. If alumina is heated up to 1500°C under pressurized hydrogen (a few bars), than humidity of hydrogen may be substantially lower, Fig. 10.

The formation of metallic aluminum has been experimentally confirmed,^[20] where alumina was reduced by hydrogen dissolved in aluminum. The authors^[20] have indeed recognized the difficulty of the reduction due to very low water traces to be continuously and efficiently removed. This method may be successfully applied but possibly in the non-equilibrium conditions (plasma, etc.), where rather favorable reduction may occur in limited volumes and proceed with higher rates.^[20,16]

Generally, for the above-mentioned alternative processes, the Aluminum Association has identified the following needs:^[15]

- long-term R&D on alternative reduction and refining processes (closed loop, use of chemical energy)
- R&D for electrolysis of solid aluminum

- alternative raw materials (alumina sources like kaolin, kyanite)
- elimination of intermediate refining steps
- development of durable equipment for the handling of molten salts and aggressive reagents

Below is shown how some of these problems may be solved using aluminum alloy direct production instead of making pure aluminum first.

DIRECT REDUCTION OF ALUMINUM ALLOYS

A significant part of all aluminum alloy production is occupied by aluminum–silicon cast alloys (silumines), aluminum-based engineering alloys (cast and wrought – with magnesium, copper, zinc and other elements) as well as various master alloys (Al–Me). The majority of these alloys have been manufactured by mixing electrolytic aluminum with other elements. Taking into account the high costs of

Fig. 10 The Al–O–H phase stability diagram at 1500°C

pure aluminum, silicon, magnesium, etc., the costs of these alloys were rather high.

Aluminum–Silicon Alloys

As shown in the next chapter, there is no practical or theoretical reason why pure elements have to be manufactured first (if they will be mixed together later at the next stage). Lack of high-quality bauxites for aluminum electrolysis has initiated more active research in the use of other raw materials (kaolin, kyanite, disten-sillimanite) for aluminum alloys. If these materials are used for alloy smelting instead of making pure aluminum first, there is no need for the separation of alumina either in the removal of other compounds.^[21,14] In the 1960s for the first time in the world, such a plant has been built in Zaporizhzhya, Ukraine. Here, the new process of direct reduction of alumina–silica raw materials by coke into the so-called “primary alloy” (58–60% Al, 37–39% Si, 1.4–1.6% Fe, 0.5–0.6% Ti, 0.8–1.0% Ca) was commercially realized.^[21,22]

Here, the raw materials used were enriched kaolin (37–40% Al_2O_3 , 46–47% SiO_2 , 0.3–0.7% Fe_2O_3 , 0.25–0.35% TiO_2 , 0.15–0.50% CaO). This kaolin (~40%) was mixed with technical alumina (4–25%), gas-grade coal, oil coke (altogether 30–40%) and binder to form briquettes. Later, kaolin was substituted by enriched disten-sillimanite $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$ to reduce the kaolin share to 8–25% only.^[14,21,23] This mineral concentrate is a waste product from titanium–zirconium ore dressing plant^[24] and has significantly higher melting temperature with respect to kaolin. This ensures better reduction process. The smelting is performed in open-hearth ore reduction furnaces of 16.5 MVA power with self-baked electrodes of diameter 1200 mm.

The costs of the Al–12% Si alloy made by the direct reduction of primary alloy and then its mixing with aluminum are 20–25% lower than for the mixing of primary aluminum with silicon. The productivity of the process is higher by 35–40% and investment required is lower by 30–33%.^[14,24]

How does the direct reduction proceed? Reduction of alumina by carbon was considered above. Silica is usually reduced to SiC, unless special conditions^[21] are created for the silicon formation (CO removal). Mullite $3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$ can be reduced by carbon:

but this reaction would be thermodynamically impossible until 2000°C, if the mutual dissolution of aluminum and silicon is not taken into account (i.e. if aluminum and silicon are considered as pure phases with unit activity). For the reaction balance, it can be seen that 3 mol of aluminum are formed per 1 mol of silicon – a solution with ~70% Al would result. Even then, the direct reduction of mullite to aluminum–silicon melt would be only slightly favorable.

As soon as carbon is present with the Al–Si–O system, the reduction of alumina proceeds through oxycarbides and carbide.^[14] As a result of the reduction, simple carbides (SiC , Al_4C_3) and complex carbides ($\text{Al}_4\text{SiC}_4 = \text{Al}_4\text{C}_3 \cdot \text{SiC}$, $\text{Al}_8\text{SiC}_7 = 2\text{Al}_4\text{C}_3 \cdot \text{SiC}$) are formed. These carbides are very refractory (melt over 2350°C) and they, with oxycarbides, retard the reduction process.^[24] Depending on the silicon concentration, equilibrium carbide may appear in different composition: Al_4C_3 and Al_2OC (at low silicon), Al_8SiC_7 (at higher silicon), SiC (more than 30% Si). If after oxygen removal the carbon potential is still high (e.g. $\log(P_C) = -10$), the metal alloy may be only produced above 1850°C (Fig. 11). If carbon was already consumed (i.e. not much excess carbon was left, $\log(P_C) = -20$), liquid Al–Si alloy may be received already at 1200°C (Fig. 12).

The Al–Si system is known to have a non-ideal behavior. The activity coefficients of aluminum and silicon may be expressed as a function of their molar fraction:^[21]

$$\log(\gamma_{\text{Al}}) = -0.4187X_{\text{Al}}^3 - 0.2486X_{\text{Al}}^2 + 1.535X_{\text{Al}} - 0.887$$

$$\log(\gamma_{\text{Si}}) = -0.3531X_{\text{Si}}^3 - 0.2984X_{\text{Si}}^2 + 1.5352X_{\text{Si}} - 0.8881$$

where X_i is the molar fraction of the element i , γ_i is the activity coefficient in the activity definition as $a_i = \gamma_i X_i$.^[14,21,25]

When the charge composition is optimized and electrical and temperature parameters are being held within the operation window,^[14,21,23,24] liquid Al–Si alloy can be made by the direct reduction of alumina–silica raw materials in the electrical furnace with self-baked electrodes. Besides the alloy, slag of variable composition is also formed (30–60% Al_2O_3 , 35–50% SiC , <2% CaO , <20% SiO_2 , <5% oxycarbides). To avoid contamination of the primary alloy with these inclusions, special fluxes are being added into the ladle before melt pouring from the furnace. Resulting unpurified alloy may contain up to 2–3% of these inclusions.

Why is direct reduction of primary alloy more advantageous? There are several important reasons for this:^[14]

- higher specific power (kWh/m^3) of ore reduction furnaces vs. electrolytic cells
- no DC is required, conventional AC from the grid is used (no AC/DC conversion losses)
- no special alumina production stage is needed (hydrometallurgical Bayer process is bypassed)
- different alumina and alumina–silica raw materials may be used, which cannot be used for alumina extraction
- no cryolite and other fluorine salts are required
- low-cost carbon reducing agents (coke, pitch) can be used
- higher recovery of aluminum and silicon

Fig. 11 Phase stability areas in the Al-Si-C-O system at higher carbon potential ($\log(P_C) = -10$)

- lower impurities (non-ferrous metals) when used for steel killing
- low capital investment required

The second stage of the commercial Al-Si alloys making is in the mixing of molten primary alloy (~35% Si) with molten aluminum for the electrolytic process in the neighborhood^[24] of about 750–800°C. Protecting and refining fluxes can be added to the metal mix and its temperature is maintained by built-in gas burners.^[21]

As a result of mixing, silicon content in the alloy is reduced to a desired value (7–22%) and liquidus temperature of the alloy is decreased. Some metallic impurities (Fe, Ti, Ca, etc.) react with aluminum and

silicon forming intermetallides of higher melting temperature. These intermetallides must be removed from the alloy, because they usually weaken properties of silumine castings.^[24] This is achieved by adding manganese (to reach the ratio of Mn/Fe ~1.5–2.0) and solid Al-Si alloy of similar composition (to decrease temperature to 595–600°C). Manganese reacts with Fe and Si and releases aluminum from intermetallides. The melt is then being vacuum filtered through silica sand, where all high-temperature intermetallides remain. These tails have nominal composition of 72–74% Al, 17–20% Si, 1.5–2.5% Fe, 1.2–1.5% Ti, 2–4% Mn and are recycled in a separate furnace (900°C, with flux of 60% NaCl+Na₃AlF₆).

Fig. 12 Phase stability areas in the Al-Si-C-O system at lower carbon potential ($\log(P_C) = -20$)

During filtration, a part of the melt oxidizes and turns into slag (~80% Al_2O_3 , ~2.5% Al_4C_3 , ~3% SiC, 2–3% SiO_2 , ~2% CaO, and ~10% alkali halides). Slag may contain up to 30% of metal phase as inclusions and droplets.^[24] All tails and slags of the process are being nowadays used as raw secondary materials in the adjacent metallurgical processes.^[14,24]

Aluminum-Based Master Alloys

The authors^[21,26] have developed a technology for the complex processing of practically all kinds of alumina–silica raw materials (poor bauxites, kyanite, kaoline, disten–sillimanites, etc.) with high level of impurities (iron, titanium, etc.). It consists of several stages of smelting. The first stage includes smelting of raw material with some iron (steel) chips and coke. Here, alumina is not actually reduced, but silicon reduces to form nearly standard grade ferrosilicon (18–30% Si) alloy. Alumina remains in the slag which turns into “electrocorundum” – eventually pure alumina (96–98% Al_2O_3) with low silica, titania, calcia and iron oxides. This electrocorundum is a commercial product, which is used for the abrasive and refractory manufacturing,^[5,14] hydrochemical extraction of alumina^[21] or for synthetic slag smelting (45% Al_2O_3 , 53% CaO) used in steel making. Electrocorundum is also used instead of kaoline for aluminum alloys smelting, as shown above.

If quartzite and coke is added to the charge, in an electrical furnace, they do form primary aluminum alloy (~36% Si). If ferroalloys are added (Fe, FeMn, FeCr, FeSiCr, FeSiMn), complex composition master alloys may be easily produced.^[26] Alternatively, some alloying elements (Zr, Ti) may already be present in the raw alumina–silica materials as oxides and their reduction (up to 10% in the final alloy) can be realized during electrothermal reduction during primary alloy smelting.

In iron and steel making, a significant part of aluminum used for steel killing is a cheaper secondary metal (recycled). Because of recycling problems, it may contain 5–12% of non-ferrous metals (<4.5% Cu, <2% Zn, <0.4%

Pb, <0.3% Sn), which are undesirable in steel. In any case, the use of primary or secondary aluminum in steel making has become problematic due to its low density and high affinity to oxygen. During the alloying of the molten steel bath, the aluminum use efficiency is 20–30% only and the resulting fine alumina particles contaminate steel ingots.^[26] This is why the use of ferroaluminum (10–30% Al) with lower aluminum activity, higher density (6.9–7.1 g/cm³), and higher recovery (50–60%) is much more advantageous.

Recently, many kinds of ferroalloys with aluminum (Al–Fe, Al–Fe–Mn–Si, Al–Si–Ca, Al–Cr–Fe, Al–Zr–Fe) are being produced with this method (Table 2). These alloys do require less energy for their smelting (3.9 kWh/kg for FeAl, 5.2 kWh/kg for FeAlSiMn), so, their application in steel making is more cost effective than pure aluminum:

	Primary Al	FeAl alloy
Aluminum content (%)	95–98	8–30
Energy required (kWh/kg)	13–16	3–4
Al utilization at steel killing (%)	20–30	50–90
Costs for use in steel making (relative units per kg Al)	55–70	10–40

It is well established that aluminum production for steel making and foundry is much more efficient by making a direct reduction in the form of ferroalloys of aluminum-rich primary alloys.

ELECTRODES FOR ALUMINUM PRODUCTION

Self-Backing Electrodes (Söderberg Type)

Self-baking anodes for aluminum production seem to be used for the first time in 1923 in Norway. At that time, it was found that the main problem was in the high potential losses ~1.5 V between contact plate and the anode.^[27,28] New technical solutions have resulted in two principal kinds of current leads – side leads and top leads, the latter being the most used recently.

Table 2 Typical compositions of some commercial aluminum-contained master alloys

Master alloy	Leading element(s) (%)	Other elements (%)
Ferroaluminum	8–30 Al	<4 Si, <4 C, <0.06 P, <0.06 S, balance Fe
Manganoaluminum	12–16 Al, 40–80 Mn	<2.5 Si, <1.5 C, <0.03 S, <0.3 P, balance Fe
Ferrosilicaluminum	10–15 Al, 5 0–55 Si	Balance Fe and minor impurities
FAMS (Fe–Al–Mn–Si alloy)	10–14 Al, 22–26 Mn, 1 2–14 Si	<1.5 Ti, <0.7 Zr, <2.5C, <0.08 P, balance Fe
FAMSC (Fe–Al–Mn–Si–Ca alloy)	4–10 Al, 17–22 Mn, 45–50 Si, 7–12 Ca	Balance Fe and minor impurities
Ferrochromealuminum	>20 Al, >50 Cr	<1 Si, <0.06 C, <0.02 S, <0.035 P, <0.06 Cu (Si content may be increased if necessary)
Ferrozirconiumaluminum	17–20 Zr, 20–28 Al	2–3 Si, <0.08 P, <0.08 C, <0.01 S, balance Fe
Aluminumchrome (complex alloys)	26–38 Al, 20–30 Cr, 25–32 Mo	1–18 W, <3 Si, balance Fe

Self-baking anodes are usually composed of a metal shell (steel) and a carbon-based mass, which form a carbon block during baking.^[27] The shell is usually welded of steel sheets of 2–4 mm in the form of a cylinder or an ellipse. The diameter of the shell is usually 400–2000 mm or 2800 × 650 or 3150 × 650 mm. Inside the shell are special ribs (fins) for better adhesion of the anodic mass to the shell. This type of construction is practically used in all kinds of electrometallurgy furnaces.

All kinds of self-baked anodes (anodic mass) are being fabricated using the following scheme.^[27,28] Solid carbonaceous raw materials (coke, anthracite, etc.) are being crushed, heat treated and classified. Secondary raw materials (recyclable electrodes, graphite pieces, etc.) are also crushed and sieved. Binder (pitch, oils and other additions) is mixed and delivered for dosing with solid and secondary materials. Mixed charge (e.g. thermoanthracite –20% of 4–10 mm, 24% of 10–20 mm, 16% of crushed (<4 mm), then 40% coke <4 mm, and additionally (over 100%) 24% of the coal pitch as binder) is used to form briquettes of ~1.5 kg in the special machines. Ready briquettes may be promptly used in the electrolysis or put in a warehouse. The properties of the mass are shown in Table 3.

The briquettes are loaded into the shell and are being first sintered and then melted under the heat flow from the furnace. Normally, in the electrode, there are four main zones:^[27]

Zone I: The mass is being heated and sintered at temperatures up to 65–70°C.

Zone II: In this zone, the binder (pitch) is liquid, temperatures 70–350°C.

Zone III: Here, the baking of coke starts at temperatures 350–550°C.

Zone IV: At higher temperatures, the mass is already baked and forms a solid electrode. Here, four sub-zones may be also detected.^[27]

To produce 1 t of aluminum, about 400–500 kg of anode mass are needed (370–420 kg are consumed for electrochemical oxidation, for foam and side oxidation by CO₂ 30–80 kg, and for oxidation of secondary anode 10–15 kg). This means that electrode mass production should be roughly half of the primary aluminum production. Electrode mass should have the following parameters:^[27]

- low specific resistance (<75 μΩ m)
- low porosity (<30%)
- relatively high strength (>30 MPa)
- low oxidation rate

Because self-baking anodes emit significant amount of hydrocarbon, etc. emissions, their use in aluminum smelters has been gradually decreased. New cells, nowadays, use pre-baked anodes.

Pre-Baked Electrodes

Pre-baked electrodes may be of two kinds: graphitized (graphite) and carbonaceous (coal). Carbon electrodes have higher specific resistance (~40 μΩ m) than graphite electrodes (~10 μΩ m), but bear higher compression loads (~36 MPa vs. ~25 MPa for graphite).^[27,14] Previously, these electrodes were seldom being used in aluminum electrolysis because of their higher costs and design peculiarities, allowing them little freedom to be fitted into the existing electrolysis cells. In the 1970s however, the use of pre-baked electrodes was favored also due to the growing environmental concerns.^[29]

For graphitized electrodes, thermoanthracite, petroleum coke (low ash), pitch coke, and coal pitch are used.^[14,27] All raw materials are annealed at 1200–1300°C to reduce moisture (<0.5%), volatiles, decrease resistance and increase density. Raw materials are screened, mixed and pressed (extruded) into green bodies which are being baked at 1200°C (green electrodes). These electrodes are being treated in special graphitizing furnaces by direct heating with electrical current at 2700–2900°C for a long time (almost one month). Ready electrodes are extracted from the furnaces and are mechanically treated to achieve the standard dimensions (Fig. 13). Coal electrodes are manufactured under the same scheme as for the graphitized electrodes, but their baking is completed at 1200–1300°C after 300–400 h, i.e. without graphitization. The quality of coal (carbon) electrodes is usually lower than that of the graphite ones.^[27]

Anode properties in the cell influence the behavior by three different mechanisms: air reactivity (oxidation kinetics), carbon dioxide reactivity (CO₂ + C → 2CO reaction) and physical losses due to thermal shocks, fatigue and possible mechanical damages.^[29] Pre-baked anodes have less porosity (typical density range of 1.53–1.60 g/cm³) and, thus, gas permeability (typically 10 ± 5 Darcy units – higher for lower density anodes). Nevertheless, the reaction of anode with CO₂ (~960°C) is the dominant reaction for the carbon consumption in the bath. At higher levels, the temperature drops but the air penetration is more probable. The critical area is, thus, the alumina crust – air interface, where both carbon oxidation and burning due to air and carbon dioxide (~450–800°C) are possible.^[29]

Thermal conductivity of pre-baked anodes depends mostly on the baking temperature – the higher the

Table 3 Typical requirements and properties for anodic mass

Property	Mass type		
	A	B	C
Volatiles (%)	13–18	13–19	13–18
Ash (%)	<8	<9	<7
Resistance (μΩ m)	90	150	87
Tensile strength (MPa)	1.47	1.47	1.47
Fluidity coefficient	1.5–2.5	2.2–3.0	2.0–2.7

Fig. 13 Practically achievable standard dimensions and current densities in the pre-baked graphitized (◆) and carbon (■) electrodes (after M. I. Gasik)

temperature (i.e. the larger the graphitization), the higher the thermal conductivity, which will result in: 3 ± 0.3 W/m K at 1000°C or $5\text{--}6.5$ W/m K at 1350°C . Higher baking temperature affects also the mechanical properties of the electrode and its reactivity with CO_2 . Higher temperatures decrease it.

Normally, the pre-baked electrode has four main zones:^[27,29]

Zone I: The electrode is being heated at temperatures $200\text{--}400^\circ\text{C}$ (at the edges).

Zone II: Carbon oxidation starts, temperatures $450\text{--}600^\circ\text{C}$.

Zone III: Electrode fully immersed in the alumina crust, temperatures $700\text{--}850^\circ\text{C}$.

Zone IV: Electrode is at its working position, intensive reaction with carbon dioxide and with alumina, temperature $\sim 960^\circ\text{C}$.

In zones I and II, temperature distribution is usually non-uniform. The excess carbon consumption for pre-baked anodes is similar to self-baked anodes, normally at $20\text{--}150$ kg C/t Al.^[29] Pre-baked anodes have smaller dimensions than self-baked ones because there is the difficulty to manufacture high-quality homogeneous graphite or carbon blocks of more than 1500 mm diameter.^[27] There are also some activities in coated electrodes – many coating compositions (Al + SiC, Al + TiO_2 , H_3BO_3 , SiC, Si) have been tested. Usually, a coating of ~ 0.8 mm thickness is stable until very high temperatures ($<1850^\circ\text{C}$), and its application decreases anode consumption at $15\text{--}20\%$. However, the costs of coating are also $15\text{--}25\%$ higher, so the use of coating pre-baked anodes has to be carefully considered from the point of economy.^[27]

Inert Anodes

For the past years, all primary aluminum has been produced using an anode typically made of carbon. From an operating perspective, these types of anodes and cathodes are far from ideal. The carbon in the anodes is continuously consumed during the conversion process, forcing them, in the case of pre-baked cells, to be replaced about every two to three weeks. In addition, the undulating surface of the molten aluminum in the cell creates a large gap between the anode and the cathode to prevent short circuiting of the cell.^[17,19] This gap makes the cell consume much more electricity than is needed to convert the alumina. The production of aluminum also creates fluoride and carbon dioxide emissions, as shown above.^[15,18,30]

The combination of an inert (non-reacting) oxygen-evolving anode, which would not be consumed during the electrolytic process, and an aluminum-wettable cathode, whose surface would remain stable (unlike the sloshing of molten aluminum) would allow for a more energy-efficient, productive, and environmental friendly cell operation. A narrowed anode–cathode gap requires less electricity (voltage drop) to produce aluminum. Use of a non-carbon anode will also reduce CO_2 and PFC (CF_4 and C_2F_6) emissions. In addition, the life expectancy of an inert anode (approximately 5 years) will significantly reduce the down time associated with anode replacement.

If such anodes can be combined with chemically stable cathodes and cell-lining materials, the cells can be made much more compact and probably also more energy efficient than the traditional cell.

The recent developments in inert anodes have been outlined in^[18,31–33] in more detail. Basically, what the inert anode must be:^[31]

- Physically stable at application temperatures ($950\text{--}1000^\circ\text{C}$).
- Corrosion resistant (to both electrolyte and environment).
- Electrically conductive and electrochemically stable.
- Resistant to thermal shock.
- Mechanically robust.
- Easy to assemble and deploy.
- Recyclable.
- Cheap.

The efforts to date have been concentrated on the three major types of materials for inert anodes: ceramics, composites and metals.^[31] The advantages and limits of these materials are shown in Table 4. For example, a composite of copper with nickel ferrite (NiFe_2O_4) and nickel oxide (NiO) was successfully tested (Fig. 14). Here, the cathode was also made of $\text{TiB}_2\text{--Al}_2\text{O}_3$ composite.^[31,34] However, despite a successful test operation, the industrial application of these anodes was found to be difficult due to

Table 4 Material comparison for inert anodes

Material class	Advantages	Disadvantages
Ceramics	Does not easily oxidize (or not at all) High melting point Electrochemically stable	Low electrical conductivity Reacts with electrolyte Low thermal shock resistance Low mechanical properties
Metal-ceramic composites (cermets)	Higher stability and conductivity as for ceramics Composition may be tailored	Reacts with electrolyte Questionable long-term stability Electromigration problem Higher manufacturing costs Metal contamination
Metals and alloys	High electrical conductivity Good mechanical properties	Difficult to find proper inert metal Could be oxidized Potential bath contamination in an abnormal operation

problems with aluminum purity and catastrophic failure of anodes due to thermal shock.^[31]

All oxide candidate materials are, in fact, nobler than alumina and do have a limited noticeable solubility in the electrolyte.^[32] This means that these oxides will be continuously reduced (i.e. anodes corroded) and will contaminate aluminum. The economy of the inert anode application was analyzed in.^[33] To minimize the wear and corrosion rate to 2 mm/year, 1.7% of silver has been suggested to be added to the anode composition, as shown in Alcoa patent.^[33] The cost of the inert anodes in a typical smelter operation was found to be compatible with that of carbon anodes. If additional advantages of the inert anodes will be taken into account (such as greenhouse gas emissions, PFCs, etc.), and the reasonable investment made for

retrofitting the existing cells, inert anodes of the above composition may have an operating cost improvement over existing technology.^[33]

Application problems were also found for metal-based inert anodes. One of the more or less successful approaches includes Cu–Al bronze (7–15% Al) and it was developed by MIT.^[31] During the operation, aluminum dissolved in copper, reacts with oxygen to form a protective thin alumina layer. This layer prevents copper from oxidation and reaction with aluminum, yet being too thin to conduct electricity within acceptable voltage drops. If the coating is broken or dissolved in the electrolyte, a new portion of aluminum will oxidize and form new coating. The wide range of current densities (0.25–2.5 A/cm²) have been reported with very low level of copper in reduced aluminum (<0.1%).^[31]

**Fig. 14** The comparison of traditional (carbon) and inert anodes operation in the electrolysis^[34]

Fig. 15 The experimental device for analysis of performance of inert anode^[35]

On the other hand, if the anode has failed, the whole aluminum bath was immediately contaminated with a large amount of copper. Besides copper, nickel-based superalloy with an optimal composition was reported to have a good oxidation resistance and high stability in the electrolyte at 960°C.^[31,32]

Other candidates for anode and cathode materials are also being studied, e.g. as shown in Fig. 15.^[35] Whereas, titanium diboride (TiB₂) was nominated as the best cathode material, it is expensive and far from optimal.^[32,33]

In general, despite its importance, the choice for the best “inert” anode material is still open. The metal seems to provide the best parameters of electrolysis but makes a huge problem with aluminum contamination, which cannot be recently solved in a cost-effective way.^[32,33] One of the issues, which should be considered, is new advanced cell design, which may be more suitable for specific anode and cathode types than for conventional or retrofitted cell.^[33]

CONCLUSIONS

In this chapter, the following main areas of primary aluminum processing have been briefed: thermodynamics of alumina(s) and its reduction, basics of modern electrolysis (the Hall–Héroult process), alternative methods of aluminum extraction and electrode issues (self-baked, pre-baked, inert). In addition, attention has been paid to the direct reduction of alumina-contained raw materials into aluminum-rich primary alloys and special master alloys

Each of these areas is a subject of intensive studies and developments of over more than 100 years and the limited space of this book would not be enough to list the critical references only. The authors have made an attempt to give

a concise yet detailed outline for the process background, their technical realization, environmental, energy and economic issues. Many of these questions are outside of this chapter, but readers will find more details in the references below as well as in other chapters of this book.

The authors would like to thank all the contributors, who have taken part in the research in the last few years – particularly, in the area of direct reduction and electrode baking process development.

Solidification of Aluminum Alloy Weld Metal

S. Ota, K. Asai, and S. Oya

Musashi Institute of Technology, Japan

Abstract

The characteristics of the structure of solidified weld metal vary with its solidification process, which affects the occurrence of defects such as blowholes and solidification cracking. With respect to the solidification process during casting, a great deal of research has been carried out to control the process so that the solidification structure and its characteristics can be adjusted preferentially. This article describes the analytical results for the same two concerning the cooling behavior of the solid-liquid zone during the solidification process, the change in fraction of solid and local solidification rate.

Keywords: Continuous cooling solidification process (CCSP) diagram; Cooling curves; Equilibrium diagrams; Eutectic; Liquidus; Solidification front.

PREFACE

It is a well-known fact that the characteristics of the structure of solidified weld metal vary with its solidification process, which affects the occurrence of defects such as blowholes and solidification cracking. With respect to the solidification process during casting, a great deal of research has been carried out to control the process so that the solidification structure and its characteristics can be adjusted preferentially.

However, with respect to the solidification process during welding, there are many unclarified points since sufficient data from actual measurements have not been available. This is because experiments are technically very difficult because the arc heat source produces extremely high temperatures, the relevant region is very small, and solidification is an extremely rapid phenomenon. Therefore, the authors firstly established an experimental method of measuring with high precision the whole thermal cycle of the weld metal throughout the weld, using aluminium (Al) and Al alloys which are easier to handle for experiments since they have lower melting points and do not show any solidus transformation after solidification. Subsequently, in the authors' first report, the cooling and solidification processes during arc spot welding of high purity Al (99.99%) were analysed.^[1] Using the same method, further experiments were conducted for the 2024 and 5083 Al alloys, and results on the temperature distributions and cooling speed of the molten pool during the cooling process were published in a second report.^[2] As a follow-up, this report will describe the analytical results for the same two concerning the cooling behaviour of the solid-liquid zone during

the solidification process, the change in fraction of solid and local solidification rate.

MATERIALS AND TEST METHODS

Materials used in the experiment were, as in the previous study, thin sheets ($t=1$ mm) of two commercial Al alloys, i.e. an Al-Cu group alloy, 2024, and an Al-Mg group alloy, 5083. Specimens were made by stamping round-shapes of 60 mm diameter out of the sheets. The compositions of the materials used in the test are shown in the Table 1. Since their major alloy elements are different, the materials have different physical constants related to heat transfer such as thermal conductivity, density and specific heat, and show some difference in the behaviour of solutions occurring with solidification. Hence, it was expected that some difference would emerge in the solidification process. For the welding method, as described in the previous report, to clarify the solidification phenomenon during welding to prevent hot cracking, TIG arc spot welding was employed. Welding was performed on to the centre of the specimens with arc current of 40 A, arc voltage of 20 V and arc time of 10 seconds (electrode diameter of 3.2 mm DCEP). During welding, the thermal was measured by the experimental method described in the previous two reports. The cooling curves obtained were then analysed so that a study could be made of the behaviour of the solid-liquid zone during the solidification process, mainly of change in the fraction of solid and local solidification rate. Furthermore, differential calorimetry was conducted so as to clarify various transformation points for both 2024 and 5083 materials.

Table 1 Chemical composition of material used

Materials (Al-alloy)	Chemical composition (wt.%)								
	Cu	Si	Fe	Mg	Mn	Cr	Zr	Ti	Zn
2024 (t = 10 mm)	4.46	0.41	0.20	1.44	0.56	0.00	0.04	0.03	0.01
5083 (t = 10 mm)	0.02	0.14	0.24	4.59	0.62	0.11	0.01	0.01	—

RESULTS

The characteristics of cooling curves and a study of the solidification process by equilibrium diagrams

Examples of heating and cooling curves obtained in this experiment are shown in Fig. 1. However, (c), which shows the result with extremely pure Al described in the first report, is added for comparison. (1) - (6) in the figures are thermocouple numbers with the same meaning as in previous reports. That is, (1) implies that the position of the thermocouple is the closest to the centre of the molten pool; (1) - (4) or (5) are inside the molten pool; (4) or (5) - (6), are on the HAZ side; (6) is the farthest from the molten pool. What is to be noted is that, even with the same welding conditions, the diameter of the molten pool differs with base materials. For example, with the materials used in Fig. 1, it is about 9 mm for 2024 and about 8.7 mm for 5083. With the high purity Al, it is about 8 mm under the welding conditions of 50 A, 20 V and 5 seconds. Hence, even with the same thermocouple number, the position varies with base materials and welding conditions. When attention is paid to the cooling side of these heating and cooling curves, the cooling curves for all the measuring positions inside the molten pools show that cooling starts as soon as arc stops and the cooling speed continues to decrease up to the solidification starting point. This was described in previous reports.

The figure also shows that the cooling curves change after passing the solidification point according to the position inside the molten pool and the kind of material. This

**Fig. 1** Examples of heating and cooling curves

point will first be examined in this report. For example, when the curves of the alloy materials in Fig. 1 (a) and (b) are compared, the shapes of the curves are considerably different at the point at which latent heat of solidification is evolved. Since the point on the cooling curve which corresponds to the position of initial solidification, i.e. the solidification starting point, is important in analysing the curves, this point (f.p.) was determined by conducting high-speed photography synchronised with temperature measurement as in our previous reports. When the trend of the cooling curves is observed on the basis of these points, with high purity Al, the curves show a steeper gradient, suggesting a higher cooling speed. On the other hand, with the alloys, the shape of the curves does not change so drastically, showing a gentle downward gradient for a while, and then the cooling speed shows a tendency for a gradual increase. This difference in the shape of the cooling curves after passing the solidification starting points is considered to reflect a difference between alloys and high purity materials in the cooling conditions resulting from the evolution of latent heat and heat transfer during the solidification process. In other words, with high purity materials, the solidification front nearly coincides with the end of solidification because of its almost plane profile. Therefore, the end of solidification is not delayed by the release of latent heat. This is why the shape of cooling curves is considered to be shown as the reflection only of heat transfer at that point. Since the cooling speed at the solidification starting point is far higher with high purity materials than with alloy materials, as shown in previous reports, it is presumed that the efficiency of heat transfer which is conducted in the three modes, i.e. radiation, convection and conduction, is extremely high, and, as a result, the gradient of the cooling curves becomes considerably steeper. On the other hand, with the alloy materials, since solidification progresses producing a mixed solid-liquid zone as well, a certain length of time is naturally required for the point of temperature measurement to pass from the solidification starting side to the finishing side. Therefore, latent heat is released in correspondence to the continuously changing amount of solidus production. Moreover, as shown in previous reports, the cooling rate at the solidification front is far smaller with alloys than with high purity materials. These two reasons are considered to induce the gradient of the cooling curves to become gentler after the f.p. The difference between the two alloys in (a) and (b) can be presumed to show the above-mentioned difference in the conditions, in short, a difference in solidification process.

Thus, the solidification process will be investigated on the basis of this difference in cooling curves, but the first necessary procedure in analysing the cooling curves is to recognise the solidification starting points as well as finishing points on the curves. As described before, the solidification starting points (f.p.) were determined by the method of putting together the data from the temperature measurement and high-speed photography which were carried out

simultaneously. The results were shown in Fig. 1. Contrary to this, identification of the solidification finishing points on the cooling curves was difficult even with the use of high-speed photography. However, in the case of the Al-Cu group alloy, 2024, as seen on the cooling curves in Fig. 1 (a), the second exothermic point (Point B) is recognisable as the final stage of release of latent heat by solidification. The temperature at this point is around 440 - 460 °C. To clarify the significance of this exothermic point, usual thermal analysis of the material was conducted and also differential thermal analysis was carried out to detect any even finer reaction. The results are shown in Fig. 2 (a) and (b). In the usual thermal analysis in (a), discontinuous points (ternary eutectic point, E_T) due to heat generation are recognisable at 508 °C apart from melting points. In the differential thermal analysis, too, apart from melting points, an endothermic reaction is recognisable at 503.3 °C during the heating process, whilst an exothermic reaction is distinguishable at 505.5 °C during the cooling process. There is no other change recognisable. Judging from these, heat generation at the second peak (Point B) on the welding cooling curves is thought to correspond well to the above-mentioned discontinuous points when super cooling is taken into account.

Now, by regarding 2024 as a ternary group alloy only with main alloy elements, i.e. Al-Cu-Mg, the process of liquidus broadening during the solidification process will be studied on the Al-Cu-Mg ternary equilibrium diagram^[3,4] shown in Fig. 3. When the alloy with the

Fig. 3 Estimation of solidification process in Al-Cu-Mg ternary equilibrium diagram

composition of point X_0 in the diagram (Cu: 4.46, Mg: 1.44 wt%, remainder: Al) precipitates α solid solution as the initial solidification product, the solution in the liquidus at the solid-liquid interface becomes broadened and changes as solidification progresses. However, since the distribution coefficient of each element will inevitably be different from that with simple binary group alloys owing to interaction among solutions, the liquidus broadening behaviour of this 2024 Al alloy during the solidification process is not strictly defined. However, it is considered that, in the Al-Cu-Mg ternary equilibrium diagram, the liquidus broadening occurring with solidification runs, at least, through the region with hatching above the line connecting approximately the X_0 and the pseudo-binary eutectic point (E_0 : 518 °C), i.e. the highest temperature point on the binary eutectic line, and leads to the ternary eutectic point (E_T : 508 °C). When calculation is made by using the equation of Senda et al for obtaining composition change curves,^[5] though with the conditions of $\alpha=0$ and $k_0=\text{const}$, the result becomes as shown with the broken line in the diagram, i.e. going through the region estimated by the authors. This suggests that the authors hypothesis can be developed without any adjustment. In other words, if the cooling rate is high during the solidification process, eutectic points are also cooled excessively. Its extent, which is larger than that at the solidification starting point, is known easily to reach 40-50 °C.^[6] Hence, the second exothermal point at 440-460 °C on the cooling curves actually measured in this experiment is considered to be the ternary eutectic point (E_T) which has appeared owing to excessive cooling. Therefore, it was decided that the range of actual solidification temperatures of 2024 during the welding solidification process in this experiment should be treated as the range from the solidification starting point to the average temperature (450 °C) of exothermal points

Fig. 2 An example of differential thermal analysis and thermal analysis for Al alloy (2024)

appearing with the crystallisation of ternary eutectic crystals. It should be added that 2024 is a practical material and so it is naturally not a pure ternary group alloy, but an alloy of multiple elements, including impurities in its actual composition. Therefore, the solidification finishing temperature of liquid films at some places, for example, triple and quadruple points in the grain boundary at the final stage of the solidification process, can even be lower.

On the other hand, with respect to 5083, apart from the solidification starting point, the thermal analysis does not show any recognisable change like the one with 2024 which is considered to be related to solidification finishing. Since no change is recognisable on the cooling curves during the actual welding (Fig. 1 (b)), either, it is not possible to determine the solidification finishing temperature of this material on the basis of characteristics on the cooling curves. Therefore, since the main alloy elements of 5083 are Mg and Mn as shown in the Table 1, the liquidus broadening behaviour during the solidification process is considered on the Al-Mg-Mn ternary equilibrium diagram^[3,4] shown in Fig. 4. When the alloy with the initial structure, X_0 , starts solidifying, the calculated values by the Matsuda's equation become included in the region with hatching on Fig. 4 as in the above-described discussion on the Al-Cu-Mg group alloy, indicating that the following discussion will not be affected, either. This alloy is considered to have a relatively simple solidification process in which solidification finishes as the remaining thickened solution vanishes. However, when solidification is non-equilibrium such as that in welding, it is still unknown at what level of temperature solidification finishes. Therefore, as described later, when obtained from Fig. 10 which shows the relationship between temperature decrease and change of fraction solid using the solidification parameter,

Fig. 4 Estimation of solidification process in Al-Mg-Mn ternary equilibrium diagram

α , the solidification finishing temperature (temperature at fraction solid $\approx 100\%$) for 5083 with the welding conditions in this experiment and $\alpha \approx 0.09$ is $440 - 450^\circ\text{C}$ approximately. This nearly coincides with the invariable point (E_T)= 437°C in Ref 4. When super cooling is taken into account, the solidification finishing temperature is considered to go down a little more. Therefore, in this experiment, the solidification finishing temperature is taken as about 400°C .

The progress of the solidification front and the temperature decrease in the mixed solid-liquid zone during solidification

Figures 5 and 6 show the relationship between time elapsed and temperature decrease after the arc stop which was obtained from this experiment with 2024 and 5083 respectively. It is shown both by (a), the actual measurement, and by (b), the continuous cooling and solidification process diagram (called CCSP diagram from now on), for the whole area within the molten pool. In this diagram, the thick solid line, (solid circles) shows the progress of the solidification front, whilst the thick broken line (open circles) shows the isothermal line of equilibrium solidification temperatures (M.P.). The broken line was obtained by plotting the equilibrium solidification temperatures obtained by thermal analysis on the cooling curves of welding and defining the time from the arc stop to these temperatures as the time passed. Its difference from the solid line (solid circles) corresponds to super cooling. The solidification ending temperature of 2024 is shown by the thick line, (solid triangles) in Fig. 5 (a) and (b)

Fig. 5 Distribution of temperature during solidification and continuous cooling solidification process diagram (CCSP diagram) in TIG arc spot weld metal for Al alloy 2074

Fig. 6 Distribution of temperatures during solidification and continuous cooling solidification process diagram (CCSP diagram) in TIG arc spot weld metal for Al alloy 5083

by regarding it as about 450°C on the basis of the discussion in the previous section. Accordingly, the temperature range from the solid circle line to the solid triangle is the real solidification temperature range during the welding of this alloy, and the time elapsed between them becomes the local solidification time, θ_f . On the other hand, Fig. 6 (a) and (b) are concerned with 5083, which show the same features as Fig. 5, but where the solidification finishing temperature is set at about 400°C approximated also on the basis of the discussion in the previous section. In short, since the distance between the solid circle and triangle lines in Figs. 5 and 6 is the region where the mixed solid-liquid zone exists, the issue is now what kind of phenomena occur between them. The solid circle data points in Figs. 5 and 6, which display parabolic lines, show the progress of the solidification front as time passes. The solidification rate is a major factor in determining the characteristics of solidification structure. In the case of alloys, the solidification rate can be expressed in two ways; one, by the rate of solidus increase in the mixed solid-liquid zone, and the other, by the speed of the solidification front. The latter is used more often. When the solidification rate is obtained as the speed of solidification front, it is essential to know the relationship between time elapsed (t) and the distance moved (d) of the solidification front. It is thought that the relationship $d=A \cdot t^{1/2}$ can often be established between them, but there are also some suggestions that it becomes more generally $d=A \cdot t^n$ since the index does not always become 1/2 but it varies slightly.^[7] Therefore, the authors also studied this point with high purity Al in the experiment in the first report, and showed that it is better to express the relationship by $d=A \cdot t^n$ for welding solidification. With high purity materials, because the solidification

front $\approx$ solid-liquid interface, the speed of the solidification front is equivalent to the solidification rate expressed by the rate of solidus movement. Therefore, for alloy materials, too, the relationship between t and d of the solidification front was rearranged, based on the actual measurement, to logarithmic graphs as shown in Figs. 7 and 8. The figures also show relationships with the welding conditions different from those shown in Figs. 5 and 6. Figure 7 also shows the one for high purity Al for reference. As is clear from Figs. 7 and 8, in the welding solidification process of alloy materials, too, the relationship between elapsed time (t) and the distance (d) moved by the solidification front can be

Fig. 7 Relation between distance from F.B. to solidification front and elapsed time after arc stop for Al alloy 2024 and high purity (99.99%) Al

Fig. 8 Relation between distance from F.B. to solidification front and elapsed time after arc stop for Al alloy 5083 and 2024

expressed by $d=A \cdot t^n$, and the value of n varies considerably, i.e. about 1.6 - 2.5, suggesting that the solidification rate is very high.

Incidentally, the thin lines in (b) of Figs. 5 and 6 are isotherms which make it possible to know quantitatively the state of temperature decrease in the mixed solid-liquid zone of the whole area inside the molten pool as time passes after the start of solidification. That is, for 0.1 - 0.3 seconds after the start of solidification shown by the line with solid circles, temperature fall is uneven in any position within the molten pool, and the cooling rate becomes lower at positions closer to the centre of the molten pool. However, after that, the isotherms are nearly parallel until solidification ends, showing that the temperature decreases gradually in the form of stationary waves. This is considered to show that, for 0.1 - 0.3 seconds after the beginning of solidification, the closer to the centre of the molten pool, the slower is the fraction of solid increase in the solid-liquid zone than in the outer circumferential part near F.B. The behaviour of the fraction solid increase is important in studying the formation process and the characteristics of the solidification process. Thus the fraction solid will be obtained in the next section for investigation from the temperature which changes continuously within the solidification temperature range.

The behaviour of fraction solid increase in the solid-liquid zone during the solidification process

With binary alloys and the conditions which can be regarded as semi-equilibrium solidification, the relationship between temperature and fraction solid during the solidification process can be obtained geometrically from the equilibrium diagram by supposing the liquidus line to be straight. The relationship obtained is as follows:

$$f_s = \frac{1}{1-k_o} \cdot \frac{T_L - T}{T_o - T} \quad (1)$$

In which, f_s : fraction solid, k_o : equilibrium distribution coefficient, T_o : melting point of pure metal, T_L : temperature of liquidus line.

However, with multiple-element alloys like practical materials, even when they can be regarded as practically ternary alloys having semi-equilibrium solidification, it is not possible to know the relationship between the temperature and fraction solid immediately from the ternary equilibrium diagram. This is because the equilibrium distribution coefficient changes owing to interaction among solution elements at the solid-liquid interface during the solidification process, and therefore it is not possible to determine the tie line on the equilibrium diagram which shows the equilibrium relationship between solidus and liquidus. Therefore, in this experiment, the relationship between the temperature and the fraction solid during the

solidification process of multiple-element alloys was calculated approximately by using the following equation which was an equation for the relationship between fraction solid and solution density based on the model by Brody et al^[8] combined with the relationship to the fall of the solidification point^[9] with the increase in solution density at the solid-liquid interface.

$$T = T_o - \sum m_{L(i)} \cdot C_{o(i)} \left[1 - (1 - 2\alpha k_o) f_s \right]^{\frac{k_{o(i)} - 1}{1 - 2\alpha k_{o(i)}}} \quad (2)$$

In which, $m_{L(i)}$: gradient of liquidus line of alloy element (i), $C_{o(i)}$: initial solution density of alloy element (i), solidification parameter $\alpha = D_s \cdot \theta_f / l^2$ (D_s : diffusion coefficient in solidus, θ_f : local solidification time, l : dendrite cell size or half the length of dendrite secondary arm spacing)

With $\alpha=0$, (α_o) is when the solidification conditions are such that the diffusion of solution in the solidus is restrained totally. Then, the Eq. 2 can be simplified to the following:

$$T = T_o - \sum m_{L(i)} \cdot C_{o(i)} (1 - f_s)^{k_{o(i)} - 1} \quad (3)$$

Moreover, $\alpha=0.5$ when the diffusion of solution in the solid phase is perfect, that is, when equilibrium is realised. When roughly calculated with the solidification conditions used in this experiment, α values for solution elements, Cu and Mg, were $\alpha_{Cu} \approx 0.1$ and $\alpha_{Mg} = 0.09$ respectively. Thus, the degree of influence of various α values on the relationship between temperature and fraction solid was calculated by using Eq. 2. The results are shown in Figs. 9 and 10 in which 2024 and 5083 are treated as ternary alloys of Al-Cu-Mg and Al-Mg-Mn respectively. Out of various values used in the calculation, m_L and k_o are average values on the equilibrium diagram and shown in Figs. 9 and 10. D_s and θ_f are average values in the solidification temperature range. They are $D_{s(2024)} \approx 5 \times 10^{-9} \text{ cm}^2/\text{s}$, $D_{s(5083)} \approx 3 \times 10^{-9} \text{ cm}^2/\text{s}$,^[10] $\theta_{f(2024)} \approx 0.9 \text{ s}$ and $\theta_{f(5083)} \approx 1.2 \text{ s}$ respectively. For the l value, $l_{2024} \approx 2.1 \mu\text{m}$ and $l_{5083} \approx 2.0 \mu\text{m}$ were obtained by measuring the secondary arm spacing (Z_2) of dendrites from the solidification structures of both materials and taking the half of the average values ($Z_2/2$) to represent volume. The reasons why the criteria for l are set at Z_2 include the following. With both materials, there exists, in the solidification structure, a large equiaxed crystal region for which it is considered appropriate to use 1/2 of the secondary arm spacing as the volume element in the model of Brody and Flemings. It is also generally known that there is good correlation between Z_2 and θ_f . From these points of view, it seems reasonable to use Z_2 in calculating α values.^[6,9,11]

As inferred from Figs. 9 and 10, for the level of the α values in this experiment, the relationship between temperature and fraction solidified is, as a whole, close to that for $\alpha=0$. In particular, within the range of solid fraction, 0.6 - 0.7, there is practically no difference from that of $\alpha=0$. It is generally said that the nature of the solidification structure is virtually

Fig. 9 Relation between temperature and fraction solidified obtained by using solidification parameter α for Al-Cu-Mg alloy 2024

Fig. 10 Relation between temperature and fraction solidified obtained by using solidification parameter α for Al-Mg-Mn alloy 5083

determined before approximately $f_s \approx 0.4$,^[12,13] and also that the liquidus in the solid-liquid zone which has not been solidified remains fluid up to approximately $f_s \approx 0.6-0.7$.^[12,14] Hence, important characteristics of solidification structure are considered to be determined before $f_s \approx 0.6-0.7$. Therefore, it can be assumed acceptable to calculate the behaviour of fraction solidified increase occurring with decrease of temperature on the assumption of $\alpha=0$ (that is, by using Eq. 3). Since solidification starts from the fusion boundary (F.B.) and ends at the centre of the molten pool, the area in between is taken as the whole solidification process. The process is divided into three stages and called expediently the initial stage, when the solidification front is near F.B. (outer circumference of the molten pool: from F.B. to

0 - ca.30 % of the radius of the molten pool), the final stage when the solidification front reaches near the centre of the molten pool (centre of the molten pool : from F.B. to ca.70 - 100% of the radius of the molten pool) and the middle stage when it is between the two positions.

The temperature during the solidification process is read continuously from the cooling curves obtained from actual measurement in this experiment. The fraction solid (f_s) is calculated by substituting it into Eq. 3 to show its value by using the position in the molten pool as the parameter. It then becomes possible to know the variations of fraction solidified (f_s), in correspondence to the time (t) elapsed after arc stop, at each of the initial, middle and final stages during the solidification process, i.e. in the solid-liquid zone at each position in the molten pool. Figures 11 and 12 show some examples of the results. They show the behaviour of fraction solidified increasing in the solid-liquid zone (its front edge is at the fraction solidified $f_s=0$ and its back

Fig. 11 Relation between variation of fraction solidified and elapsed time after arc stop obtained for Al alloy 2024 by using position of molten pool as a parameter

Fig. 12 Relation between variation of fraction solidified and elapsed time after arc stop obtained for Al alloy 5083 by using position of molten pool as a parameter

edge, at $f_s=1.0$, i.e. at the position of actual solidus at each stage) at the individual stages in which solidification progresses from F.B. to the centre of the molten pool. In the figures, the gradient, df_s/dt , of a curve (called fraction solidified variation curve from now on) at a given time or at a given fraction solidified shows the rate of fraction solidified increase (volume solidification rate). Hence, the figures make it possible to identify a general trend in fraction solidified increase rate and also a detailed difference between 2024 and 5083. That is, in the solid-liquid zone at the initial stage of the solidification process, both 2024 and 5083 show nearly the same trend (though 5083 shows slightly higher values), and that the fraction solid increase speed, df_s/dt , is extremely high at $f_s=0$ or the beginning of passing the solidification front. If the range of fraction solidified is now divided into a region with low fraction solidified for $f_s=0-0.3$, one with medium fraction solidified for $f_s=0.3-0.7$ and one with high fraction solidified for $f_s=0.7-1.0$, this trend is maintained roughly to the medium fraction solidified range with 5083 and to the end of the low fraction solidified range with 2024. After that, with both materials, df_s/dt shows a continuous exponential reduction from the medium to the high fraction solidified. This increase in fraction solidified in the solid-liquid zone will now be examined in terms of materials effects and by following the stages of the solidification process on the basis of the fraction solidified variation curves.

Firstly, with 5083, the above-mentioned trend during the initial stage of solidification continues to the middle stage of the solidification process, but, when the fraction solidified passes the low region in the solid-liquid zone, df_s/dt starts going down at a considerable rate. This tendency increases gradually until the fraction solidified finally becomes $f_s \approx 1.0$. In other words, the fall of df_s/dt in the medium to high fraction solidified region of the fraction solidified variation curves becomes distinguishable when solidification progresses to the middle stage. Then, when solidification approaches the end of the middle stage, localised concavities start to become recognisable on the fraction solidified variation curves (that is, inflection points appear). This tendency, that inflection points are recognisable in the medium to high fraction solidified region, becomes very distinguishable when solidification reaches the middle and final stages in the process. This leads to the emergence of the fraction solidified region in which the rate of increase in fraction solidified is severely reduced. On the other hand, with 2024, Fig. 12 shows that the overall trend in the fraction solidified variation curves hardly differs from that of 5083 at the initial stage of the solidification process. However, when solidification progresses from the middle to final stage, there appears a distinct difference between the two materials in the trend in their fraction solidified variation curves. For example, during the middle and final stages of the process, the rate of increase in the average fraction solidified at the top of the solid-liquid zone is lower for 2024 in the low fraction solidified

region than for 5083, whilst df_s/dt of 2024 becomes higher in the medium and high fraction solidified regions than that of 5083. Thus, it has been clarified that there is a distinct difference between 2024 and 5083 in the way that the fraction solidified increases during the middle and final stages of the solidification process.

These solidification characteristics should be affecting the structure and properties of the weld metal. Therefore, interactions among them will need to be examined quantitatively in further studies.

CONCLUSIONS

With respect to practical Al alloys, 2024 and 5083, temperatures during welding thermal cycles were measured, and, on the basis of the cooling curves obtained, an investigation was carried out into the way in which temperature decreased and the fraction solidified increased during the solidification process from the start to the end of solidification. The following conclusions were obtained:

1. This experiment made it possible to produce a continuous cooling solidification process diagram (CCSP diagram) which shows the relationship between the position of welds with the F.B. as the datum, and change in temperature and phase with the time elapsed after arc stop.
2. It clarified that, when the speed of the solidification front is used to indicate the solidification speed for alloys, it is essential to know the relationship between the elapsed time (t) during the solidification process and the distance moved (d) by the solidification front, showing that the relationship can be expressed by $d=A \cdot t^n$.
 n values varied approximately in the region 1.6 - 2.5 in this experiment in which solidification speed was low.
3. By using the equation of approximation showing the relationship between temperature and fraction solidified, the increase in fraction solidified in the solid-liquid zone was calculated and fraction solidified variation curves showing its continuous change were obtained. Presenting these results using the position in the molten pool as a parameter made it possible to clarify how fraction solid increased at each of the initial, middle and final stages during the solidification process (See Figs. 11 and 12 for reference).
4. It was found that, at the initial stage of the solidification process, there was hardly any difference between the materials in the increase in fraction solidified. However, when solidification progressed to the middle and final stages, inflection points emerged on the fraction solidified variation curves, and this tendency became distinguishable at the final stage. The fraction solidified region in which inflection points

emerged was considerably different, i.e. the low region with 2024 and the middle and high regions with 5083. That is, the solidification processes of both materials have large differences in increase in fraction solidified at the latter stage.

Steel: Aluminum Coatings

Aruna Bahadur

National Metallurgical Laboratory, Jamshedpur, Bihar-831007, India

Abstract

Aluminum coated steel possesses excellent oxidation and corrosion resistance in sulfur and marine environments and can substitute for expensive alloy of steels. Hot dip aluminizing (HDA) and pack cementation calorizing (CAL) are dealt with in detail. IN HDA coats, some alloying action takes place, when the substrate is dipped in molten Al at 973 K for 1–2 minutes. The coat consists of an outer pure Al layer, followed by a hard intermetallic layer consisting of FeAl_3 and Fe_2Al_3 , forming a serrated interface with the base. Isothermal holding of such samples at 773–933 K for 10 minutes leads to further diffusion and phase changes. This improves resistance to thermal shock and bending. In CAL coats, the process parameters (1173–1223 K/2–4 h and pack composition), were optimized, resulting in appreciable alloying. The surface layer consists of Fe_3Al and FeAl , which is comparable to the inner alloy layer of HDA coats. The structure/ property correlation is carried out for both coatings and the results compared.

Keywords: Diffusion; Hot dip aluminizing (HDA); Pack cementation calorizing (CAL).

INTRODUCTION

Aluminum (Al) protects steel primarily due to the instantaneous formation of a thin, compact and tenacious oxide film. This alumina film is practically insoluble in most common corrosive media. Thus, though more anodic than either iron or zinc, Al has only a very limited capacity to protect steel (sacrificially), since in most environments, its preferential corrosion is essentially self-limiting.^[1] Coating Al on steel is an economical way of combining the corrosion resistance properties of Al with the inherent ductility, toughness and strength of steel. Al coating on steel provides excellent oxidation and corrosion properties at ambient and elevated temperatures in sulfur and marine environments, as well as good wear and scaling resistance.

The diffusion coating could be produced by calorizing, cladding, welding, electrodeposit, hot dipping, spray metallizing, laser process, and vapor deposition. However, hot dipping (HDA) and pack cementation calorizing (CAL) are the most important commercial processes for aluminizing of steel.^[2,3] Continuous hot dipping of wide strip remains the most economical process for the mass production of aluminized steel.^[4] Hot dipping with zinc or the newer Al-Zn alloys cannot match the advantage of combining good corrosion and oxidation resistance with exceptional heat and light reflectivity, apart from the non-toxic nature of aluminized steels.

The use of HDA is limited in the high temperature range (above 963 K). Surface Al diffuses inside, enhancing vulnerability to oxidation at the surface. Due to a discontinuity in the inter diffusion behavior,^[5] progressive

separation between the coating and the substrate takes place, leading to spontaneous exfoliation of the coating on cooling.^[6]

CAL steels with outer aluminide layer have been considered as substitutes for expensive alloy steels at ambient and high temperatures in corrosive (sulfur and marine) environments.^[3] Such steels are used in conveyor chains, retorts, thermocouple sheaths, frame of heat treatment furnaces, heat exchanger components, steam engine exhausts and in oil refinery equipments.^[7]

An in-depth study is made in this work for both HDA and CAL coatings on mild steel with respect to structural characteristics and structure/property correlation. The results of both types of coatings are compared critically.

EXPERIMENTAL METHODS

Hot Dip Aluminizing (HDA)

Mild steel sheet specimens of composition (0.2% C, 0.54% Mn, 0.28% Si, 0.016% S, 0.02% P, and 0.01% Cu) were degreased, descaled, pickled, washed and fluxed. The HDA coatings were produced by an NML-process^[8] in which specimens were dipped in molten commercial Al bath at 973–993 K for 1–2 minutes and air cooled. The transverse sections were polished, etched with 2% nital and NaOH solutions alternately. The thermal stability of these coatings was studied by heating the coated samples at 773, 923 K for varying duration (upto 1 h) and furnace cooling (FC). The effect of holding at higher temperatures of 973 and

1123 K for 10 minutes followed by water quenching (WQ) or furnace cooling was also examined. Optical microscopy, microhardness profiling and X-ray diffraction studies were conducted on the surface and at various depths.

Calorizing (CAL)

CAL coatings were produced on cleaned degreased mild steel in a retort, packed with powders of Fe-Al alloy (Fe-62 wt% Al or Fe-35 wt% Al), sintered alumina and NH_4Cl . The retort with the packing was heated at 1123–1223 K for 2–4 h in the furnace and cooled in-situ. The specimens were polished and etched with 2% nital. Optical metallography, micro hardness and X-ray diffraction studies were conducted at the surface as well as on deeper layers (by removing layers electrolytically).

Some CAL samples were subjected to tensile and fatigue tests. The fatigue tests were carried out in a rotating bending cantilever fatigue testing machine at 240 MPa and 50 Hz. The fatigue crack initiation tests were conducted under three point bending in a high frequency Vibraphone machine at a mean stress of + 123 MPa and dynamic stress of + 106 MPa and 90 Hz frequency. The criterion for crack initiation was taken as 1 mm crack from a V-notch having stress concentration factor of 2.27.

RESULTS AND OBSERVATIONS

Considerable skill and expertise are required for preparation of transverse sections of coated samples for metallographic examination. The problem arises because of the composite nature of the coating.

Optical (Fig. 1), X-ray diffraction and micro hardness studies show that HDA coats consist of a soft, thick outer layer primarily of Al. The micro hardness data was taken with a diamond indenter and loads varying between 0.15 and 0.64 N. The values are 130–250 VHN upto (13) μm , 425–700 VHN upto 65 μm , 810–915 VHN at 85–185 μm .

Fig. 1 Optical microstructure of HDA coat on mild steel shows soft outer layer, hard intermediate intermetallic layer having serrated interface with base, 200x

The intermediate intermetallic layers having serrated interface with the base reveal the following phases at increasing depth from the surface: Al+ FeAl_3 ; Al + FeAl_3 + Fe_2Al_5 ; FeAl_3 + Fe_2Al_5 . TEM diffraction reveals the presence of Fe_3Al in some deeper layers. Bending 90° and back produced no peeling-off of the coating.

Optical (Fig. 2), X-ray diffraction on CAL coats, reveals phases such as FeAl and Fe_3Al generally. Only under calorizing condition of 1223 K/4h, an additional phase FeAl_3 forms for 62% Al pack. The calorizing condition of 1173 K/4h is found to be optimum for both pack compositions. The micro hardness studies shows that in contrast with HDA, in CAL coats the outermost layer is the hardest (515 VHN); the inner phases are softer (475–330 VHN). CAL (1173 K/4h) with Fe-62 Al pack produces a 132% increase in hardness, no change in percent elongation, a 9% decrease in reduction in area, and a 5% increase in UTS, compared to uncalorized mild steel. A considerable decrease in high cycle fatigue properties in CAL are noticed due to a multiple crack initiation sites; CAL layer peeled off during the test.

The effect of heating HDA samples at 773–923 K shows a gradual thinning of the outer Al layer, due to reaction diffusion of Al with the base, Fig. 3. The layer disappeared on heating 923 K/10 min. The phases detected by XRD, as temperature and time of holding increase, are as follows: Al + FeAl_3 , FeAl_3 + Fe_2Al_5 and only Fe_2Al_5 . High temperature studies (1123 K/10 min) show no discontinuity in the layer between the intermetallics and the base, inspite of the possibility of encountering stresses in the latter (Fig. 4).

DISCUSSION

The starting material in HDA being pure Al is expected to yield Al-rich phases. A wider range of phases is not observed at the outset because of a quasi-equilibrium situation (short time of dipping). The predominance of

Fig. 2 Optical microstructure of CAL coat on mild steel, shows the harder outer layer, softer intermediate layer, and large elongated ferrite grains near the base, 200x

Fig. 3 Optical microstructure of HDA mild steel heated 873K/30 min./ FC, shows thinning of outer Al layer, 200x

Fig. 4 Optical microstructure of HDA mild steel heated 1123 K/10 min/WQ shows flattening of spikes and no spalling of coat near base, 200x

Fe_2Al_5 is explained by high number of lattice defects^[9] or high vacancy concentration,^[10] resulting in a greater interdiffusivity within Fe_2Al_5 than in FeAl_3 , causing the former to grow rapidly at these temperatures (973–1023 K). Large number of vacancies along c-axis is known to cause maximum diffusion along (002) plane, giving a serrated interface.^[11]

The presence of outer pure Al layer limits the use of these coatings at high temperatures. Heating below the melting point of Al (773–923 K) causes further reaction diffusion of Al and the conditions move towards equilibrium. Diffusion also takes place between the Fe-base and the intermetallic region through the serrated interface, rounding off the spiked interface. The outer Al layer thins down giving rise to only FeAl_3 initially, then in coexistence with Fe_2Al_5 and finally Fe_2Al_5 only, leading to thermal stability, as further transformations do not take place under the given conditions.^[12,13] HDA is then expected to behave like diffusion coatings, although types of phases present are different. Fe_2Al_5 is practically undeformable and it is imperative to restrict the growth of this layer to achieve good overall mechanical properties.^[14] However, in the present case, despite

the large thickness of this layer, the coating did not peel off on bending 90° and back. Also, on holding at higher temperatures (973, 1123 K) and water quenching, the inner coating layer (next to the base) did not spall off. The occasional presence of Fe_3Al found in HDA coats and the formation of Fe_3Al on holding may be providing the ductile linkages.

In contrast, the starting material in calorizing being FeAl_3 or FeAl (stoichiometrically), produces more of the ‘favorable’ phases as defined by Pilling and Bedworth.^[15–17] As far as temperature and time of CAL is concerned, 1173 K/2 h appears optimal. Lower temperatures retard the process and higher temperatures impair the quality of the coating. In CAL, the absence of Fe_2Al_5 in appreciable quantities implies that in solid state alloying, iron atoms diffuse outwards towards the Al rich layer. Unlike HDA coats, the coating metal in CAL does not enter into the coating structure except as mechanically entrapped particles at excessively high temperatures. The pack composition appears to be the most important parameter in calorizing, for determining the type of phases forming.^[18,19]

The larger volume of aluminide introduces compressive residual stresses on the calorized surface and should lead to improved fatigue properties. However, deterioration in tensile and fatigue properties on calorizing could be ascribed to the following reasons; reduced load bearing cross-section on calorizing (due to consumption of a portion of alloy during formation of coating) as well as in service (due to interaction between substrate and coating). A modification of chemical composition of substrate zone adjacent to the coating due to this interaction could also reduce mechanical strength of the component. Further, inherent strain bearing capacity of aluminide coatings may also detrimentally affect fatigue behavior of the component. Large difference in moduli between the aluminide and matrix is also responsible. This deterioration severely affects extremely thin sections viz. cooled blades.^[20] Thicker coats obtained at National Metallurgical Laboratory, India at 1173 K/4 h lead to lower high cycle fatigue life, compared to thinner coats obtained at 1173 K/2 h, confirming earlier findings.^[21]

CONCLUSIONS

- The thickness of outer Al-layer in HDA coats decreases on heating due to the phase transformation in the inner alloy layer.
- HDA layer appears quite adherent and resistant to thermal shock, due to the formation of Fe_3Al .
- CAL does not contain any pure Al layer. 35% Al pack gives favorable phases only.
- Calorizing condition of 1173 K/2 h is considered suitable for mild steel to produce favorable phases with either pack material.

Abstract

Several types of powders can be deposited on metal alloys for property improvement using thermal spray processes. Aircraft grade 7075 aluminum alloy possesses good mechanical properties but poor wear and corrosion resistance. Thermal spray coatings can improve the poor wear performance of 7075 so that it is suitable for use in severe conditions by depositing a hard, wear-resisting layer over the base material. This can be done by a simple production process while maintaining the base material properties. Among the available coatings, cobalt-base superalloys, such as Stellites, provides excellent protection against corrosion and wear. However, the treatment must not deteriorate the substrate hardness. In the High Velocity Oxygen Fuel (HVOF) thermal spray process, the short resident time of the powder in the flame results in a relatively small temperature increase, which in turn results in a lower substrate temperature during the coating deposition. In the present work, HVOF thermal spray process was used to coat 7075-T3 aluminum alloy samples with Stellite 6 superalloy. This treatment resulted in layers of high hardness and improved wear performance while keeping the base material properties unchanged.

Keywords: Aluminum; Stellite; Thermal spray.

INTRODUCTION

The aerospace industry continues to require materials with increasing mechanical resistance/weight relationship. Aluminum alloys are largely used in aeronautical applications because they generally meet this requirement; however, they possess some limitations concerning wear and corrosion resistance. Wear and corrosion resistance of aluminum alloys can be improved by the application of coatings with more resistant materials onto the surface of parts, which will provide a material with the advantages of the good mechanical resistance and low density of aluminum alloys and corrosion and wear protection attributable to the more resistant material coatings.

Starting in the 1940s, there has been a substantial and ongoing development in coating deposition techniques such as thermal spray, which, in addition to being relatively simple to perform in production, often does not influence the base material.^[1] Thermal spray processes can be divided into two groups: the first uses combustible gases as the source of heat and the second that uses the energy produced by an electric arc. The Low Velocity Oxygen Fuel (LVOF) process uses acetylene and oxygen flame as the energy source. The material after being heated

is atomized through compressed air. Wire, or the powder of the material that will be deposited on the surface of the metal substrate, can be used in the process.

HVOF deposition utilizes a mixture of combustible gases, and oxygen is injected in the combustion chamber to produce a flame in the range of 2900°C and with a mixture speed of ~2000 m/s. The powder of the material to be deposited is injected into the chamber, and it reaches the surface to be coated at high speed and temperature, forming a smooth layer with low porosity, high hardness, and good adherence. As with the LVOF process, the energy for the HVOF process is originating from a flame and the surface layer that is formed contains oxides. The properties of the deposited coatings depend on the factors such as porosity, cohesion between the particles, and adhesion to the substrate. The density of the deposited layer will depend on the type of the material, the deposition method, and the powder dispersion conditions.

The 7075 alloy studied in this work is widely used for applications in general mechanical and aerospace industries. The use of cobalt-base alloys for wear resistance applications began in the early 20th century, with the development of the family of cobalt–chrome–tungsten alloys. They were named “Stellite” because of their

brilliant appearance without the use of stains. Their excellent erosion resistance is due to the high percentage of chrome present in the alloy, and the good wear resistance is due to carbide formation, even at high temperatures. Another very important factor was the development and characterization of the alloy to improve its performance in situations where there is no metal–metal contact, such as erosion by high-speed fluid or by shock of solid particle impingement. All of these factors have facilitated the use of Stellite alloys in different equipment ranging from turbines to bombs and valves, and even in nuclear applications.^[2–4]

Laboratory characterization of the wear properties of these previously mentioned alloys can model the performance under actual use conditions.^[5] The wear characterization of the layers produced by HVOF processes can be performed by the free-sphere micro-abrasive wear test using an alumina suspension in distilled water as the abrasive. Porosity and layer thickness were also measured using optical microscopy.

MATERIALS AND METHODS

The HVOF process was used to deposit the layers of Stellite 6 over 7075-T3 aluminum alloy.

For sample characterization, the following procedures were used:

- Optical microscopy (microstructural aspects of the layers, thickness, and porosities).
- Microhardness testing of the layers and substrate.
- Micro-abrasive wear test (determination of the diameter of the caps and the wear volume).

Materials

Table 1 shows the chemical composition of the 7075 aluminum alloy used for this work and Table 2 shows the Stellite 6 cobalt-base alloy composition.

Table 1 Chemical composition of the 7075 aluminum alloy base material

Material	Chemical composition (wt%)				
	Zn	Mg	Cu	Cr	Al
7075	5.6	2.5	1.6	0.23	Balance

Table 2 Chemical composition of Stellite 6 coating material

Material	Chemical composition (wt%)			
	Cr	Co	W	C
Stellite 6	28	Bal.	4	1.1

Test Specimens

Test specimens measuring 10 × 20 × 25 mm were obtained from the 7075-T3 aluminum alloy previously coated with Stellite 6 and used for micro-abrasive wear testing.

Preparation for the Optical Microscopy Analysis

For the porosity and thickness measurements of the layers, the samples were cut in the orthogonal direction. The samples were then ground followed by final polishing with 0.3 μm alumina.

Microhardness

For Microhardness testing of the layers and the substrate, a Vickers-type indenter was used. The measurements were performed in the transverse section of the layer. Ten measurements of hardness were obtained for each layer. Tests were performed according to ASTM E384 “Standard Test Method for Microindentation Hardness of Materials.”

Optical Microscopy Analysis

To measure the porosities and the thickness of the different layers, samples were polished and micrographs of 10 different areas were taken.

Images of the caps formed in the micro-abrasive tests were captured and later measured (average of 10 measurements). With the values of the cap diameters for each layer type and for different traveled distances, the graph was constructed, which illustrates the amount of wear for each layer.

Wear Tests

Wear resistance was determined using a free-sphere micro-abrasive wear testing machine utilizing an AISI 52100 steel sphere with a hardness of 850 HV and with a diameter of 25.4 mm, which is rotated against the test specimen. The abrasive solution is dripped between the sphere and the sample, with a concentration of 0.32 g of 5 μm abrasive alumina for each mL of distilled water. The rotation speed of the sphere was 159 rpm with a tangential speed of 0.22 m/s. Wear was measured after total distances of 158.4, 237.6 and 316.8 m. The test was repeated three times for each distance for the calculation of the average cap diameter.

For a wear cap with spherical geometry with a radius R in a plane sample, the consumed volume can be calculated from the following equation:^[5–7]

$$V = \pi \frac{b^4}{64R^2} \left(R - \frac{b^2}{8R} \right) \approx \frac{\pi b^4}{64R} \quad \text{for } b \ll R \quad (1)$$

where R is the radius of the sphere, b is the median diameter of the cap, and V is the wear volume.

For the coating wear volume to be correct, it is necessary to assure that the depth of the cap does not surpass the thickness of the deposited layer. The cap depth is calculated from the following equation:

$$h = \left[\pi \frac{V}{R} \right]^{0.5} \quad \text{for } h \ll R \quad (2)$$

where h is the wear depth.

RESULTS AND DISCUSSIONS

The coating layer formed by the HVOF process on the aluminum alloy substrate is shown in Fig. 1. The low porosity levels and their good homogeneity are verified. Also, it is observed that the coating process caused a close fit between the contacting surfaces.

The typical aspects of the caps formed by the micro-abrasive wear test with free sphere in a distance of 158.4 m are shown in Fig. 2.

Table 3 shows the cap depth and layer thickness. The calculated average cap depth is $25.3 \mu\text{m}$ and the layer thickness measured is $\sim 600 \mu\text{m}$, indicating that the deposited layer is much thicker than the cap depth (which is necessary for valid micro-abrasive wear tests).

Hardness values for coating and substrate are shown in Table 4.

The surface hardness increased 3.5 X, improving the wear resistance and decreasing the abrasion scar.

Table 5 provides hardness test measurements performed on the substrate before thermal spraying and after the thermal spray process near the deposited layer.

Fig. 1 Photomicrograph of the layer formed by Stellite 6

Table 3 Average caps thickness for each material and the calculated cap depth from Eq. 2 for three sliding distances

Material	Cap depth (μm)			Average layer thickness (μm)
	158.4 m	237.6 m	316.8 m	
Stellite 6	25.2	25.3	25.4	600

Table 4 Coating and substrate hardness (HV)

	Coating hardness (HV) load 3 N	
	Average value	Standard deviation
Stellite 6	570.2	± 42
7075-T3 Aluminum alloy	149.4	± 9.5

Through hardness test results, it is possible to verify that the thermal spray processes did not significantly influence the substrate hardness, indicating the effectiveness of this treatment to improve the performance of aged aluminum alloys.

Table 5 Results of the substrate hardness (HV) before and after coating deposition

Substrate hardness (HV) load 200 g		
Deposited material	Before	After
Stellite 6	149.4 ± 9.5	145.3 ± 8.8

Fig. 3 Electronic micrography of the 7075 alloy substrate and the deposited coating of Stellite

The porosity of the Stellite layer is shown in Table 6, indicating a low porosity level and the good performance of the coating process.

In Fig. 3, a scanning electron microscopy micrograph of the aluminum substrate is shown (left) with the layer of deposited Stellite (right). The line where a scanning elemental analysis is performed using a energy dispersive spectroscopy (EDS) microprobe is also shown.

In Fig. 4, the EDS line scan obtained for the aluminum, magnesium, chromium, and cobalt elements is shown; an abrupt interface between the substrate and the coating layer indicates that essentially no dilution among the elements occurred between the two layers.

Table 7 contains the values of the wear coefficients obtained for the deposited layers and for the 7075-T3 aluminum alloy, calculated from the wear test with a total traveled distance of 316.8 m. The graphs of the volumes

Fig. 4 Scan line obtained by EDS microprobe

Fig. 5 Graph of the micro-abrasive wear tests of the layer and the substrate

consumed in relation to the traveled distance are shown in Fig. 5.

It is observed that the highest specific wear rate obtained at the coating is inferior to the wear rate of the aluminum alloy 7075-T3 substrate. This result illustrates the effectiveness of the Stellite surface layers to act as wear-resistant coatings for aluminum.

CONCLUSIONS

The thermal spray process did not impart a significant influence on the 7075 aluminum alloy substrate. This is important because a significant decrease of substrate hardness would indicate an unacceptable loss of properties.

The results reported here indicate that with respect to hardness and micro-abrasion wear test results, Stellite 6 provides an excellent wear resistance to 7075 aluminum alloy. This shows that the deposition of such materials can be an efficient form of improving the performance of aluminum when higher wear or erosion resistance is needed.

Strain Rate Sensitivity of Commercial Aluminum Alloys

R.C. Picu

Rensselaer Polytechnic Institute, Troy, United States

Abstract

This article presents a review of the strain rate-dependent mechanical behavior of aluminum and its commercial alloys. The importance of strain rate sensitivity (SRS) stems from its relation with ductility and formability. Plastic deformation is stable and localization less likely in alloys with higher SRS. After discussing the basic formulation used to interpret experimental data, the methods used to measure the SRS parameter are presented. This is followed by a brief review of the main mechanisms that render the flow stress sensitive to the deformation rate, including mechanisms leading to positive and negative SRS. The generic dependence of the SRS parameter on the strain, temperature, and strain rate are further presented using data for pure Al. The effect of alloying is analyzed in the context of solid solutions and precipitated commercial alloys. Results on solid solutions are discussed separately at low and elevated temperatures in order to evidence the role of solute diffusion on SRS. This article ends with a brief discussion of the grain size dependence of SRS, with emphasis on recent efforts to produce nanocrystalline and ultrafine-grained materials by severe plastic deformation.

Keywords: Aluminum alloys; Ductility; Rate theory; Severe plastic deformation; Strain rate sensitivity; Thermal activation.

INTRODUCTION

Aluminum and its alloys have good ductility, relatively high strength and, in general, exhibit good formability. The stability of plastic deformation and hence the formability limit are controlled by the strain hardening ability of the material and its strain rate sensitivity (SRS). Therefore, establishing how these parameters depend on strain, strain rate, temperature, and the state of the microstructure is essential in alloy development. This article presents a review of the current understanding of the SRS of Al alloys. The physical mechanisms responsible for SRS are briefly reviewed, but dwelling into detailed model-based interpretation of the experimental data is avoided.

This article is organized as follows: the importance of SRS is first presented. Experimental data showing that ductility and formability depend on SRS are presented and a plastic flow stability analysis is outlined in support of these observations. Further, the key parameters and concepts used to quantify SRS are reviewed. This provides a framework within which the experimental results discussed in the rest of this article can be interpreted. Several methods developed to measure the SRS of materials, such as the strain rate jump and the relaxation tests, are reviewed, and their advantages and limitations are outlined. The following subsection focuses on the SRS of pure Al and its alloys. The generic features of SRS, such as its dependence on

strain/stress, temperature, and strain rate, are presented in the context of pure Al. Similar trends are observed in most Al alloys. The effect of free solute on SRS is discussed at low temperatures, when solute is immobile, and at elevated temperatures at which solute is mobile. Solute mobility leads to dynamic strain aging (DSA) and negative SRS, which in turn causes a form of unstable plastic flow known as the Portevin–Le Chatelier (PLC) effect. This behavior is observed in Al–Mg alloys tested in certain range of temperatures and strain rates. Precipitation generally reduces the SRS parameter since precipitates are more of a thermal obstacle to the motion of dislocations than solute. This effect is demonstrated using examples from the Al–Cu, Al–Mg–Si and Al–Li alloys. This article ends with a brief discussion of the effect of the grain size on SRS. It is shown that in Al the SRS increases as the grain size decreases. This is relevant for the current efforts to produce stable fine-grained alloys of high strength and good formability.

GENERAL CONSIDERATIONS

The physical metallurgy of Al and its alloys has been extensively studied. The flow stress is defined primarily by the dislocation–dislocation, dislocation–solute, and dislocation–precipitate interactions. Grain boundaries interact strongly with dislocation motion.

Without being concerned with the deformation mechanisms, one can write the stress as a generic function:

$$\sigma = \sigma(\varepsilon, \dot{\varepsilon}, T, \wp), \quad (1)$$

where the macroscopically controllable parameters are the total strain, ε ; the strain rate, $\dot{\varepsilon}$; and the temperature, T . $\wp$ stands for a set of internal parameters that are not directly controlled and, in most cases, not even specified. This reduced set of variables embodies the result of the heuristic coarse graining of the real phase space of the material, which has dimensionality $3N_A$ per mole (where N_A is the Avogadro number), to the much smaller space defined by the variables of σ in Eq. 1. This dimensionality reduction is currently poorly supported by theoretical considerations and the definition of set $\wp$ depends on the model used for the underlying physical processes of deformation.

Function (1) can be expended in series in the vicinity of the reference, unloaded state defined by $\varepsilon=0$, $\dot{\varepsilon}=0$, and $T=T_0$, with T_0 being a reference temperature of choice. The increment of the stress associated with the variation of the macroscopic controllable parameters is as follows:

$$d\sigma = \left. \frac{\partial \sigma}{\partial \varepsilon} \right|_{\varepsilon, T, \wp} d\varepsilon + \left. \frac{\partial \sigma}{\partial \dot{\varepsilon}} \right|_{\varepsilon, T, \wp} d\dot{\varepsilon} + \left. \frac{\partial \sigma}{\partial T} \right|_{\varepsilon, \dot{\varepsilon}, \wp} dT + \dots \approx \theta d\varepsilon + m \frac{\sigma}{\dot{\varepsilon}} d\dot{\varepsilon} + \left. \frac{\partial \sigma}{\partial T} \right|_{\varepsilon, \dot{\varepsilon}, \wp} dT. \quad (2)$$

The approximation corresponds to neglecting the higher-order terms. $\theta = \partial \sigma / \partial \varepsilon$ evaluated at constant $\dot{\varepsilon}, T$ and structure, $\wp$, represents strain hardening and

$$m = \left. \frac{\partial \log \sigma}{\partial \log \dot{\varepsilon}} \right|_{\varepsilon, T, \wp} \quad (3)$$

is the SRS parameter. In general, both θ and m are functions of $\varepsilon, \dot{\varepsilon}$, and T . This article focuses on the dependence of m on these parameters and on the metallurgical state of various Al alloys.

THE IMPORTANCE OF RATE SENSITIVITY

The importance of SRS in the mechanical behavior of materials is twofold. As summarized below and in most reviews on this subject,^[1-4] this measure provides valuable information about the mechanisms of plastic flow. The interpretation of experiments is based on models representing deformation mechanisms. Due to the large number of such models, the discussion of the microscopic implications of macroscopic experimental data is kept here to a minimum.

From a practical point of view, the SRS is related to the stability of plastic deformation. Strain localization is prevented and homogeneous plastic flow is favored when the strain hardening, θ , and the SRS parameter, m , are large.

Fig. 1 Relation between the SRS parameter, m , and the elongation at failure. The upper part of the curve ($m \gtrsim 0.3$) corresponds to superplastic conditions^[5]

The correlation between the value of the SRS parameter and the failure strain is reported in the literature for various materials. Figure 1 shows a plot of this type indicating that ductility increases with increasing m .^[5] Similar results for pure Al and Al alloys can be found in Refs. [6,7].

A stability analysis can shed light on the origin of the result shown in Fig. 1 and on the relative roles of strain hardening and SRS in plastic flow stability.^[8-10] Let us start from Eq. 2 and consider an isothermal uniaxial deformation. The constitutive equation becomes:

$$d\sigma - \theta d\varepsilon - m \frac{\sigma}{\dot{\varepsilon}} d\dot{\varepsilon} = 0. \quad (4)$$

The condition that deformation is isochoric leads to:

$$\frac{d\sigma}{\sigma} = d\varepsilon. \quad (5)$$

Hence, Eq. 4 becomes^[11] as follows:

$$\frac{d\dot{\varepsilon}}{\dot{\varepsilon}} = \frac{\sigma - \theta}{m\sigma} d\varepsilon. \quad (6)$$

Consider now a perturbation strain increment taking place in some region of the sample expressed by:

$$d\varepsilon(t) = d\varepsilon_0 \exp \lambda t. \quad (7)$$

From Eqs. 6 and 7, one infers

$$\lambda = \frac{\sigma - \theta}{m\sigma} \dot{\varepsilon}. \quad (8)$$

It is clear from Eq. 7 that if $\lambda > 0$, the perturbation grows exponentially in time and deformation is unstable. Hence, instability is triggered when:

$$\frac{\sigma - \theta}{m} > 0. \quad (9)$$

Fig. 2 Localization bands are seen on the surface of a AA5182 specimen deformed at room temperature with a strain rate of 10^{-4} s^{-1}

This condition is fulfilled when $m > 0$ and $\sigma - \theta > 0$, or when $m < 0$ and $\sigma - \theta < 0$. Under positive SRS conditions, $\sigma - \theta > 0$ represents the well-known Considere criterion. This represents instability driven by the reduction of strain hardening. Equation 9 indicates that instability may set in when $m < 0$, even though the Considere criterion is not fulfilled and deformation is supposed to be stable from the strain hardening point of view alone.

Several limitations of this treatment should be outlined: (a) the formulation does not take into account the stiffness of the loading system (the “machine equation”), (b) instability can be produced by fluctuations in temperature, such as in adiabatic shear banding; this case is discussed in Ref. [10]. A different criterion leading to the condition for instability being

$$\sigma - \theta > m\sigma \quad (10)$$

has been proposed in Ref. [11]. This formulation has the advantage that it predicts the deformation to be stable for negative values of m close to zero provided θ/σ is sufficiently large, which is in agreement with experimental observations.

SRS-driven instabilities ($m < 0$) reflect in serrated stress-strain curves, i.e., the PLC effect. Deformation is heterogeneous and localizes in bands that leave traces on the surface of the sample, as shown in Fig. 2 for a AA5182 specimen. The bands increase the surface roughness. Each localization event produces a stress drop and the stress-strain curves are serrated.

Closing this brief discussion on stability, it should be remarked that the critical conditions for localization also depend on sample geometry and the presence of stress concentrators. Even the surface finish has been reported to have an influence on conditions for the onset of serrated yielding associated with DSA in Al-Mg alloys.^[12]

FORMULATION

Within the small strain approximation, the total strain ϵ is written as a sum of the elastic and plastic strains, i.e., $\epsilon = \epsilon_{el} + \epsilon_{pl}$. In rate form, this becomes

$$\dot{\epsilon} = \dot{\sigma} / E(T) + \dot{\epsilon}_{pl}, \quad (11)$$

where the elastic behavior is taken to be linear and defined by Young’s modulus, E . The stress increment

associated with an increment of the strain can be written $d\sigma = E(d\epsilon - d\epsilon_{pl})$.

Elastic deformation is strain rate independent, and E is not a function of $\dot{\epsilon}$. The temperature dependence of the elastic strain is only associated with the temperature dependence of the modulus. Therefore, the rate dependence of the stress is associated with ϵ_{pl} . It should be noted here that in experiments one normally controls $d\epsilon$, and not $d\epsilon_{pl}$, and hence a correction is needed when evaluating m from experimental data using Eq. 3. The resulting SRS value is known as “precision strain rate sensitivity”.^[3]

Stress is usually written as a superposition of thermal and athermal components:

$$\sigma = \sigma_t + \sigma_a. \quad (12)$$

Of these, only the thermal components, σ_t , is strain rate dependent. With Eqs. 11 and 12, Eq. 3 becomes

$$m = \left. \frac{\partial \log \sigma_t}{\partial \log \dot{\epsilon}_{pl}} \right|_{\epsilon_{pl}, T, \phi}. \quad (13)$$

The superposition expressed by Eq. 12 is not straightforward. It implies that the mechanisms producing the athermal and thermal components are decoupled and operate on different length scales. This issue is similar to that encountered when writing the flow stress as a superposition of contributions of various mechanisms. For example, it is generally considered that the strengthening contribution of the solute in solid solutions with immobile solute atoms can be written in this additive form together with the contribution to stress from dislocation-dislocation interactions. Likewise, here, one imagines that the athermal component is due to long range interactions that cannot be thermally activated efficiently. The characteristic length scale of variation of the athermal component of stress is larger than that of the thermal component; hence the athermal contribution can be regarded as a background stress when viewed from the scale at which interactions that can be thermally activated operate.

The plastic strain rate is related to the dislocation activity through the Orowan relation:

$$\dot{\gamma}_{pl} = \alpha \rho_m b v, \quad (14)$$

where ρ_m is the mobile dislocation density, b is the magnitude of the Burgers vector, and v is the mean velocity of mobile dislocations. Since Eq. 14 is written at the slip system level, we use here the resolved plastic shear strain, γ_{pl} , in place of the global plastic strain, ϵ_{pl} , of Eq. 11.

Dislocation motion is intermittent, with fast jumps from a stable configuration to the next and long wait times in each of these successive stable configurations. This is broadly supported by electron microscopy observations. Hence, one can write $v = l/(t_f + t_w)$, where l is the average distance traveled between two successive equilibrium

configurations, while t_f and t_w are the flight and wait times, respectively. The characteristic length l is bounded below by a length inversely proportional to the square root of the density of obstacles, which can be taken proportional to the mean length of the dislocation segment between pinning points or the mean distance between obstacles. Usually, t_f is neglected relative to t_w and the mean velocity becomes $v = l\xi$, with $\xi = 1/t_w$ being the frequency at which a dislocation is unlocked from a stable configuration.

This classical description is appealing since it is intuitive. However, it applies exactly only to an isolated dislocation in contact with fixed obstacles. Plastic deformation is a collective process in which large groups of dislocations move in a correlated way.

To represent thermal activation, the rate theory formulation is used. Bypassing an obstacle is considered a thermally activated process that takes place with a frequency described by an Arrhenius dependence on temperature. Therefore, the mean dislocation velocity reads

$$v = v_0 \exp\left(-\frac{\Delta G}{kT}\right), \quad (15)$$

where ΔG is the stress-dependent free energy of activation and k is Boltzmann's constant. The local activation process is described by the Gibbs free energy since the process takes place at constant temperature and local stress. With Eq. 15, Eq. 14 becomes:

$$\dot{\gamma}_{pl} = \alpha \rho_m b v_0 \exp\left(-\frac{\Delta G}{kT}\right). \quad (16)$$

Two difficulties exist related to Eq. 16. ΔG is interpreted as the energetic barrier a dislocation segment faces when attempting to bypass an obstacle. Since an isolated dislocation is in contact with many obstacles at a time, it is not clear that the effective energy barrier describing the dislocation unpinning process is equal to that corresponding to bypassing an individual obstacle, even in the case in which all obstacles are identical. This result holds only if motion takes place by a process called “unzipping,” which assumes that the dislocation bypasses one obstacle at a time.^[13–15] If correlated unpinning takes place, dislocation motion can still be described by Eq. 16, but the effective activation free energy is different from that associated with an individual obstacle.^[16–20]

A more fundamental observation is related to the fact that the Arrhenius form originates from the Boltzmann distribution of energies for classical systems in equilibrium. While the distribution is not perturbed significantly in nonequilibrium situations which are not far from the thermodynamic equilibrium state, plastic deformation is a far nonequilibrium process characterized by very large dissipation. Therefore, it is surprising that the exponential form is well supported by experimental data. A possible interpretation of this apparent contradiction is, appealing to the mean field view, that the thermal component of

stress is defined by local interactions that involve groups of several hundred atoms and energies on the order of few eV. In other words, local interactions play the role of a low-energy controller regulating a larger scale and much higher energy dissipative process.

In view of this discussion, regarding Eq. 16 as a phenomenological relation removes the uncertainties related to its physical basis. Of course, this is unsatisfactory if SRS measurements are to be related to the microscopic details of the deformation process, as is frequently done in the literature.

It is common in rate theory to write the total rate at which a thermally activated process takes place as the sum of two Arrhenius terms (Eq. 15), representing the forward and backward components of the process, respectively. This recognizes the fact that the probability of the system returning to the initial state once it has moved over the barrier is not zero. The probabilities of the two types of evolution differ since the energy barrier viewed from the two equilibrium states is different. The net rate results as a product of an exponential function similar to Eq. 15 and a *sinh* function. The *sinh* was included in some early formulations,^[1] but it was eventually eliminated based on the observation that, for conditions common in metallic alloys, the return barrier is too high for the backward flux to be important.^[21,22]

The activation energy is written in terms of the local stress that drives the dislocation against the obstacles, i.e., $\tau_i = \tau - \tau_a$, where τ is the applied stress and τ_a is a thermal component. As above, the resolved shear stress in the respective glide plane is relevant here instead of the global normal stresses, σ . The resolved shear stresses are related to the global normal stresses through the Taylor factor. In the following discussion, we use the actual stress τ (or σ) in place of the more physically meaningful τ_i (or σ_i) in the expression of the SRS parameter, Eq. 13, because the athermal component of stress is considered rate insensitive.

Atomistic and dislocation dynamics studies of the interaction of dislocations with obstacles, as well as generic considerations, indicate that the functional form of $\Delta G(\tau)$ can be approximated as^[23] follows:

$$\Delta G(\tau) = \Delta G_0 \left(1 - \left(\frac{\tau}{\hat{\tau}} \right)^p \right)^q, \quad (17)$$

where $\hat{\tau}$ is the stress required to bypass the obstacles without thermal activation. This is approximated as the critical resolved shear stress at 0 K.^a Equation 17 is a concave function of τ and it can be shown that ΔG cannot be a convex function.

^aThe stress increases with decreasing temperature; but at very low temperatures, this trend is modified due to quantum effects. Hence, in order to infer $\hat{\tau}$ from experimental data, it is necessary to extrapolate the monotonic branch of the curve defined by the measurements above ~ 70 to 0 K.

While Eq. 17 provides more flexibility, a simpler form is needed in order to fit experimental data. A linear form is more common:

$$\Delta G(\tau) = \Delta G_0 - \tau V. \quad (18)$$

The coefficient multiplying τ has units of volume and is known as the activation volume. This quantity is important since it results directly from certain types of experiments (see next subsection). Replacing Eq. 18 in Eq. 16 and evaluating m with Eq. 13 leads to:

$$\frac{1}{m} = \frac{\tau V}{kT} + \frac{\partial \log \rho_m}{\partial \log \tau}. \quad (19)$$

Assuming that the mobile dislocation density does not vary during a strain rate jump, the second term vanishes and:

$$m = \frac{kT}{V\tau}. \quad (20)$$

The activation volume is given by:

$$V = \frac{kT}{m\tau} = kT \left. \frac{\partial \log \dot{\gamma}_{pl}}{\partial \tau} \right|_{\gamma_{pl}, T, \phi} \quad (21)$$

Other quantities are also used in the literature to denote the SRS. In particular, m/kT is called “thermodynamic rate sensitivity”.^[3,24]

The inverse activation volume

$$\frac{1}{V} = \frac{m\tau}{kT} = \frac{1}{kT} \left. \frac{\partial \tau}{\partial \log \dot{\gamma}} \right|_{\gamma_{pl}, T, \phi} \quad (22)$$

is usually plotted against τ in a representation of the SRS behavior that is known as the Haasen plot. Plots of this type for pure Al and several Al alloys are presented in Figs. 5 and 7a.

Note that the physical quantity that results directly from an experiment in which the strain rate and the stress are varied is the activation volume, V . The free energy barrier height, ΔG , cannot be evaluated from this type of data. However, by taking the derivative with respect to T in Eq. 16, it can be seen that:

$$kT^2 \frac{\partial \log \dot{\gamma}_{pl}}{\partial T} = \Delta G - T \frac{\partial \Delta G}{\partial T} = \Delta G + T \Delta S = \Delta H. \quad (23)$$

Here, it was assumed that the group $\alpha \rho_m b v_0$ of Eq. 16 is temperature independent over the duration of the temperature jump. Equation 23 indicates that by performing a test in which the variation of the plastic strain rate associated with a variation of temperature is measured at constant material internal structure, it is possible to evaluate the activation enthalpy, ΔH , directly from the experiment. Unfortunately, a temperature jump cannot be applied

instantaneously and creep takes place during the temperature transient. This leads to substantial structural evolution in the material. Such tests became popular after the seminal work of Cottrell and Stokes^[25] has been published but were eventually superseded by the strain rate jump tests (see next subsection). Nevertheless, Eq. 23 is still being used to evaluate, for example, the activation enthalpy for the onset of the PLC effect from the boundaries of the domain of negative m in the strain rate–temperature plane (see Fig. 12 and the associated discussion).^[26]

EXPERIMENTAL EVALUATION OF SRS

Various methods have been developed to evaluate the SRS experimentally. The quantities entering Eq. 13, i.e., the thermal component of stress and the plastic strain, are not directly measurable/controllable in the experiment. However, as discussed above, assuming that σ_a is strain rate independent, σ_t can be replaced with σ . Furthermore, in experiments one controls the total strain rate and not the plastic strain rate. However, one may use Eq. 11 to impose a specified plastic strain rate jump by correcting the total strain rate. This precision SRS method is reviewed in Ref. [3].

Equations 3 and 13 indicate that the evaluation of m should be performed at constant strain, temperature, and material structure, ϕ . Of these, the most difficult condition to impose is the last one: the dislocation structure should remain unchanged during the strain rate transition. In particular, the density of mobile dislocations, ρ_m , should not vary in this process—note the difference between Eqs. 19 and 20.

Also, to evaluate m , the derivative in Eqs. 3 and 13 is computed based on finite differences:

$$\Delta \log \dot{\epsilon} = \log \frac{\dot{\epsilon}_1}{\dot{\epsilon}_2} \text{ and } \Delta \log \sigma = \log \frac{\sigma_1}{\sigma_2}.$$

The most common technique used today to evaluate the SRS is that of strain rate jumps. In this method, a strain rate jump from a base rate $\dot{\epsilon}_1$ to another rate $\dot{\epsilon}_2$ (strain rate differential $\dot{\epsilon}_2 / \dot{\epsilon}_1$) is imposed at a prescribed strain. The test is performed under isothermal conditions. Figure 3 shows a schematic of the expected response in materials with $m > 0$ and with $m < 0$.

The response to the imposed total strain rate jump has an instantaneous component defined by the variation of the flow stress from σ_1 to σ_2^i , followed by a transient in which the stress varies from σ_2^i to σ_2 . The value of σ_2 is defined by extrapolating the asymptote of the stress–strain curve after the jump to the moment of the jump, as shown schematically in Fig. 3.

Therefore, the SRS parameter can be decomposed in instantaneous and transient components as:

$$m = m_i + m_t = \frac{\log \sigma_1 / \sigma_2^i}{\log \dot{\epsilon}_1 / \dot{\epsilon}_2} + \frac{\log \sigma_2^i / \sigma_2}{\log \dot{\epsilon}_1 / \dot{\epsilon}_2}. \quad (24)$$

Fig. 3 Schematic representation of stress–strain curves obtained from strain rate jump tests. Both (a) and (b) correspond to cases with $m > 0$, but in (b) and (c) the transient leads to negative m_t . If $m_t < 0$ and $|m_t| > m_i$, the total m is negative as in (c)

The instantaneous component m_i is always positive. The transient component can be positive or negative and, if $m_t < 0$ and $|m_t| > m_i$, the total SRS parameter results negative, $m < 0$ (Fig. 3c). It should be observed that the conditions of constant structure required by Eq. 3 are strictly fulfilled only during the instantaneous jump in flow stress. The transient is associated with some level of structural evolution, ϕ . Note also that in order to obtain transients that are representative for the material behavior, the test has to be performed with a stiff, screw-driven machine.

Occasionally, m is evaluated from constant strain rate tests, in which two samples are loaded monotonically at $\dot{\epsilon}_1$ and $\dot{\epsilon}_2$ and at the same temperature. The stress values σ_1 and σ_2 (σ_2^i cannot be estimated through this procedure) are read directly from the two curves at given strain. This procedure is not ideal since the microstructures, ϕ , at given strain are different in the two samples due to the different loading history.^[27]

Another test that was developed to evaluate the SRS parameter is based on performing repeated relaxations.^[28] The concept is shown schematically in Fig. 4. In this test, a sample is loaded up to a specified strain and a relaxation period is imposed (segment AB in Fig. 4). During time Δt , stress relaxes from σ_A to σ_B . At point B, the stress is ramped up rapidly back to σ_A and a new relaxation period is imposed. The total strain during each of these relaxation periods is constant, $\dot{\epsilon} = 0$, and from Eq. 11, $\dot{\epsilon}_{pl}(t) = -\dot{\sigma}(t)/E$. Therefore, monitoring the relaxation of stress is equivalent to measuring the plastic strain rate. Since a stress jump is imposed between points B and C, the plastic strain rates measured just before B and right after C are different. It is possible to evaluate m based on this information:

$$m = \frac{\log \sigma_B / \sigma_C}{\log \dot{\epsilon}_{AB}(t_B) / \dot{\epsilon}_{CD}(t_C)} \quad (25)$$

Here $\sigma_c = \sigma_A$, $\dot{\epsilon}_{AB}(t_B)$ is the plastic strain rate measured at $t = t_B$, just before point B, and $\dot{\epsilon}_{CD}(t_C)$ is the plastic strain rate measured at $t = t_C$, right after the stress jump BC. Note that this method provides a measure similar to that of Eq. 13, while the strain rate jump without the correction implemented in the precision SRS test^[3] provides a quantity similar to that of Eq. 3.

Fig. 4 Schematic representation of the repeated relaxation test

It has been shown that the microstructural evolution during the stress jump BC is minimal (see, e.g., Ref. [4] and references therein). A complementary method based on repeated creep tests was also described,^[4] but its quality is inferior to that based on relaxation since the microstructural evolution during creep is more pronounced than during relaxation.

MECHANISMS CONTROLLING THE SRS OF ALUMINUM ALLOYS

A brief account of the physical mechanisms responsible for rate sensitivity is provided in this section. It is necessary to distinguish between the mechanisms leading to positive and negative m . As discussed in the Introduction, the fact that plastic deformation exhibits the signature of thermally activated processes at the macroscopic scale indicates that SRS is due to localized, small-scale interactions. The activation volume measured in strain rate jump tests is large in Al; it ranges from approximately 100 to 1000 b^3 , where b is the length of the Burgers vector. This is usually interpreted as the size of the material subdomains that participate in a local thermally activated event.

The Peierls barriers provide weak obstacles to dislocations in Al. At room temperature, bypassing these barriers is fully thermally activated and hence their effect on SRS is negligible.

The interaction of (mobile) dislocations with other (forest) dislocations depends on the orientation of the two Burgers vectors and on the angle of intersection.^[29–31] Two dislocations moving in different glide planes can form repulsive or attractive junctions. If they repel, the interaction is too long-range to be thermally activated and its contribution is included in the athermal component of stress. If the interaction is attractive, the two dislocations may form a junction. The strength of the various junctions has been studied extensively by atomistic^[32] and dislocation dynamics/line tension models.^[33–35] This parameter has a broad range of variation and depends on the geometry of the junction and the Burgers vectors of the two interacting dislocations. In general, breaking a strong junction, such as a Lomer–Cottrell lock, cannot be thermally activated because the energies associated with unzipping the jog are too large. However, a large number of weak junctions exist and their failure under stress can be thermally activated.

It should be observed that a mobile dislocation is in contact at all times with many forest dislocations and its interaction with each of these is different. In presence of a distribution of obstacle strengths, the motion of the dislocation is stochastic and most likely jerky, i.e., a gradual unzipping process in which the dislocation breaks free from one obstacle at a time is not expected. It has been shown by dislocation dynamics simulations^[20] that the mean velocity of a dislocation moving over a field of obstacles of random energy barrier heights can be described by an Arrhenius expression, with an effective activation enthalpy. The issue of the superposition of contributions to the flow stress of the various types of obstacles and how this reflects in the effective activation energy and SRS parameter at finite temperatures is complex and cannot be reviewed here. The reader is referred to Refs. [20,21,36,37] and references therein for further insight into this important topic.

Precipitates are effective obstacles to dislocation motion. Dislocation interaction with coherent precipitates with a strong long-range field is usually of athermal type. Interactions with incoherent precipitates are more local and may be thermally activated. In particular, if precipitate bypassing is conditioned by climb or cross-slip, thermal activation plays a role.^[22] Specifically, creep is a thermally activated process with activation energy equal to that of self-diffusion, which implies that the key physics controlling the release of dislocation from obstacles is based on diffusion and dislocation climb.

In solid solutions with immobile solute, dislocations interact with solute atoms in the short range and these interactions contribute to the thermal component of stress. They are much more local than the interaction of dislocations with forests or precipitates and hence scale decoupling exists between dislocation–solute and all other interactions. This allows representing the contribution of solute in physically based constitutive equations of plasticity

as a frictional stress.^[38] However, since solute is not uniformly distributed in the host lattice, long-range interactions between dislocations and solute clusters are expected and these should have athermal character. Experimental evidence exists that in systems as diverse as Mg–Al^[39] and Ag–Al^[40] solid solutions, the athermal component of the flow stress is a function of the solute concentration.

All mechanisms described above produce positive SRS. The negative SRS is associated with the presence of mobile atoms and with some level of coupling between the dynamics of dislocations and the rearrangement of solute. Solute interacts with dislocations in the long range via the strain field produced by the size difference between the solute and host atoms, and in the short range due to the modification of bonding in the dislocation core and across the glide plane. The misfit interaction favors solute clustering at cores, which, in turn, pins the dislocation, thus increasing the stress needed to put it in motion. These concepts have been used in various ways over the last half century to explain the occurrence of negative SRS. They are known collectively as DSA.

The first DSA mechanism proposed implied that solute clouds form around moving dislocations.^[41] According to it, at small velocities, dislocations would drag the clouds as they move, which would require large resolved shear stress. As the strain rate increases, dislocations would detach from the slower moving cloud and hence would require a smaller stress for motion. This leads to negative SRS. It was recognized later that solute diffusion is not fast enough to allow the solute clouds to move along with dislocations. In addition, such extensive solute diffusion would require large vacancy concentrations. Clearly, the thermal vacancy concentration (associated with a vacancy formation energy of 0.681 eV in pure Al^[42]) is too low to sustain this process. Deformation produces excess vacancies, but whether this is sufficient for extensive solute diffusion is still a matter of debate.^[43,44]

It was further proposed that solute diffusion to the core of mobile dislocations may take place during the arrest time at obstacles. McCormick^[45] and van den Beukel^[46] developed DSA models based on this idea. The mechanism requires that solute diffusion (bulk diffusion) toward the arrested mobile dislocation leads to a temporary increase of the strength of the obstacle. The smaller the deformation rate, the longer the average wait time and the larger the added strength of the respective obstacle; this means larger flow stresses at lower strain rates, i.e., negative m . Another mechanism was proposed by Mulford and Kocks^[47] based on an earlier suggestion by Sleeswyk.^[48] They suggested that solute diffusion does not occur by bulk diffusion, as bulk diffusion is too slow and needs to be assisted by vacancies. Rather, it should take place by pipe diffusion, or diffusion along the core of the dislocation. An important argument in favor of this type of diffusion was the initial belief that pipe diffusion may take place without being assisted by vacancies. Therefore, the proposed mechanism

appears to bypass the discussion of whether an excess vacancy concentration produced by deformation is needed in DSA. The basic assumption behind the pipe diffusion mechanism was investigated by means of atomistic simulations^[49] in the Al-Mg system. It was concluded that in the presence of vacancies, pipe diffusion is significantly faster than bulk diffusion, but vacancies are still required for this type of diffusion. Another mechanism proposed in Ref. [50] is based on the observation that forest dislocations are stationary for a much longer time than mobile dislocations. Hence, the forests develop solute clusters whose size changes in time. It was shown that the strength of a junction formed by an unclustered mobile and a clustered tree depends on the size of the solute cluster of the forest. This, in turn, depends on the time the forest is stationary, which is a monotonic function of the strain rate.

It has been recognized early^[51] in the research on DSA that extensive dynamic solute redistribution is not needed in order to produce weak locking of dislocations. PLC was observed in Cu-Al alloys at temperatures as low as 1/5 of the melting temperature,^[52] at which long-range diffusion is precluded. Since close to the dislocation core the stress field is large, stress and vacancy-assisted local rearrangement of solute is possible.^[53] Such rearrangements lead to small fluctuations of the solute–dislocation interaction energy, but the fact they take place dynamically, correlated with the motion of dislocations, is important in the overall dynamics of the dislocation population. The concept is supported by experimental data on AA6061 and by data on BCC Fe for which it was suggested that the occurrence of single interstitial jumps over distances smaller than the lattice parameters may lead to DSA.^[54]

SRS OF ALUMINUM ALLOYS

The effect of the strain (or stress), temperature, strain rate, and state of the microstructure on the SRS of pure Al and Al alloys is discussed in this subsection. We begin by considering AA1050 and discuss its SRS at room temperature, in as-received conditions. Figure 5 shows the variation of $\partial\sigma/\partial \log \dot{\epsilon}$ with the stress (Haasen plot). Note that $\partial\sigma/\partial \log \dot{\epsilon} = \frac{kT}{V} = m\sigma$ is proportional to the inverse of the activation volume. The plot is a straight line that goes through the origin of the coordinate system, which indicates that m —the slope of the line in Fig. 5—is constant during deformation.

All pure face-centered cubic (FCC) metals, single and polycrystals, have a Haasen plot similar to that shown in Fig. 5, which indicates that the Cottrell–Stokes (CS) law applies.^[25] Working with Al single crystals, Cottrell and Stokes discovered that the ratio of the flow stress at two temperatures and the same material structure is only a function of the two temperatures at which the test is performed and is independent of strain. If the CS law is valid

Fig. 5 Haasen plot for AA1050

for any two temperatures, this leads to the conclusion that $\frac{1}{\sigma} \frac{\partial\sigma}{\partial T}$ is strain independent.^[25] Equation 16 suggests that the variation of temperature is equivalent with a variation of $\log \dot{\epsilon}$ and hence the CS law implies that $\frac{1}{\sigma} \frac{\partial\sigma}{\partial \log \dot{\epsilon}} = m$ is

strain independent. Early studies showed that the law is valid in pure Al, Ni, and Ag,^[25,55,56] while later works have shown that it applies to single crystals, fine-crystalline, and sub-microcrystalline Ni,^[57] as well as to non-FCC materials (Cd and Zn),^[58] and Ni₃(Al,Hf)B intermetallics.^[59]

The currently accepted physical interpretation is that in cases in which the CS law applies, the same obstacles (e.g., forest dislocations) control both the strength and the SRS. As the density of such obstacles increases, these two macroscopic parameters increase in proportion.

At larger strains, the Haasen plot becomes nonlinear with an increasing slope. To enter this regime, the deformation has to be sufficiently stable and premature fracture should be prevented. This regime can be reached, for example, in torsion. The rapid increase of m in Stage IV of the deformation has been demonstrated in 99.99% pure Al, technically pure 99.38% Al, Al-Mn-Cu at room and elevated temperatures,^[60,61] Cu,^[62] and many other systems. As with the CS law, this rapid increase of m associated with the accumulation of dislocation debris in the material is another general feature of the SRS.

The variation of m with temperature for various nominally pure Al samples is shown in Fig. 6. The plot includes data for polycrystalline pure Al tested at various temperatures with a strain rate of $1.5 \times 10^{-4} \text{ s}^{-1}$,^[63] Al single crystals from Refs. [24,64], as well as a data point representing the AA1050 data of Fig. 5. m decreases slowly with increasing temperature in the range 78 to ~200 K and then increases fast with further temperature increase. As discussed later in this subsection, the value of m at the minimum may be positive or negative, but the shape of the curve is essentially identical in many Al alloys. At temperatures below ~70 K, the behavior is different, but that range of temperatures is less important for engineering applications.

Alloying elements are added to Al to increase the flow stress. These remain in solid solution in non-heat-treatable

Fig. 6 Variation of m with the temperature for pure Al. Data for polycrystalline pure Al^[63] (triangles), pure Al single crystals^[24] (circles) and^[64] (squares), and AA1050 (Fig. 5) (diamond) are included

alloys of the 5000 class and form precipitates in the heat-treatable alloys. These additions have significant effects on the SRS. The effect of immobile solute on SRS in solid solutions is discussed first.

In such alloys, the flow stress is defined by the interaction of dislocations with other dislocations and with solute. As discussed above, the flow stress is written as a linear superposition of contributions of the solute, σ_s , and forest, σ_d , strengthening mechanisms:

$$\sigma = \sigma_d + \sigma_s. \quad (26)$$

Taking the derivative of Eq. 26 with respect to $\log \dot{\epsilon}$, one obtains the following equation:

$$\frac{1}{V} = \frac{1}{V_d} + \frac{1}{V_s}, \quad (27)$$

where V_d and V_s are the activation volumes for the dislocation–dislocation and dislocation–solute interactions, respectively. While kT/V_d is expected to be proportional to σ , as shown in Fig. 5 for the pure Al case, kT/V_s

is expected to be a constant for given temperature. Hence, the Haasen plot, $kT/V(\sigma)$, for a solid solution with immobile solute should be a line parallel to that for pure Al and shifted up by a constant that depends on the solute concentration. Figure 7a shows results for Al–Mg alloys with 0.44 at. % and 0.8 at. % of Mg, respectively.^[65] In these alloys, Mg is in solid solution and the test is performed at 78 K, such that Mg is immobile.

The experimental data follow the expectations based on Eq. 27. The intercept of the vertical axis increases with the solute concentration, c . Figure 7b shows the variation of the intercept of the Haasen plot (Fig. 7a) with the solute concentration for solid solutions of Fe, Cr, Cu, and Mg in Al, all tested at 78 K. The intercept is proportional to $\sqrt{c}$ since

$$\frac{kT}{V_s} = m_s \sigma_s \sim m_s \sqrt{c} \quad (28)$$

i.e., due to the proportionality of the contribution of solute strengthening to the flow stress, σ_s , with $\sqrt{c}$. The lines in Fig. 7b are drawn to guide the eye. Their slope represents the constant of proportionality omitted in the second part of Eq. 28, which indicates how effective is the respective alloying element in strengthening the solid solution.

In heat-treatable alloys, solute forms precipitates with Al or with other solute added for this purpose. Precipitates, which are more athermal obstacles for dislocations than solute, generally reduce m .^[66,67] Consequently, as precipitation takes place, the intercept of the Haasen plot should decrease. This trend is demonstrated by the data in Fig. 8^[3] obtained with a heat-treatable Al–1.7 at. % Cu alloy. This material was initially put in solid solution and then annealed at 125°C for various times. The Haasen plot of the resulting materials was evaluated at 78 K. The annealing time corresponding to peak age conditions is indicated in the Fig. 8.

If the test is performed at higher temperatures, the Haasen plot intercept decreases and may become negative,

Fig. 7 (a) Haasen plot for Al–Mg alloys with 0.44 at. % and 0.8 at. % Mg measured at 78 K. The horizontal axis is the difference between the flow and yield stress. The Haasen plot intercept, i.e., the extension of the fitted lines to the vertical axis, is shown by arrows. (b) The variation of the Haasen plot intercept with solute concentration for solid solutions of Fe, Cr, Cu, and Mg, all measured at 78 K using precision SRS measurement^[65]

Fig. 8 Variation of the Haasen plot intercept (measured at 78 K) with the annealing time or state of precipitation of an Al-1.7 at % Cu alloy. The annealing time corresponding to peak age conditions is indicated^[3]

Fig. 9 Variation of the yield stress with the strain rate for AA2139, at the two temperatures indicated. The slope of the curves represents $kT/V = m\sigma$ ^[68]

which obviously does not imply that the activation volume becomes negative. The decrease of the intercept of the Haasen plot during precipitation, before peak age, is observed at higher temperatures too. It is interesting to note that the Haasen plots corresponding to all data points (annealing conditions) shown in Fig. 8 are linear and of the same, stress-independent slope, m .

The SRS parameter is particularly sensitive to the change of the dominant mechanism controlling plastic flow. An example is presented in Fig. 9,^[68] which shows the variation of the yield stress (0.2% offset) with the strain rate for AA2139 measured at room temperature and at 200°C. The slope of these curves is $\partial\sigma/\partial\log\dot{\epsilon} = \frac{kT}{V} = m\sigma$ (equivalent to a measurement from constant strain rate tests). At strain rates below $\sim 100 \text{ s}^{-1}$, the activation volume is essentially independent of the strain rate. However, as dislocation motion enters the phonon drag regime, the slope increases and hence V decreases fast.

Let us consider now situations in which solute is free to diffuse. This leads to new phenomenology, including

Fig. 10 Variation of m with the temperature for AA5182. Strain rate jump tests were performed at room temperature, with a base strain rate $\dot{\epsilon}_1 = 10^{-3} \text{ s}^{-1}$ and a strain rate differential of 100. The two curves correspond to strains of 10% and 20%^[71]

serrated flow and strain localization.^[10] The diffusivity of most alloying elements of commercial Al alloys is high enough to allow solute clustering and dynamic interaction with evolving dislocation populations. The diffusion coefficient for Mg, Si, and Zn in Al at 300°C is larger than $10^{-12} \text{ cm}^2 \text{ s}^{-1}$, while for Co, Fe, Mn, Ni, and Cr is smaller than $10^{-13} \text{ cm}^2 \text{ s}^{-1}$.^[69]

The most studied alloys in the context of DSA are the Al-Mg alloys. In these systems, the formation of the thermodynamically stable phase Al_3Mg_2 has slow kinetics and Mg is thought to remain in a metastable solid solution. Mg has high diffusivity and hence dynamic reorganization of Mg atoms and clusters is likely. However, other elements, such as Zn and Si, have similar diffusion coefficients over the same range of temperatures.^[69] DSA has been observed in Al-Zn alloys leading to PLC in the temperature range $\sim 210 \text{ K}$ to $\sim 350 \text{ K}$,^[70] but this is not as much a concern in this system as it is in Al-Mg. The reason is that both Al-Zn and Al-Si form precipitates that take out the solute from solid solution, hence reducing the DSA effect.

Figure 10 shows the variation of m with temperature for AA5182 (4.5 wt% Mg) measured at 10% and 20% plastic strain, with a base strain rate of 10^{-3} s^{-1} .^[71] The figure shows the same generic features with those observed in pure Al (Fig. 6). m decreases with increasing temperature up to about 80°C and then increases rapidly. The major difference between this data and Fig. 6 is that m becomes negative in the approximate temperature range -80°C to $+100^\circ\text{C}$. In this range, PLC is observed at the macroscopic scale.

The range of strain rates and temperatures in which m is negative is shown in Fig. 11.^[71] The region marked by filled symbols corresponds to $m < 0$, while the rest of the map corresponds to $m > 0$. The curve in Fig. 10 is a

Fig. 11 Strain rate-temperature map of conditions in which $m < 0$ (filled symbols) for AA5182. Open symbols indicate conditions for which $m > 0$. The strain rate has units of $1/s$. The figure includes data from Ref. [12] shown with smaller square symbols, while the two dashed lines are the boundaries of the region of $m < 0$ from Ref. [26]^[71]

horizontal cut of the map in Fig. 11. The plot includes data from Refs. [12,26]. The domain of negative SRS is bounded above at the strain rate of $10^{-1} s^{-1}$, while the lateral boundaries of the map are inclined.

Their slope has been used to estimate, using Eq. 23, the activation enthalpy for the onset of the PLC effect, which results approximately 0.5 eV/atom.^[26] Similar data are presented for AA5754 in Ref. [7]; for AA5083, AA5052, and AA5154 in Ref. [6]; and for Al-1 wt% Mg in Ref. [46].

The effect of the Mg concentration on unstable plastic flow in Al-Mg alloy was discussed in Refs. [72,73]. As the solute concentration decreases, the domain of negative SRS in Fig. 11 shifts slightly to higher temperatures and lower strain rates. However, the overall effect of Mg concentration is rather small.

An interesting feature that proved to be important in the development of the mechanism-based understanding of DSA is shown in Fig. 12.^[71] In the range of temperatures and strain rates in which $m < 0$ and DSA is active, the strain hardening, θ , is independent of temperature. Similarly, the yield stress (or flow stress at specified strain) of AA5182 becomes temperature insensitive, while in some other alloys it may increase slightly with temperature. A similar behavior has been observed in all solid solutions exhibiting DSA (see, e.g., Ref. [47] for Inconel600 and Ref. [43] for AA6061).

It has been suggested that solute clustering is important in DSA, clustering being associated with a reduction of m .^[52,74] This issue is also discussed in the review of serrated flow in Al alloys presented in Ref. [75]. A set of experimental data is presented here to demonstrate the effect.^[74] AA5182 was solution heat treated and then quenched to $-40^\circ C$, temperature at which the SRS was measured using strain rate jumps tests. Other samples were kept at room

Fig. 12 The stress dependence of the strain hardening, θ , of AA5182 at temperatures within ($T \in (-40^\circ C, 100^\circ C)$), and outside the range in which $m < 0$ (Fig. 11)^[71]

Fig. 13 SRS parameter m versus strain for samples solubilized at $380^\circ C$ and $480^\circ C$ and tested right after quenching from the temperature of the solubilization treatment to $-40^\circ C$ (open symbols), and for samples kept at room temperature for 48 h after quenching and then tested at $-40^\circ C$ (filled symbols). The as-received material not subjected to the solubilization treatment is taken as reference^[74]

temperature for 48 h before being tested at $-40^\circ C$. Figure 13 shows the values of m measured with the two types of samples. Samples tested right after the quench had negative values of m , but closer to zero than those of the samples kept at room temperature and in which solute clusters were allowed to reform after solubilization. m for the samples kept at room temperature was identical to m for the initial material, before the solubilization treatment. It is interesting to observe that samples tested right after quench had a higher vacancy concentration, which did not make their SRS more negative.

Heat-treatable alloys exhibit behaviors characteristic for solid solutions and for alloys with precipitates, function

Fig. 14 Haasen plot for AA6022 and AA6061 tested at room temperature. Stages 1–4 correspond to the solid solution, underaged conditions with pre- β'' precipitates, peak aged, and overaged conditions, respectively^[80]

of the heat treatment received and the exact composition. The Al-Mg-Si alloys of the 6000 class are interesting since the precipitation sequence and the structure of the precipitates are understood down to atomistic details. These alloys do not exhibit new features compared with those discussed above. SRS data are reported for AA6063 in Refs. [76,77], for AA6069 in Ref. [78], and for AA6111 in Ref. [79]. To demonstrate how the SRS of these alloys changes with heat treatment, Fig. 14 shows the Haasen plot of AA6061 and AA6022, which have been heat treated to different stages of precipitation.^[80] AA6061 has excess Mg relative to the composition that allows the incorporation of all Mg and Si atoms in precipitates, while AA6022 has excess Si. Samples from both alloys were solution treated and then annealed at 200°C for various durations. Stage 1 corresponds to a supersaturated solid solution. Stage 2 corresponds to 90 min of annealing, which produces pre- β'' precipitates. Stage 3 corresponds to peak age, while Stage 4 corresponds to an overaged state obtained after 1100 and 1500 min of annealing for AA6022 and AA6061, respectively. The supersaturated solid solutions of Stage 1 give similar Haasen plots, with large and positive intercept and negative slope ($m < 0$). All other states of the Si-rich AA6022 give a linear Haasen plot with almost zero intercept and positive slope. Interestingly, all states of the Mg-rich AA6061 exhibit a behavior similar to the solid solutions, i.e., $m < 0$.

Al-Li alloys exhibit SRS features similar to those of the Al-Mg-Si alloys.^[75,81–83] Negative SRS is observed in the approximate range of temperatures -50°C to $+50^\circ\text{C}$, and the variation of m with temperature is similar to that shown in Fig. 10. Less data is available in the literature for these alloys, but the general trends observed in Fig. 11 are expected to remain valid, although the domain of $m < 0$ is slightly different.

This system has been studied as an example of material in which the “pseudo-PLC” effect proposed in Ref. [84] is presumably active. This mechanism is based on the idea that fluctuations in flow stress are produced by the dissolution of small precipitates which are sheared by dislocations.

It is envisioned that the process occurs dynamically, with the characteristic time of dissolution being comparable with the wait time of dislocations at obstacles (the characteristic time of unpinning). Opinions have been voiced in favor and against the idea that this mechanism, rather than normal DSA, controls flow localization in Al-Li alloys. The discussion appears to be now settled in favor of the classical DSA mechanism.

SRS IN SMALL GRAINED ALLOYS AND ALLOYS SUBJECTED TO SEVERE PLASTIC DEFORMATION

Reducing the grain size leads to a rapid increase of the yield and flow stress as dictated by the Hall–Petch effect. Hence, grain reduction is beneficial in some applications and efforts have been made to stabilize fine-grained versions of the usual engineering alloys.

A convenient (and potentially scalable) method to produce nanocrystalline and ultrafine-grained materials is to subject the coarse-grained alloys to severe plastic deformation. Common methods to apply large plastic strains to the material while preventing fracture are equal channel angular pressing and asymmetric rolling (ASR). Plastic deformation leads to the dynamic organization of dislocations and formation of sub-grain structures. The process has been studied extensively, and data for high-purity polycrystalline Al are presented in Ref. [85,86]. With continued plastic deformation, this process leads to the formation of nanoscale grains.

SRS changes as the grain size is reduced. Both trends, increasing and decreasing m with decreasing grain size, are reported in various materials. A general agreement seems to exist that in Al and its alloys, the SRS parameter increases upon grain refinement. Figure 15 shows a compilation of literature data for Al 99.5% pure,^[87–90] AA5083,^[91] and AA5182.^[92] The scatter of the results is significant and is likely associated with the fact that different methods are used for grain refinement in these works. However, the increasing trend of m with grain size reduction is clearly visible. A similar collection of experimental data for Cu is presented in Ref. [93] and the trend is similar. In the case of Cu, the grain size or the twin spacing has to decrease below $\sim 1\ \mu\text{m}$ for the increasing trend of m with the grain size reduction to be visible. It is harder to define a similar threshold in Al, but Fig. 15 indicates a more significant effect in materials with grain size smaller than $1\ \mu\text{m}$.

The effect of solute concentration on m in severely plastically deformed materials has been studied in Ref. [94] for Al-Mg alloys of increasing Mg content. Grain refinement was obtained in this study by confined channel–die pressing, which led to grains as small as $\sim 200\ \text{nm}$ once more than six passes were applied. Increasing the number of passes did not lead to further grain refinement. Increasing

Fig. 15 Collected data showing the increase of m with decreasing grain size: AA5182 from Ref. [92] (filled diamonds); Al 99.5 from Ref. [87] (filled triangles), Ref. [88] (filled squares), and Ref. [89] (open squares); Al film from Ref. [90] (open triangles); and AA5083 from Ref. [91] (open diamond)

Fig. 16 Dependence of m on the degree of thickness reduction of a sheet of AA5182 subjected to ASRR. The squares and diamonds correspond to 30 and 120 min of annealing at 195°C at the end of rolling and before testing (no annealing). m increases toward zero once the rolling reduction is larger than 50%^[92]

Mg concentration allows obtaining finer-grained microstructures. For comparison, the smallest grain size obtained by applying the same procedure to pure Al was $\sim 10 \mu\text{m}$. The SRS decreases ($m < 0$) with increasing Mg content just as observed in commercial 5000 class alloys with usual grain sizes.

The possibility of rendering m positive by severe plastic deformation was studied in Ref. [92]. In this work, AA5182 was subjected to ASR and sheet thickness reductions up to 90% were applied. This procedure produced grains of about 300 nm. Figure 16 shows the variation of m with the percentage reduction during asymmetric reversed rolling (ASRR) resulting from these tests. It indicates that m is essentially constant for reductions below $\sim 50\%$ and increases toward zero as the rolling reduction increases. The increasing trend is similar to that seen in Fig. 15, but m remains negative in all cases. Similar results were obtained in^[95] where it was concluded that rolling a Al-6.5 wt% Mg to about 70% reductions did not have a significant effect on m .

CONCLUSION

Aluminum alloys have low density, good formability, and strength at temperatures commonly encountered in engineering applications. The information presented in this article focuses on the SRS of these materials, parameter linked to their formability. The general features associated with SRS are reviewed, including the effect of temperature, stress, strain rate, state of precipitation and grain size on the SRS parameter. Examples for pure Al, Al-Mg, Al-Cu, Al-Mg-Si and Al-Li alloys are presented.

A large number of reviews of the mechanical behavior of Al alloys have been published to date. A relatively small subset of those include information about SRS. The present article, which is focused on this SRS, does not cover all relevant literature data, rather it presents a view general enough to provide the reader with the basic information that applies to a broad class of material systems.

Strength and Intergranular Corrosion of Aluminum Alloys: Effect of Cooling Rate

Patricia Mariane Kavalco and Lauralice Canale

Department of Materials, Aeronautical and Automobile Engineering, Universidade Federal de São Paulo, São Carlos, Brazil

George Totten

Portland State University, Portland, OR, United States

Abstract

Although cooling rate and strength correlations for a wide range of quenching conditions are routinely discussed, cooling time–temperature data are shown less often. However, intergranular corrosion is also cooling rate and pathway dependent, but such data correlation is much less likely to be encountered, especially by commercial quenchant suppliers. Even cooling rate data, strength, intergranular corrosion, and either residual stress or distortion correlations are more rarely reported together. This entry discusses the mechanism of intergranular corrosion and provides an illustrative example of the dependence of intergranular corrosion on the cooling rate.

Keywords: Aluminum alloys; Cooling rate; Corrosion; Intergranular; Quenching.

INTRODUCTION

Aluminum is solution treated at temperatures generally in the range of 400°C–540°C (750°F–1000°F). During solution treatment, some alloying elements are redissolved to produce a solute-rich solid solution. The objective of this process is to maximize the concentration of hardening elements including copper, zinc, magnesium, and (or) silicon in the solid solution. The concentration and rate of dissolution of these elements increase with temperature. Therefore, solutionizing temperatures are usually near the liquidus temperature of the alloy.^[1,2]

If an aluminum alloy is slowly cooled from an elevated temperature, alloying elements precipitate and diffuse from solid solution to concentrate at the grain boundaries, at small voids, on undissolved particles, at dislocations, and at other imperfections in the aluminum lattice as shown in Fig. 1.^[2] For optimal properties, it is desirable to retard this diffusion process and maintain the alloying elements in solid solution. This is done by quenching from the solution temperature. For quench-hardenable wrought alloys such as 2xxx, 6xxx, and 7xxx, and casting alloys such as 356, this is accomplished by the quenching process. The objective is to quench sufficiently fast to avoid undesirable concentration of the alloying elements in the defect and grain boundary structure while, at the same time, not quenching faster than necessary to minimize residual stresses, which may lead to excessive distortion or

cracking. After quenching, aluminum alloys are aged, and during this process, a fine dispersion of elements and compounds is precipitated, which significantly increases the material strength. The diffusion process and precipitation kinetics varies with the alloy chemistry.

The cooling process of age-hardenable aluminum alloys affects not only the properties such as strength and ductility but also thermal stresses. Thermal stresses are typically minimized by reducing the cooling rate from the solutionizing temperature. However, if the cooling rate is too slow, an undesirable grain boundary precipitation will result. Nevertheless, if the cooling rate is too fast, there is an increased propensity for distortion. Therefore, one of the primary challenges in quench process design is to select quenching conditions that optimize strength while minimizing distortion and, at the same time, assuring that other undesirable properties are not obtained, such as intergranular corrosion (IGC), which is also cooling rate dependent.

Bates and Totten have addressed the selection of quenchants and quenching conditions that will optimize material strength and minimize the potential for distortion.^[3] However, although it is well known that properties such as corrosion resistance are also cooling rate dependent, the problem of quenching system evaluation with respect to strength, distortion, and corrosion is rarely evaluated together. The objective of this entry is to provide an overview of IGC of aluminum alloys and to illustrate the effect of the cooling rate on both strength and IGC.

Fig. 1 Schematic illustration of the solid diffusion processes that may occur during solution heat treatment of aluminum

DISCUSSION

Pitting and IGC

Pitting is the most common corrosion process encountered with aluminum alloys, and a major cause is the variation in the grain structure between adjacent areas on the metal surfaces in contact with a corrosive environment. Pitting results in the formation of very small holes (pits) in the surface and is covered by white or gray powderlike deposits appearing as blotches on the surface.^[4]

IGC (or intercrystalline corrosion) occurs most commonly in the following aluminum alloys: Al–Cu–Mg (2xxx), Al–Mg (5xxx), which is similar to the Al–Cu–Mg alloys, Al–Mg–Si (6xxx), and Al–Zn–Mg–Cu (7xxx).^[5,6] (The 2xxx, 6xxx, and 7xxx series are heat treatable.) IGC refers to a selective dissolution of the surface grain boundary zone, and typically, the grains below the surface zone are not attached, as shown in Fig. 2. As discussed previously, upon cooling from the solutionizing temperature, alloying elements may concentrate at the grain boundaries to form intermetallic compounds, which differ from the adjacent matrix electrochemically from the metal adjacent to the grain boundaries.^[7,8]

The critical temperature range and time (s) for the transition of pitting to IGC is shown by the so-called time–temperature–property (TTP) or C-curve illustrated in Fig. 3.^[9] The C-curve for 2024-T4 shows the change in corrosion behavior by correlating the critical temperature range where precipitation was fastest. Increased IGC for 2024-T4 will be favored if cooling rates are excessively slow during quenching. Similar behavior can be shown for other aluminum alloys. Therefore, it is important that cooling rates during quenching be sufficiently fast to avoid this undesirable behavior.

As the IGC process continues, exfoliation will result, which refers to the lifting of the surface grains caused by

expansion due to the increasing volume of the corrosion products accumulated in the subsurface grain boundaries.^[10] Exfoliation has been reported to result in severely reduced structural strength, plasticity, and fatigue. Exfoliation in aircraft aluminum alloy structural materials is most often observed with extrusions, where the grain thicknesses are often less than the rolled forms.^[4]

Electrochemical Behavior of IGC Processes

IGC is caused by the formation of a microgalvanic cell between the intermetallic compounds formed in the grain boundary during cooling and the adjacent metal. These intermetallic compounds may be either anodic or cathodic, with respect to the adjacent metal, depending on their composition. Figure 4 illustrates these two situations.^[11] In one case, noble (inactive) alloying elements may precipitate in the grain boundaries leaving a “depleted zone” adjacent to the grain boundary that is electrochemically active. Conversely, electrochemically active alloying elements may precipitate at the grain boundary, and then the metal adjacent to the grain boundary will be noble. Note that corrosion behavior is also dependent on microstructure changes caused by heat treatment process, which will not be discussed here. The reader is referred to Andreatta et al.^[12] for more detailed information.

To illustrate this process, IGC occurring in 2xxx or 7xxx alloys is considered, which would be caused by the loss of copper or sufficient magnesium in areas near the grain boundaries to create an anodic electrochemical potential (EMF).^a The electrochemical potential for various aluminum alloys provided in Table 1 shows that the presence of copper in solid solution with aluminum makes

it more cathodic.^{b, [13]} An aluminum alloy containing 4% copper in solid solution will exhibit an EMF of -0.69 V. However, copper concentrations in the grain boundaries may reduce the EMF to -0.84 V, making it more anodic. Grain boundary corrosion may also occur when the grain boundary precipitates are more anodic than the adjacent solid solution. For example, Mg_2 , Al_3 , $MgZn_2$, and $Al_{1-x}Zn_xMg$ are more cathodic than $CuAl_2$ and $Al_{1-x}Cu_xMg$.^{c [14]}

IGC Control

The degree of IGC may be controlled by the selection of the temper and maximizing the cooling rate permissible that will provide minimum distortion. For example, the T4 and T6 temper conditions are typically selected when optimum resistance to IGC is required.^[15] Schuler reported that the critical cooling rates (cooling rates between 750°F and 550°F) are found to be $<400^\circ\text{F/s}$ for the 7xxx series and 1000°F/s for the 2xxx series to achieve optimal resistance to IGC. The data in Table 2 show the effect of the cooling rate on IGC for 50 mm AA7075 round bar.^[16] The depth of attack was consistently greater toward the center of the round bar as the cooling rate decreased.

Other factors affecting IGC include transfer rate from the furnace to the quench, air entrainment in the quenchant, and the ratio of section mass to surface area. However,

^bThe cathode is the positive electrode in an electrochemical circuit, and therefore, it is the electrode that gains electrons or electrons flowing from the anode (which possesses the more negative potential) to the cathode (more positive potential).

^cWhen two dissimilar metal compounds with different electron affinities (EMF values) are connected, there is a potential for electrons to pass from the material with the smaller affinity for electrons (anode—the more negative pole) to the material with the greater affinity for electrons (cathode—the more positive pole). A potential difference between the materials will increase until an equilibrium is achieved. This “equilibrium potential” is defined as the potential that balances the difference between the propensities of the two metals to gain or lose electrons.

^aThe electrochemical potential is referred to as electromotive force (EMF).

Table 1 Electrode potentials of aluminum solid solutions and constituents^[1]

Solid solution composition	Potential, volts 0.1 N calomel scale ^a
α (Ag-Mg) (Mg_5Al_8)	-1.24
Al + Zn + Mg (4% MgZn_2 solid solution)	-1.07
Al + Zn (4% Zn solid solution)	-1.05
β (Zn-Mg) (MgZn_2)	-1.05
Al + Zn (1% Zn solid solution)	-0.96
Al + Mg (7% Mg solid solution)	-0.89
Al + Mg (5% Mg solid solution)	-0.88
Al + Mg (3% Mg solid solution)	-0.87
α Al-Mn (Mn-Si_6)	-0.85
Aluminum (99.95%)	-0.85
Al + Mg + Si (1% MgSi_2)	-0.83
Al + Si (1% Si solid solution)	-0.81
Al + Cu (2% Cu solid solution)	-0.75
(Al + Cu) (CuAl_2)	-0.73
Al + Cu (4% Cu solid solution)	-0.69
α (Al-Fe) (FeAl_3)	-0.56
NiAl_3	-0.52
Silicon	-0.26

^aMeasured in an aqueous solution of 53 g NaCl + 3 g water per liter at 25°C. The order of the EMF values in this table indicates the ability of a compound to reduce any compound metal below it. The values shown in the table entries are reduction potentials. The α (Ag-Mg) (Mg_5Al_8) compound at the top of the list has the most negative number, which indicates that it is the strongest reducing agent in the series shown. The strongest oxidizing agent is silicon with the least negative (most positive) EMF potential as shown in the table.

Table 2 Effect of the cooling rate on maximum intergranular penetration of 7075 as a function of cooling rate^[16]

Sample ID	Cooling rate (°C/s)		Depth of attack (mm)
	50 mm diameter bar	Location	
A	53	Surface	0.46
		Center	0.56
B	50	Surface	0.30
		Center	0.86
C	30	Surface	0.46
		Center	0.61
D	17	Surface	0.74
		Center	1.09

Note: Surface—within 3.2 mm of the cylinder surface; Center—within 3.2 mm of the centerline of the cylinder.

these factors, in the final analysis, affect the cooling rates and therefore IGC.

At this point, it is important to note that often in the industry, the cooling behavior of various quench media is determined using an INCONEL 600 probe according to

Table 3 Thermal conductivity and specific heat capacity for different materials

Material	Thermal conductivity (m^2/s)	Specific heat (kJ/kg/K)
Aluminum 99.5	95×10^{-6}	0.896
Silver 99.5	174×10^{-6}	0.235
Nickel	14×10^{-6}	0.448
CrNi steel ^a	4×10^{-6}	0.477
INCONEL 600 ^b	4×10^{-6}	0.465

^aAustenitic stainless steel SAE 30304.

^bNickel-based alloy.

ISO 9950 or ASTM D6200. However, the thermal conductivity of INCONEL 600 is much less than that of aluminum, as shown in Table 3.^[17] Clearly, the low thermal conductivity of INCONEL 600 versus aluminum renders this probe relatively insensitive to the cooling properties experienced by an aluminum alloy during quenching.

Silver probes are also used to evaluate quench severity exhibited by different quenchant. Because of the similarity of the thermal characteristics of silver and aluminum and because of the significantly lower oxidation tendency for silver relative to aluminum, the cooling behavior of AlMgSiCu and a silver (99.5%) probe was compared.^[17]

Thermal conductivity (λ) and specific heat capacity of various materials are provided in Table 1. Thermal conductivity is a measure of the “rate of propagation” of temperature change in a body and is related to the specific heat capacity by the following equation:

$$\alpha = \frac{\lambda}{\rho \times C_p}$$

where α is the thermal diffusivity, C_p is the specific heat capacity, λ is the thermal conductivity, and ρ is the density of the material.

Tensi et al. have compared the cooling curves recorded during quenching of an aluminum (AlMgSiCu) and a silver specimen (Ag 99.5) in a Type I water-soluble polymer quenchant solution. The Type I aqueous polymer quenchant concentration was 10% by volume, and the bath temperature was 25°C. The temperature of both probe materials when quenched was 520°C. Both probes were cleaned with 600 grit abrasive paper before each test. The cooling curves obtained are shown in Fig. 5.

The polymer film surrounding the probe surface ruptured simultaneously around the entire surface, also called “explosive” rewetting, for both probes, and the rewetting times ($t_f - t_s$), where t_s is the time when wetting starts and t_f is the time when wetting is finished, were extremely short. However, a stable film-boiling range lasting about 4 s was observed for the silver probe, which was not observed for the aluminum probe. The centerline probe temperature was about 440°C for silver and 500°C for aluminum.

Fig. 5 Comparison of the cooling processes of a cylindrical AlMgSiCu probe (diameter 15×45 mm length) with those of a silver probe, cooled into a 10% solution of a water-soluble polymer at 25°C (temperatures recorded at the geometric center of the probe). The solution treatment temperature is 520°C for the AlMgSiCu probe; the annealing temperature is 800°C for the silver probe. (a) Changes in temperature and conductivity as a function of time and (b) cooling rate as a function of temperature

The reason that the rewetting of the silver occurs about 4 s later for the silver probe is the greater oxidation resistance of silver. (The ratio of heats of formation of Ag_2O_2 and Al_2O_3 is 0.05.) When the quenching temperature of the silver probe is increased to 800°C, considerable stabilization of the film boiling occurs as observed in Fig. 4a. Wetting now starts at about 260°C after 24 s compared to the start of wetting of the AlMgSiCu probe after 1 s at about 500°C.

The main reason for this stabilization of the film-boiling phase of the entire surface of the silver probe is the reduction of the silver oxide at the higher temperature. The high-temperature annealing of the silver probe removes the oxide and leaves a bare metal surface, resulting in stabilization of film boiling during quenching, especially in water-soluble polymers. Accordingly, the maximum cooling rate of the silver probe is not reached until a centerline probe temperature of 200°C as shown in Fig. 4b.

If distilled water at room temperature is used as the quenchant instead of an aqueous polymer, the silver and

Fig. 6 Comparison of cooling processes of a cylindrical AlMgSiCu probe (diameter 15×45 mm length) with those of a silver probe. Probes were quenched into distilled water at 25°C (probe temperatures recorded at the geometric center). The solution treatment temperature is 520°C for the AlMgSiCu probe; the annealing temperature is 520°C for the silver probe. (a) Changes in temperature and conductivity as a function of time and (b) cooling rate as a function of temperature

AlMgSiCu probes show almost identical cooling behavior with coinciding rewetting kinematics as shown in Fig. 6. This means that the quenching behavior determined in water with silver probes can be safely compared with those obtained for aluminum probes. However, when polymer solutions are used, there are clear differences, especially with respect to initial wetting.

It is important that whatever probe material is used to evaluate the quenching behavior to be expected with the aluminum alloy of interest that it properly model the actual quenching process occurring, especially if cooling rate dependence of the quenching media and process is being used to determine the potential for IGC. For these reasons, it is recommended that heat treaters request cooling curve data obtained using either an aluminum or a silver probe. (The advantage of silver relative to aluminum is its inertness, and therefore, it may be reused, whereas aluminum alloy probes typically cannot.)

CONCLUSIONS

An overview of the IGC process was provided and contrasted to pitting corrosion. It was shown that the propensity for IGC of heat-treatable aluminum alloys is cooling rate dependent. It is recommended that in view of IGC processes in many applications such as aerospace and automotive, IGC should be evaluated along with strength and residual stress/distortion as important and more routine screening parameters than is now performed. Furthermore, cooling time–temperature data are preferably obtained using the aluminum alloy of interest. However, silver probes may, under the appropriate conditions, reasonably model the cooling behavior of the aluminum alloy of interest, but this needs to be demonstrated experimentally.

Superplastic Forming

Norman Ridley

University of Manchester, Manchester, England

Abstract

An inherent limitation of conventional aluminum alloys is that they are unstable when plastically deformed by stretching which leads to catastrophic necking when tensile testing and limitations on uniform deformation during stretch forming under tensile stress. This has led to the development of superplastic forming (SPF) process development used for the production of products for structural and non-structural applications in industries such as aerospace, automotive, architecture, transport and others. This article provides a general overview of superplastic forming and addresses: identification and characterization of superplastic alloys, processing of superplastic alloys, cavitation and failure, superplastic forming, simulation, and applications and mechanical properties.

Keywords: Mechanical properties; Processing parameters; Superplastic alloys; Superplastic forming.

INTRODUCTION

An inherent limitation of conventional aluminum (Al) alloys, like many metals and alloys, is that they are unstable when plastically deformed by stretching. This is responsible for the catastrophic necking observed on tensile testing and also for the limited extent of uniform deformation possible during processes such as stretch forming which involve mainly tensile stresses.^[1]

In recent years attention has turned to superplastic (SP) materials which are relatively stable when deformed in tension. This behavior is related to the observation that the flow stress of a superplastic material is very sensitive to the rate of deformation. The characteristic equation which describes superplastic behavior is usually written:

$$\sigma = k\dot{\epsilon}^m \quad (1)$$

where σ is the flow stress, k is a constant, $\dot{\epsilon}$ is strain rate and m is the strain rate sensitivity of flow stress. If superplasticity is regarded as a type of creep behavior then Eq. 1 may be re-written as:

$$\dot{\epsilon} = k_1 \sigma^n \quad (2)$$

where n , the stress exponent for deformation is equal to $1/m$.

A material is usually considered to be superplastic under conditions where it displays an m value > 0.3 . An important feature of SP alloys is that their flow stresses are low compared with those of conventional materials. During tensile deformation the effect of high m is to inhibit catastrophic necking. Necks which tend to develop

lead to a localized rise in $\dot{\epsilon}$ and to strain rate hardening which inhibits neck propagation. Hence, differences in cross-sectional area propagate very slowly so that necking is diffuse and relatively uniform. The m values of commercial SP alloys lie in the range 0.4–0.8. The consequences of these high m values is that SP materials are capable of undergoing abnormally high tensile strains prior to failure with elongations of 500–1000% not being uncommon, although an alloy which exhibited an elongation in excess of 200% could be considered to be superplastic. The highest elongation recorded to date is ~8000% for a commercial aluminum bronze.^[2]

The combination of low flow stresses, usually $< 10 \text{ MNm}^{-2}$, and relatively high uniformity of plastic flow has led to commercial interest in the superplastic forming (SPF) of components, often of complex shape, from sheet materials using techniques similar to those developed for the gas pressure bulge forming of thermoplastics. SPF can lead to considerable savings in materials and manufacturing costs, particularly if a component can be redesigned to take advantage of the benefits of the process or where a component of complex shape which is normally built up from several pieces can be formed as a single part. Other advantages are that SPF is a near net-shape forming process, multiple parts can be produced in one operation, there is little or no spring-back, only one major tool is required rather than an accurately matched pair of tools or multiple tools, and for Al alloys the die sets are relatively inexpensive because of the moderate temperatures associated with the process ($\sim 500^\circ\text{C}$), and they can be produced quickly.

While it is clear that SP alloys have numerous attractions for use in tensile sheet forming processes, there are

also some limitations. Firstly, superplasticity is confined to relatively few Al alloys and is a characteristic of materials which can be thermo-mechanically processed to develop fine stable grains, of size preferably $< 10\mu\text{m}$. Superplasticity is associated with slow strain rates, usually in the range $10^{-4}\text{ sec}^{-1} - 5 \times 10^{-3}\text{ sec}^{-1}$, that can lead to relatively long forming times involving several minutes, or even up to 2h for critical parts, rather than seconds, and with a limited range of temperatures, $> 0.5 T_m$, where T_m is the melting point in degrees Kelvin. For Al alloys the forming temperatures are likely to lie in the range $460\text{--}530^\circ\text{C}$, which is $\sim 0.9 T_m$, so the problem of maintaining small grain sizes requires special attention. Further, Al alloys are prone to cavitation during superplastic flow.

Superplastic forming is not a high volume production process and it caters for what have been termed niche markets involving low to medium volume production (10s to 1000s) of medium sized parts ($0.1\text{--}4\text{m}^2$), often of complex shape and high added value. However, it is an important sheet metal forming process for a number of Al alloys and is used to produce a wide range of products for structural and non-structural applications in fields as diverse as aerospace, architecture, medical equipment, telecommunications and transport.

MECHANICAL ASPECTS OF SUPERPLASTICITY; CHARACTERIZATION OF SUPERPLASTIC ALLOYS

Mechanical Aspects of Superplasticity

The most important mechanical characteristic of a SP material is its high strain rate sensitivity of flow stress, m , as defined in Eq. 1. It can be seen from this equation that if the relationship between σ and $\dot{\epsilon}$ is plotted logarithmically, then the slope of the plot is m where:

$$m = \frac{\partial(\log \sigma)}{\partial(\log \dot{\epsilon})} \quad (3)$$

There are two main types of superplastic behavior: fine grain or micro-grain superplasticity, and internal stress superplasticity. In the latter case, internal stresses of magnitude similar to the flow stress of the material can be developed by thermal cycling of a polycrystalline metal or solid solution exhibiting a phase change, or having anisotropic thermal expansion coefficients, or of a composite with constituents of different thermal expansion coefficients, e.g. Al alloy/SiC. Under these conditions the material exhibits $m \sim 1$. Hence, the application of a small external stress leads to an increment of tensile plastic flow during each cycle, while repeated cycling can give substantial tensile strains. The potential for bulge forming of metal matrix composites (MMCs) by thermal cycling has been demonstrated for AA6061-10% volSiC_p sheet material.^[3] However, an internal stress superplasticity has not so far been exploited as the basis of a commercial process, the present Chapter will be concerned only with fine grain superplasticity. Internal stress superplasticity has been reviewed by Nieh et al.^[4]

Data for AA7475 for several temperatures are shown plotted in Fig. 1(a).^[5] It is seen that where the stress-strain rate curve is fully developed it has a sigmoidal shape and that m (~ 0.85) is observed at passes through a maximum (Fig. 1b). For this material, maximum m (~ 0.85) is observed at 516°C at a strain rate of $\sim 3 \times 10^{-4}\text{sec}^{-1}$. A value of $m > 0.3$ delineates the superplastic regime (Region II). The high (Region III) and low (Region I) strain rate regions exhibit values of m in the range $0.1\text{--}0.3$, although for Region I the slope of the curve can vary.

At high strain rates (Region III) $m \sim 0.2$, deformation is by recovery controlled dislocation creep (power law creep). Strain is accumulated by the glide of dislocations within the grains but is dependent on the rate at which obstacles such as other dislocations, solutes and precipitates, can be by-passed. It is generally assumed that dislocation climb is the rate controlling process. The observed activation energy for flow in Region III is similar to that for lattice diffusion and the strain rate is relatively insensitive to grain size. Other features of this region are the observation of slip lines and the development of high dislocation densities within the grains. Crystallographic texture increases and significant grain elongation occurs.

At intermediate strain rates in Region II where high relatively uniform strains are observed, i.e. the SP regime, the flow process is less well understood, although there is substantial agreement on the microstructural features associated with it. Equiaxed grains tend to remain equiaxed throughout deformation, regions which initially show microstructural banding tend to develop a more uniformly equiaxed structure, and crystallographic texture may be reduced. The activation energy for flow in Region II is similar to that for grain boundary diffusion. Strain is accumulated in the SP regime by the motion of individual grains, or groups of grains, relative to each other by sliding and rotation.

If grain boundary sliding occurred in a completely rigid assembly of grains then holes or cavities would develop in the microstructure. However, as several SP materials do not cavitate, grain boundary sliding must be accommodated. The most probable accommodation processes involve diffusion and/or glide and climb of dislocations. Many attempts have been made to develop theories capable of predicting both mechanical and microstructural features of SP deformation but none has been completely successful. The various models proposed are outside the scope of the present text but some have been subject to review.^[6-8]

At low strain rates (Region I) the slope of the stress versus strain rate plot can vary. In many alloys m is low and this has been interpreted as evidence for some form of threshold stress for SP flow, although grain growth hardening at low strain rates can complicate the interpretation of this region.

Fig. 1 (a) Stress versus strain rate; (b) m versus strain rate, for AA7475.^[5]

The mechanical behavior of superplastic materials is very sensitive to temperature and grain size. In general, increasing temperature or decreasing grain size have similar effects on the variation of flow stress with strain rate. Increasing the temperature decreases the flow stress, particularly for Regions I and II [Fig. 1(a)]. Maximum m has been found to increase with increasing temperature and decreasing grain size, and the strain rate for maximum m moves to higher values [Fig. 1(b)].

While the strain rates at which superplasticity is normally observed in aluminum alloys, $10^{-4} \text{sec}^{-1} - 5 \times 10^{-3} \text{sec}^{-1}$, are considerably less than those often associated with conventional hot and cold shaping processes, there has recently been a substantial interest in high strain rate superplasticity ($> 10^{-2} \text{s}^{-1}$). Aspects of this phenomenon will be outlined in a later section.

Characterization of Superplastic Alloys

To determine whether a given material is superplastic it is necessary to characterize its flow behavior as a function of strain rate and temperature. As noted above, the most important mechanical characteristic of a superplastic alloy is its high strain sensitivity of flow stress, or m value, and the optimum conditions of strain rate and temperature would be those which led to a maximum value of m . However, alternatively, or additionally, characterization could involve measurement of tensile elongation for a range of constant strain rates, including that for optimum m if this was known, since during SPF a part being shaped can experience significant variations in strain rate. In addition these tests could be used to gain metallographic information about cavitation and the effect that this has on fracture behavior.

Fig. 2 Stress versus strain curves at various constant strain rates for 7475.^[9]

Constant strain rate tensile tests also give useful information about flow stress levels and hence, the pressures required for SPF. They frequently provide evidence of significant hardening which may occur during SP flow (Fig. 2).^[9] This is primarily related to grain growth. At higher strain rates approaching Region III of the stress-strain rate curve, hardening is associated with dislocation creep in the material.

The above tests would normally be carried out under laboratory conditions using uniaxial testing, but it has been shown that the information gained can reflect behavior during biaxial forming.^[10,11] Grimes and Butler used a drape forming tool devised by Superform Aluminum, which had corner radii of progressively increasing severity, for the qualitative evaluation of SP formability.^[10] Only material showing high tensile ductility was capable of being formed without failure at the sharpest radii.

Attempts to produce a standard test for SP formability led to the development of the biaxial cone test^[12] (Fig. 3). Sheet is bulged into a conical die of constant angle ($\sim 57^\circ$), designed to give a constant average strain rate by maintaining constant pressure conditions after the expanding sheet had just made contact with the side of the die. The geometry was subsequently modified by Goforth et al. to a variable angle to give a more constant strain rate throughout the test.^[11]

The cone test can be carried out with an imposed hydrostatic pressure (back pressure). The parameters measured from the test include the radius of curvature and sheet thickness at the pole, and the height of the cone. Material flow stress, strain and strain rate, obtained from the cone test provides useful data for the modeling of SPF. Metallography can be used to detect cavitation in the cone. The cone test is also used as an acceptance test for SP sheet material in that the cone is required to rise to a predetermined height when subjected to a given pressure-time cycle.

An essential component of any process model of SPF is the constitutive relationship for the material, that is the relationship between stress, strain, strain rate, temperature, and microstructure. The strain rate, $\dot{\epsilon}$, at which a SP material will deform has been defined by the simple relationship

given in Eq. 2. This can be restated in an expanded temperature dependent form given by:

$$\dot{\epsilon} = \frac{AGbD}{kT} \left(\frac{b}{d} \right)^p \left(\frac{\sigma_{\text{eff}}}{G} \right)^n \quad (4)$$

where G is shear modulus, b is the burgers vector, k is Boltzmann's constant, T is absolute temperature, d is grain size and p is the exponent of inverse grain size (usually 2 or 3 in Region II); D is a diffusion coefficient ($= D_0 \exp(-Q_s/RT)$), where D_0 is a frequency factor, Q_s is the activation energy for the appropriate diffusion process and R is the gas constant. Deformation is driven by the deviatoric (shear) component of the effective stress field characterized by σ_{eff} equal to $\sigma - \sigma_0$, where σ is the applied stress and σ_0 is a threshold stress. A is a dimensionless constant.

For constant stress and temperature it can be seen from the above equation that:

$$\dot{\epsilon} \propto \frac{1}{d^p} \quad (5)$$

Since the value of p lies between 2 and 3 for SP flow, the dramatic effect that a reduction in grain size could have on strain rate is clearly apparent, e.g. an order of magnitude reduction in grain size could lead to an increase of 10^2 – 10^3 in SP strain rate. Alternatively, for a given strain rate, a reduction in grain size could enable SPF to be carried out

Fig. 3 Cone test carried out on 1.5 mm thick 7475 SP sheet

at a lower temperature, although this would be accompanied by an increase in flow stress. Procedures used to develop ultra-fine grain sizes and the effect that these have on SP behavior will be considered in the final section.

To establish a constitutive relationship such as Eq. 4 it is necessary to determine values for the materials parameters m , p , Q_s , and σ_0 . Procedures for obtaining these values are outlined. Since the effective stress, σ_{eff} , rather than the applied stress, σ , should be used in the determination of the first three parameters, unless σ and σ_{eff} are little different, then the principles involved in the measurement of σ_0 will be considered first.

Determination of σ_0

It can be seen from Eq. 4 that the threshold stress, σ_0 , for a given T and grain size, can be obtained by plotting the applied stress, σ , against $\dot{\epsilon}^m$ and extrapolating to zero strain rate. Although the value of this parameter may be relatively small compared with stress levels in the middle of the SP range (Region II) its existence can have a significant effect on the magnitude of σ_{eff} at lower strain rates.

Determination of m

In an ideal material where the microstructure remains constant, true flow stresses can be obtained by carrying out tensile tests at a range of constant strain rates and measuring the steady state loads. As indicated above, most engineering materials are microstructurally unstable at elevated temperatures and the flow stress will continue to increase with increasing strain due to the effects of grain growth (Fig. 2). It is therefore important to determine the flow stress at constant structure and this can be done by carrying out step strain rate or strain rate jump tests, originally developed by Backofen et al.^[13]

To measure m over a range of strain rates a tensile specimen is deformed at a velocity which will produce a strain rate in the middle of the range until a steady state is attained. The crosshead speed is reduced to a low value and allowed to stabilize before being measured. A repeated incremental increase in crosshead velocity allows the load to be measured at a range of strain rates. A typical load-time plot is shown in Fig. 4. The true stresses are calculated from the maximum loads, crosshead velocities and instantaneous lengths of the sample, and corrected for threshold stress. The derivative of the best fit curve to a logarithmic plot of true effective stress against true strain rate then gives m and its variation with strain rate in the range of interest [Fig. 5(a) and (b)]. It should be noted that the data shown in these figures have not been corrected for σ_0 , which is relatively small for 8090.

Determination of p

To obtain the grain size exponent, p , for a given temperature, it is necessary to obtain logarithmic plots of σ_{eff} versus

Fig. 4 Load versus time record for a repeated velocity jump test on AA8090 at 500°C. Crosshead speed in mm/min is given on graph

Fig. 5 (a) True stress versus true strain rate derived from data in Fig. 4; (b) m versus strain rate calculated from the best fit curve to Fig. 5(a)

$\dot{\epsilon}$, as outlined above, for material with a range of grain sizes. It then follows from Eq. 4 that p can be obtained from plots of $\log \sigma_{\text{eff}}$ versus $\log d$ for constant $\dot{\epsilon}$ and T , or $\log \dot{\epsilon}$ versus $\log d$ for constant σ_{eff} and T .

Determination of Activation Energy, Q_s

To determine the activation energy for SP flow, Q_s , the temperature dependence of the relationship between flow stress, σ , and strain rate, $\dot{\epsilon}$, for a constant microstructure must be determined as described above. To a first approximation Eq. 4 may be written:

$$\dot{\epsilon} = B \exp(-Q_s / RT) / kT \cdot \sigma_{\text{eff}}^{1/m} \quad (6)$$

which for a narrow range of temperature gives:

$$\ln(\dot{\epsilon}) = C + 1/m \ln(\sigma_{\text{eff}}) - Q_s / RT \quad (7)$$

where B and C are material constants. Provided m remains constant over this range of temperatures, then Q_s may be obtained from an Arrhenius plot of $\ln \dot{\epsilon}$ versus reciprocal of absolute temperature at constant stress (slope = $-Q_s / R$). In practice the temperature range used may not be insignificant, m may vary with T at a given stress, and measurements should be made for a modulus compensated stress rather than the actual stress. For these reasons it may be difficult to relate the measured Q_s value to a particular physical process. The significance of constitutive equations in relation to SPF will be considered later.

TYPES OF SUPERPLASTIC MATERIALS: ALUMINUM ALLOYS FOR SPF

For superplastic behavior a material must be capable of being processed into a fine grain equiaxed structure which will remain stable at the forming temperature. It is important also that processing leads to a predominance of high angle boundaries (lattice misorientation $> 15^\circ$), in order that grain boundary sliding and grain rotation, characteristic of

superplasticity, can occur. There are two main types of SP alloys: microduplex and pseudo-single phase. The former materials are thermomechanically processed to give a fine grain/phase size and grain growth is limited by having a microstructure containing roughly equal proportions of two or more chemically and structurally different phases. Materials of commercial interest in this group include the α/β Ti alloys, particularly Ti-6Al-4V, and to a lesser extent α/γ stainless steels, while Zn-22Al alloy finds a limited number of non-load bearing applications at ambient temperature. Eutectic alloys based on Al-33Cu, Al-5Ca-5Zn and Pb-Sn, have been processed to develop superplasticity, and along with Zn-22Al, are used as model systems to investigate fundamental aspects of superplastic flow.

Pseudo-single phase alloys, which include the SP aluminum alloys of commercial interest, would normally contain $< 10\%$ by volume of second phase. They are processed to develop a distribution of fine precipitates (dispersoids) so that on recrystallization the alloy will have a fine grain size. This is due to the pinning effect of the dispersoids which will also inhibit grain growth during SPF. The conditions for the pinning of high angle grain boundaries by dispersoids (Zener pinning)^[14] is given by:

$$P_g = \frac{3F_v \gamma}{2r} \quad (8)$$

where P_g is the restraining pressure of a group of particles of radius, r , and volume fraction, F_v , and γ is the grain boundary energy. For the boundary to move away from the particles, P_g must be exceeded. The pinning effect of closely spaced, small particles, may also inhibit recrystallization and restrict subgrain growth. It has been proposed for a group of fine particles that Zener pinning will occur when $F_v/r \geq 2$.^[15]

While numerous aluminum alloys have been shown to exhibit superplasticity, those of commercial interest are included in Table 1 with typical room temperature mechanical properties and include SUPRAL 100 (AA2004; unclad), SUPRAL 150 (AA2004; clad), AA7475 and AA5083. The alloys can be subdivided into 2 groups: those which are recrystallized prior to SPF, and those which

Table 1 Compositions (wt%) and typical room temperature properties of superplastic aluminum alloys

Alloy	Composition, wt%	Temper	0.2% PS MNm ⁻²	UTS MNm ⁻²	El %	Modulus GPa	Density Mgm ⁻³
2004	Al-6 Cu-0.4 Zr (UNCLAD)	T6	315	420	9	74	2.84

2090	Al-2.3 Li-2.5 Cu-0.12 Zr	T6	340	450	5	79	2.57

develop a super-plastic microstructure during the early stages of hot forming. The former group includes the 7000 series alloys, e.g. AA7475 and AA5083, while the latter includes AA2004. The Al-Li alloys, AA8090/AA2090, are also listed in Table 1 because of their interesting SP properties, even though they are currently not of great commercial interest as will be discussed below. These alloys can be processed by either route to develop superplasticity.^[16]

The SUPRAL alloys based on Al-Cu-Zr are unique in that they were designed so that they could be readily processed to develop superplastic microstructures, while having useful ambient temperature properties typical of existing medium strength alloys.^[17,18] However, because of the resistance to the adoption of new alloys, attention was subsequently turned to existing qualified alloys which were capable of developing SP microstructures by thermo-mechanical processing, and hence to be shaped by SPF. These included 7000 and 5000 series alloys.

PROCESSING OF ALLOYS FOR SPF

The procedures used to develop superplastic microstructures in 7000 series alloys by static recrystallization, using AA7475 as an example, and in AA2004 by dynamic recrystallization, will be outlined. Consideration will also be given to the increasingly important AA5083 and also to Al-Li-based alloys.

AA7475 (Al-Zn-Mg-Cu-Cr)

Several variants of the processing route exist but they all involve the production of microstructures with mean grain sizes of 10–15 μm , by rapid heating of heavily warm- or

cold-worked material containing a bimodal distribution of precipitates. The most well documented of these is the “Rockwell” route shown schematically in Fig. 6.^[5,19] After initial processing, the material is solution treated at 480°C to dissolve all the precipitates except the Cr-rich dispersoids, which are typically 0.1–0.2 μm in diameter. The alloy is quenched to retain the solute in solution, and then held at 400°C for 8 h to produce an overaged distribution of large M-phase and T-phase precipitates.

On heavy warm working (~80%) at ~200°C, these particles lead to intense localized deformation and lattice rotation which provide sites for discontinuous recrystallization (i.e. particle stimulated nucleation, PSN).^[20] Rapid heating to 480°C results in a large number of recrystallization nuclei in the locally deformed regions adjacent to the coarse precipitates, and thus to the development of a small grain size. At this temperature the large precipitates dissolve, but the small Cr-rich precipitates inhibit grain growth following recrystallization and during subsequent SPF by exerting a drag effect on grain boundaries (Zener pinning). After processing the grains tend to have a “pancake” shape, i.e. the grain dimensions in the transverse and longitudinal directions are equal, but greater than for the short transverse grain direction.^[5] However, the material would normally be capable of sustaining large tensile strains, e.g. 500–1000% elongation under optimum deformation conditions (515°C; $2 \times 10^{-4} \text{sec}^{-1}$). This processing route can be applied to 7000 series alloys produced by the ingot route or by powder metallurgy.

AA2004 (Al-Cu-Zr)

The processing route for AA2004 (Al-6 Cu-0.4 Zr) has been described by Watts et al.^[17,18] The alloy is rapidly

Fig. 6 Schematic of processing route to develop fine grain sizes in AA7475

Fig. 7 Fine grain SP microstructures developed in (a) AA2004 by dynamic recrystallization; 450°C, $\epsilon = 1.39$ (300%); and (b) AA5083 by static recrystallization; 520°C

solidified from a high superheat ($\sim 780^\circ\text{C}$) to avoid the formation of coarse primary ZrAl_3 precipitates and to retain the Zr in solid solution. Fine ZrAl_3 particles ($< 10\text{nm}$) are precipitated on aging at 360°C . They have a volume fraction of ~ 0.003 and are homogeneously distributed. The alloy is solution treated at 500°C and hot rolled to break down the as-cast structure. The material is subsequently heavily warm/cold worked to $\sim 80\%$ reduction, when recovery and recrystallization are prevented by the pinning action of the ZrAl_3 . The alloy can be formed at 460°C at a strain rate of $\sim 10^{-3}\text{sec}^{-1}$, and is capable of giving very substantial tensile strains to failure, $\sim 1000\%$. To improve corrosion resistance the alloy may be roll-clad with pure aluminum.

During forming, continuous dynamic recrystallization of the heavily dislocated alloy occurs and a fine grain SP microstructure evolves [(Fig. 7(a))]. The mechanism by which this occurs is uncertain, although it has been the subject of much investigation and discussion.^[21] One view is that it involves a progressive increase in grain boundary misorientation as a result of sub-grain boundary coalescence and the incorporation of dislocations into the evolving boundaries. An alternative proposal is that if the initial grain size is not too great and the amount of warm/cold work is large then the high angle boundaries may be sufficiently closely spaced for geometrical dynamic recrystallization (GDRX) to occur on subsequent hot (SP) forming.^[22,23]

A schematic of GDRX is seen in Fig. 8. During the initial stages of hot deformation, dynamic recovery

Fig. 8 Schematic illustration of GDRX

results in the formation of sub-boundaries and the serration of the original grain boundaries. As the reduction in cross-section increases with further straining, the impingement of serrations gives rise to small equiaxed grains and hence, to favorable conditions for grain boundary sliding and grain rotation.

AA5083 (Al-Mg-Mn)

AA5083 is essentially a non-heat treatable alloy which contains 4–4.9wt% Mg and 0.4–1.0wt% Mn. A typical composition would be Al-4.7Mg-0.8 Mn-0.1 Cr, with residual levels of Fe and Si. It is a relatively inexpensive alloy with medium strength, excellent cold forming, welding and spot welding behavior, and good corrosion resistance. The alloy can be processed to give a moderate degree of superplasticity. This attractive combination of characteristics has led to its increasing use for the SPF of a range of parts for non-structural applications which do not involve substantial forming strains.

After casting and thermomechanically processing to sheet the alloy contains two types of particles: constitutive particles of size $1\text{--}5\text{ }\mu\text{m}$ which typically contain Al, Mn, Fe and Si, and Al_6Mn particles of size $0.2\text{--}0.8\text{ }\mu\text{m}$, with a mean size near the lower end of the range. Following heavy cold work (70–80% reduction), the larger particles act as nuclei for recrystallization, although at lower temperatures nucleation at shear bands has been reported, while the smaller Al_6Mn precipitates pin grain boundaries and stabilize a small grain size.^[24] The cold worked material statically recrystallizes very rapidly at temperatures of $350\text{--}570^\circ\text{C}$ to give a grain size of $10\text{--}15\text{ }\mu\text{m}$ [Fig. 7(b)]. For SP deformation at 525°C at a strain rate of 10^{-4}sec^{-1} , tensile elongations of about 600% may be obtained, while elongations of 300–350% are observed for grain sizes of about $10\text{ }\mu\text{m}$, at the commercially more attractive forming rate of 10^{-3}sec^{-1} (when $m \sim 0.5$).^[25]

AA5083 is now the dominant alloy used for the production of non-structural parts by SPF and, as a consequence, numerous attempts are being made to improve its

SP formability. Matsuo^[26] has shown for the basic 5083 alloy (coded ALNOVI-1) that reducing the levels of Fe and Si leads to a reduction in the number and size of constitutive particles at grain boundaries, and to lower levels of cavitation and higher tensile strains during SP deformation.

Matsuo also noted that AA5083 showed significant strain hardening during SP flow, which increased with increasing strain rate and reduced deformation temperature. These observations were not consistent with grain growth hardening, and were attributed to the simultaneous occurrence of slip and grain boundary sliding. While SP deformation is usually assumed to involve a unique mechanism consisting of accommodated grain boundary sliding, there is strong evidence for this material that strain is also accumulated by intragranular dislocation creep which occurs independently of grain boundary sliding.^[27] The dislocation creep leads to significant grain elongation in the straining direction.

Al-Li-based Alloys

Although the history of Al-Li-based alloys goes back some 70 years, the sharp increase in fuel prices in the late 1970s led to a dramatic growth of interest in these materials for aerospace applications.^[16,28] Most Li-bearing alloys were developed to substitute for established airframe alloys of the 2000 and 7000 series, with an expected reduction of density of about 10% and a stiffness increase of at least 10% while matching the service properties of existing alloys (Table 1). Considerable efforts were devoted to the investigation of a wide range of alloy combinations by major aluminum companies, aerospace constructors, universities, and research institutions. These materials were the exclusive subject of 6 major international conferences held between 1981 and 1991.

It was shown that several alloys produced by ingot or powder routes could be processed to develop excellent SP formability and numerous studies were made of their potential for diffusion bonding. Fine grain microstructures were produced by processes which involved static

recrystallization prior to SPF, or dynamic recrystallization in the early stages of deformation.^[16,28] For AA8090 (Lital A) sheet material processed by the SUPRAL route, tensile elongations > 1000% have been reported for temperatures of 520–530°C and a strain rate of $\sim 5 \times 10^{-4} \text{ sec}^{-1}$. Optimization of the strain rate path can lead to further enhancement of SP strain to failure.^[29]

An interesting feature of alloys such as 8090 (and SUPRAL), when processed to develop fine grain microstructures by dynamic recrystallization, is that they show a high resistance to necking in the early stages of deformation before superplasticity has developed. Measurement of m , and the strain hardening exponent, N , has shown that while m is low initially, < 0.3, it rises with strain, and while N is high at the start it decreases^[30] (Fig. 9). Thus the stability of the material is initially dependent on strain hardening for its necking resistance. A relationship appropriate to this behavior would be:

$$\sigma = k'' \dot{\epsilon}^m \epsilon^N \quad (9)$$

As the value of N falls, $\epsilon^N \rightarrow 1$ when $\sigma = k \dot{\epsilon}^m$ Eq. 1.

In 1982 Superform Aluminium exhibited a superplastically formed component in Lital A at the Farnborough International Air Show. By 1986 demonstrator parts made from AA8090, including parts produced by SPF, had been introduced into prototype models of military aircraft being test flown in the USA and Europe. In the late 1980s it was predicted by the Boeing Company that Al-Li based alloys would make up 7% and 10% of the structural weights of civil and military aircraft, respectively, by 1990, rising to 35% and 25%, respectively by 1995.^[31]

Despite these optimistic forecasts, the development of Al-Li alloys had slowed dramatically by the early 1990s because of their slow take-up by the aerospace companies. The main reasons for this were the high costs of the alloys, and the high projected costs, combined with some concern about mechanical properties, with the result that these interesting materials at present find relatively few commercial applications.

Fig. 9 Variation of m and strain hardening exponent, N , with strain at 520°C, AA8090

CAVITATION AND FAILURE OF SUPERPLASTIC ALLOYS

Failure of Superplastic Alloys

When a superplastic material fails during tensile flow it is either the result of unstable plastic flow or a consequence of the growth and interlinkage of internally nucleated cavities. In the former process, inhomogeneities in the cross-sectional area of a test piece lead to a localized increase in strain rate and the difference in cross-sectional area increases at a rate which depends on the extent of work hardening and the value of m .^[32] In SP materials, where true strain hardening is usually minimal (but not always), any neck which is present will always grow, although the rate of growth decreases with increasing m . Unstable plastic flow normally results in the material pulling down to a fine point at failure.

On the other hand, when failure occurs as a result of the nucleation, growth, coalescence and transverse interlinkage, of internal cavities the fracture surface is much more abrupt. The value of m is important in determining the rate at which cavities grow and thus to some extent controls the strain to failure, which can be substantial, in systems which exhibit cavitation. Such systems include Al alloys. In general, the higher the m value, the greater the elongation to failure, as seen in the well-known Woodford plot, although the scatter shown by the data can be considerable (Fig. 10).^[33] This is due to factors such as cavitation, and to microstructural evolution during SP flow causing significant changes to the m value. Even so, m is a first order effect.

Cavitation

Not all SP alloys pull to a fine point at failure. Two different modes of failure seen in tensile test pieces are shown in Fig. 11. Both specimens have the same strain at failure, but the flat fracture surface of the lower specimen, termed pseudo-brittle, arises from tearing of tiny ligaments between regions of internal cavitation. In addition

Fig. 10 Elongation to failure versus m for a range of alloys (after Woodford)

Fig. 11 Shadowgraphs of fracture in two SP alloys at 900% elongation showing (a) unstable plastic flow in Ti-6Al-4V alloy; (b) pseudo-brittle fracture in AA2004

to its effect on fracture behavior, cavitation may also have an adverse effect on the mechanical properties of commercially formed parts. All Al alloys are prone to cavitation during SP flow. It can be seen from Fig. 12 for AA2004 that the level of cavitation can be substantial, although

Fig. 12 Effect of increasing SP strain on cavitation in AA2004, (a) 2.26 (860%); (b) 1.31 (270%); (c) 0.69 (100%).^[34]

the highest strain illustrated is well in excess of that used for SPF.^[34] There is a substantial interest in cavitation and reviews of the subject have been given.^[35,36] Consideration will be given to some aspects of cavity nucleation, cavity growth, and coalescence, during deformation and to procedures for controlling cavitation.

Cavity Nucleation

For most SP materials, it is widely accepted that strain is accumulated primarily by grain boundary sliding. However, the relative displacements of boundaries need to be accompanied by a redistribution of matter and this may be achieved by diffusion or dislocation processes. When the accommodation processes fail to meet the requirements imposed by the deformation rate, then the stress concentrations which develop at various grain boundary features are not relaxed sufficiently quickly and cavities may nucleate.

Metallographic observations suggest that in Al alloys cavities are most likely to develop at grain boundary particles.^[37] Relationships have been developed for the critical strain below which cavity nucleation at a grain boundary particle is likely to be inhibited by diffusive stress relaxation. These predict that to minimize cavity nucleation both grain and particle sizes should be small, and that SPF should be carried out at as high a temperature (high diffusivity) or as slow a strain rate as possible, commensurate with microstructural stability and sensible commercial practice.^[38]

Factors which influence cavity nucleation include those which relate to microstructure such as grain size, the type, size, volume fraction, interfacial energy and distribution of second phase particles, and those associated with deformation conditions such as strain, strain rate, temperature and stress state. The role of grain size on cavity nucleation has been clearly demonstrated for Al alloys.^[7] The higher flow stress associated with the larger grain size reduces the critical size of a cavity which constitutes a nucleus, making nucleation easier. In addition to nucleation at grain boundary particles, the observation of intersecting rows of cavities in 7475 Al alloy deformed by biaxial bulging and in uniaxial tension have been attributed to cavity nucleation at intersecting surfaces of grain boundary sliding. However, it is not clear how general a phenomenon this might be in SP materials.^[39]

Growth of Cavities

A cavity located at a grain boundary, whether nucleated or pre-existing, may grow during SP deformation by diffusion processes and/or plastic deformation of the surrounding matrix. Relationships have been developed which describe the change of cavity radius and the change of cavity volume with strain, for different growth mechanisms.^[35,36] These relationships have been tested experimentally using metallography and or precision density measurements and it has been shown that while diffusion may be important in

the early stages of cavity growth, strain controlled growth is dominant for cavity radii above about 1 μm .

For strain control, the rate of cavity growth increases linearly with cavity size and is independent of strain rate within the SP regime.^[40] This leads to the relationship:

$$C_v = C_0 \exp(\eta \epsilon) \quad (10)$$

where C_v is the volume fraction of voids at strain ϵ , and C_0 is a constant; η is the cavity growth rate parameter and is given by the expression:

$$\eta = \frac{3}{2} \left(\frac{m+1}{m} \right) \sinh \left(2 \left(\frac{2-m}{2+m} \right) \right) \left(\frac{K}{3} - \frac{P}{\sigma_e} \right) \quad (11)$$

and

$$\left(\frac{K}{3} - \frac{P}{\sigma_e} \right) = \frac{\sigma_m}{\sigma_e} \quad (12)$$

where K is a constant whose value depends on the deformation geometry and the extent of grain boundary sliding, P is the imposed pressure, σ_m the mean stress and σ_e is equal to the uniaxial flow stress. Plasticity dominated growth is controlled by the mean stress whereas it is the principal stress which is important in diffusive growth. If 50% of SP strain is attributed to grain boundary sliding, then it can be shown that $K = 1.5$ and 2.25 for uniaxial and biaxial straining, respectively, and 2.7 for plane strain.^[7,41]

It can be seen from Eqs. 10–12, that the application of an imposed pressure will reduce η , the cavity growth rate parameter, and hence the level of cavitation for a given strain. For the same strain, cavitation will be higher for biaxial and plane strain deformation than for uniaxial flow. This is an important prediction since most studies of cavitation are made for uniaxial deformation, whereas SPF processes will involve biaxial and plane strain stress states which will be more damaging in terms of cavitation than a uniaxial tensile stress. Figure 13 shows the effect of back pressure on cavitation for AA7475 deformed in equi-biaxial tension to different strains,^[42] while Fig. 14 shows the beneficial

Fig. 13 Effect of imposed pressure on cavitation in 7475 Al alloy. Biaxial

effect of imposed pressure on the level of cavitation seen in the microstructure of AA2004 deformed to a strain of 1.7 (450%).^[41]

Cavity Coalescence

It has been noted that once plasticity controlled growth has become dominant, the predicted size to which cavities grow may be significantly less than is observed experimentally.^[43] These differences are attributed to cavity coalescence for which there is much metallographic evidence [Fig. 12a and b]. Large elongated cavities lying parallel to the rolling direction, which may be observed, are almost certainly the result of the coalescence of cavities nucleated on closely spaced inclusions. These cavities are likely to be particularly damaging in their effect on post-forming properties. Some cavities which develop in Al alloys may be associated with outgassing of hydrogen. This leads to fine localized porosity which provides pre-existing sites for cavity growth.

Control of Cavitation

To minimize cavitation in Al alloys during SPF, the first requirement is to have a material with a stable fine uniform grain size comprised predominantly of high angle

grain boundaries. Dispersoids should be small and uniformly dispersed. It is, therefore, essential that there is sound control of the processing required to produce the SP microstructure. An important requirement for cavitation is the presence of a local tensile stress. Under conditions of homogeneous compression cavitation is not observed and cavities which have been produced by SP tensile flow are removed by subsequent compressive flow.

Cavitation can be controlled by various procedures including annealing and/or the application of hydrostatic pressure either prior to, during, or after SPF.^[44] Annealing before deformation can lead to sintering of pre-existing cavities by vacancy diffusion, and if a hydrostatic pressure is also applied this will accelerate cavity closure. Annealing can also lead to hydrogen outgassing and can be particularly effective if carried out in a vacuum. However, consideration must be given to detrimental effects of grain growth and solute loss by volatilization.

The most effective and practical way of controlling cavitation is to superimpose a hydrostatic pressure during SPF. Work carried out on Al alloys deformed in uniaxial and balanced biaxial tension, and plane strain has shown that increasing imposed pressure:

- i. decreases the rate at which the volume of cavities increases with increasing strain (Fig. 13)
- ii. decreases the level of cavitation for a given strain (Fig. 13)
- iii. displaces to a higher level the strain at which cavities are first detected
- iv. increases to a limiting value the strain to failure (Fig. 13)

Since cavity growth is plasticity dominated then it can be seen from Eqs. 11 and 12 that to prevent cavity growth during SPF it is necessary for the imposed pressure, $P > K\sigma_c/3$ (or $\sigma_m/\sigma_c < 0$), i.e. $P > 0.5\sigma_c$ for uniaxial deformation (although $P > \sigma_c/3$ is also quoted in the literature), $P > 0.75\sigma_c$ for equibiaxial straining and $P > 0.9\sigma_c$ for plane strain deformation. These predictions are broadly in accord with observation. It can be seen from Eq. 12 that the ratio P/σ_c is important in determining the level of cavitation. In commercial forming, it is unlikely that P would exceed ~4 MPa (600 psi) for technical reasons, so that the value of σ_c (dependent on grain size and strain rate for a given SPF temperature) should not be too high if cavitation is to be prevented. However, even if the criterion $P > K_c/3$ is not met, any level of imposed pressure is likely to be beneficial in its effect on cavitation, as is seen in Fig. 13.

Other methods which have been proposed include annealing after SPF. This can be effective in removing small cavities, but the larger cavities which have the most deleterious effect on properties are little effected. Post-forming HIPping also has the potential to remove cavities but is likely to be limited in application because of cost and its restriction on component size. It has also been

noted for an Al alloy that some cavities may reappear on subsequent heat treatment, probably due to the presence of hydrogen. Conrad and co-workers have reported that the application of an external electric field during SPF reduced the level of cavitation for 7475 alloy, and so improved its post-forming properties.^[45]

SUPERPLASTIC FORMING OF AL ALLOY SHEET MATERIALS

Bulge Forming of a Dome

Prior to discussion of various forming procedures, important features of SP sheet forming can be illustrated by considering the bulge forming of a dome, a procedure which is frequently involved in the early stages of commercial SPF. To form the sheet, the periphery of a heated blank is rigidly clamped to provide a gas tight seal. On application of gas pressure to cause the material to stretch into the die cavity, the constraint provided by the clamped edge results in a stress system which varies across the sheet. For a circular blank, plane strain conditions exist in regions adjacent to the clamped edge while an equibiaxial strain state occurs at the pole. The differential stress system leads to thickness strains across the sheet with maximum thinning occurring at the pole. Although a thickness variation would occur if $m = 1$, the differential thinning is smallest for alloys possessing the highest m value, and increases with increasing dome height. Predictions of thickness variation in a free blown hemisphere for a range of m values, taken from the early work of Cornfield and Johnson,^[46] are shown in Fig. 15.

Simple Female Forming

This simple forming procedure involves the use of gas pressure to blow a sheet which is rigidly clamped around its periphery into a female die, as illustrated in Fig. 16(a).

Fig. 15 Predicted variation in thickness in a free blown hemisphere for different m values.^[46]

During forming both the sheet and the die are maintained at the optimum forming temperature and the rate of application of pressure is such that the strain rates induced in the sheet are maintained in the SP range. The first stage of the process involves free stretch forming, leading to thickness variations as described above. Once the pole of the bulged sheet contacts the die surface it is locked against the tool by friction and forming pressure, and this inhibits further thinning in this region. Continuing deformation leads to progressively more of the unsupported regions making contact with the die. Since the corners of the die are the last to fill, the greatest strain occurs in these regions as seen in Fig. 16(a).

Simple female forming is preferred when the height to diameter ratio is low and the corner radii are large, and when the m values are towards the lower end of the useful range. In this way, wide variations in material thickness can be avoided. Stiffening features such as deep pockets or grooves can also be incorporated into the design of the part.

Fig. 16 Illustration of (a) simple female forming; (b) drape forming.^[47]

Drape Forming

This process consists of bulge forming a sheet into a female die in which one or more male tools are located [Fig. 16b]^[47] When gas pressure is applied, the polar region of the bulging sheet will make early contact with the male tool. Continued application of pressure will drape the sheet over the male tool as it bulges into the female annular regions. The process can yield a more uniform material thickness particularly if the height of the annular space is small with respect to the dimensions of the blank.

The choice of either female forming or drape forming could be influenced by whether the internal or external dimensions of the part were the most critical. As seen in Fig. 16, if the outside shape is specified as the critical dimension, then female forming will be used. When the inside shape is critical, then drape forming will be used. If a number of male tools are placed within the female forming tool several similar parts, or different parts of a given component, can be produced at the same time.

Back-Pressure Forming

Aluminum alloys are susceptible to cavitation during SPF and in high strength alloys such as AA7475 for important structural components it is essential that the number, size and/or volume fraction, of cavities be held below critical levels to avoid degradation of service properties. Fortunately, cavitation can be controlled by the application of back pressure during forming, as was discussed previously. In back-pressure forming both sides of the sheet are pressurized, as shown schematically in Fig. 17. This produces a hydrostatic pressure capable of suppressing cavitation. Gas control creates a positive pressure differential enabling forming to be carried out. Back pressure can be applied to both female and drape forming to keep cavitation to a minimal level.

The total die separating force in back pressure forming can be quite considerable. For example, if 1 MPa (~144 psi) is required to form 7475 sheet at $2 \times 10^{-4} \text{ sec}^{-1}$ and 515°C,

Fig. 17 Illustration of back-pressure forming during SPF^[47]

into a part with sharp final detail, then back pressure of 4MPa might be needed to suppress cavitation. If the projected size of the die is $1 \text{ m} \times 1 \text{ m}$ then it can be readily calculated that the clamping force must be 7.8 GPa (560 tons US). The capacity of the press must be sufficient to contain this separating force and provide sealing round the periphery of the die.

Male Forming (Bubble Forming)

This involves the combined use of gas pressure and tool movement to enable deeper parts of more uniform thickness to be made. Male forming is carried out on presses designed by the Super form companies and the stages in the process are illustrated in Fig. 18.^[1] Male forming is applied mainly to 2004 and 5083 alloys and is a commonly used forming technique.

In the technique illustrated, the sheet to be formed is first blown into a bubble away from the sheet. The tool is then moved into the bubble and the pressure is reversed forcing the bubble to collapse onto the plug. A combination of friction and forming pressure lock the sheet in contact with the tool and effectively prevent any further deformation. As the tool continues to move, deformation switches to the relatively underformed material adjacent to the flange (Fig. 18). Parts with a depth to width ratio of 0.7 or more, with a relatively uniform wall thickness, can be formed in this way.

Other forming procedures which can be carried out include reverse billowing, in which a sheet is bulged away from a female die to a predetermined height, and the pressure is reversed to blow the sheet into the die to produce the required shape. This procedure increases the thickness at the corners at the expense of greater thinning at the pole (base). Barnes^[48] has pointed out that, if the various forming procedures outlined are available, the choice of which forming method to use to produce a component for a specific application is a complex one.

Fig. 18 Male forming (schematic)^[1]

Fig. 19 Schematic of diaphragm forming^[47]

Diaphragm Forming

Diaphragm or membrane forming uses a rigidly clamped sheet of SP alloy to deform an unclamped smaller sheet into a die (Fig. 19).^[47] The SP diaphragm deforms by stretching, while the smaller sheet is free to slide down the die and is drawn into shape by the membrane until it conforms exactly with the die. The drawing action in the part being shaped causes much less thinning than would occur by SP stretching. The process can shape non-SP alloys having limited room temperature formability, provided the material has adequate ductility at the forming temperature. Superplastic alloys can also be shaped in this way when limited thickness variations are required.

The membrane must be SP at the forming temperature and should have a low flow stress so that it carries the sheet being formed into all of the die corners. It should have low initial cost and should have adequate stretchability over a wide range of strain rates. Providing the membrane does not burst there is no need to use low forming rates. The strain in the formed part is low, 0.1–0.2. In addition to the benefits associated with low thinning, diaphragm forming avoids the expense of using back pressure to prevent cavitation associated with SPF. Properties of 7000 alloys which have been membrane formed have been shown to be comparable with those produced by SPF using back pressure.^[49]

Forming Equipment

The two main types of sheet forming equipment include the presses developed by Superform, which are currently used to form alloys 5083 and 2004, and the platen type presses used in the SPF of 7475 and 8090, which would include back pressure facilities. The generalized configuration of a Super form pressure chamber set up for male forming is seen in Fig. 20 and this would be located in a hydraulic press framework.^[1] The configuration could be changed so that simple female forming or drape forming could be carried out. Important characteristics of the equipment include: the ability to control pressure either side of the sheet, controlled tool movement, accommodation of blanks of different sizes, ability to sense bubble height, heating elements within the chambers, pressure chambers

Fig. 20 Configuration of a Superform pressure chamber set up for male forming^[1]

that can be moved rapidly with respect to each other by the hydraulic system which also provides the clamping force.

For female and drape forming, particularly of 7475 with back pressure, and diaphragm forming, the tooling package is located between the platens of a hydraulic press (or a mechanical clamping system) (Fig. 21). As above, the main function of the press is to keep the dies closed during forming by applying a clamping pressure, although the hydraulic system can also perform other functions. Hydraulic presses can be rapidly loaded and unloaded, but they represent a significant capital investment. The main features of a 4-column hydraulic press are seen in Fig. 22, while both the design and manufacture of presses for SPF have been described by Whittingham.^[50]

Heating of the tools can be achieved by conduction from heated platens, which may be metal or ceramic, or by the use of cartridge resistance heaters inserted into holes drilled in the tooling chamber. Care is taken to minimize thermal gradients during SPF as these can lead to excessive thinning or failure. A microprocessor controls all functions of the press including platen and tool temperatures, press movements, gas management systems and control of the forming pressure-time cycle.

Fig. 21 SPF Tooling package for SPF^[47]

For either type of press, machined Al alloy tools can be used for the forming of low strength alloys, whereas ferrous alloy tools, machined or cast, perform well with higher strength alloys. Forming gases can be air, nitrogen or argon. The choice is product dependent, with air being cheapest but most reactive, while argon would be preferred but has cost and safety implications. The tool/blank face is lubricated with graphite or boron nitride. Graphite is easiest to use and least expensive but can cause post-forming surface corrosion problems if not completely removed. Boron nitride is non-reactive, expensive, and must be

carefully applied and monitored in order to avoid build up on the tool. The method of trimming of parts formed by SPF depends on quantity and the quality requirement. For smaller quantities items may be hand trimmed, whereas larger numbers may be mechanically, laser or water jet, cut by numerically controlled machines.

Simulation and Control of SPF

SP sheet forming processes have usually been designed on a trial and error basis coupled with considerable experience and some simple calculations. However, if maximum benefit is to be gained from SPF then some form of numerical simulation of the process is desirable. A number of numerical analyses have been developed but the finite element (FE) method has emerged as the most potent technique for SPF.

Wood and Bonet^[51] have reviewed the numerical analysis of SPF. It was pointed out that non-FE analyses are usually confined to two special cases involving bulge-forming of a circular sheet and plane strain forming of long rectangular box sections. In the majority of cases the simple constitutive equation: $\sigma = k\dot{\epsilon}^m$ is used. These techniques are valuable as they enable insight to be gained into SPF processes as a result of changing process parameters. They are computationally inexpensive and in many cases are entirely appropriate for practical purposes.

Fig. 22 Main features of a 4-column hydraulic press^[50]

The use of FE analysis to simulate SPF is a relatively complex topic and will only be considered in outline. However, to be successful FE analysis requires an accurate constitutive equation. Kannan et al.^[52] in their investigation of SP ductility in an Al-Mg-Mn alloy used a constitutive equation based on the relationship proposed by Ashby and Verrall,^[53] which includes a transition from SP flow to power law creep, as well as a threshold stress. The form of the equation is:

$$\dot{\epsilon} = \left(\frac{K_{II}(\sigma - \sigma_0) \exp(-Q_s / RT)}{d^p} \right) + K_{III} \sigma^{n'} (\exp - Q_c / RT) \quad (13)$$

The first part of this expression is essentially identical to Eq. 4 and procedures for determining σ_0 , m ($=1/n$), Q_s and p , have been outlined; Q_s and Q_c are the activation energies for SP flow and creep, respectively; n' is the stress exponent for creep, and K_{II} and K_{III} are constants. By a combination of constant strain rate tensile tests, as described previously, and least squares fitting the constitutive model parameters for Eq. 13 can be determined.

It is well established that microstructural evolution occurs during SPF and the value of d in Eq. 13 will change. This affects only the first term and not the creep term. By incorporating microstructural evolution, the material flow properties should be more representative of local mechanical conditions, and provide for the variation of strain, strain rate and microstructure, throughout the material which can effect strain localization. The grain size, d , at any strain, (or time for constant $\dot{\epsilon}$) is given by:

$$d = d_0 + \int_0^t \dot{d} dt \quad (14)$$

where

$$\dot{d} = \frac{D}{qd^{q-1}} + \lambda \dot{\epsilon} \quad (15)$$

The first term in Eq. 15 represents static grain growth rate and the second represents the rate of dynamic enhanced grain growth. These are considered to be separate mechanisms. D , q and λ are empirical constants that can be determined by least squares fit of experimental data, and $\dot{d}$ is the overall rate of grain growth. Equation (14) can be incorporated into Eq. 13 to give a relationship which accounts for the grain growth processes.

Once the constitutive equations have been established they can be introduced into a FE simulation package that essentially solves the quasi-static equilibrium equations in order to determine, as forming progresses, the variation of the shape of the part with time, the stress and the strain rate, and the evolution of grain size. The FE simulation can also predict the final thickness distribution in the formed

part and the pressure-time forming cycle. It is also possible to introduce into the FE simulation, factors such as friction and cavitation which can affect the thickness distribution. The advantage of FE simulation is that it can enable many numerical “experiments” to be carried out before a real production run. For complex components involving chemi-etched blanks that need to form into specific locations, the simulations can substantially reduce the cost of trial runs.

SOME APPLICATIONS OF PARTS/COMPONENTS PRODUCED BY SPF

The present section will deal with products produced by the SPF of sheet material although there is some interest in the SP bulk forging of Al alloys and composites. Much of the success of the SPF of Al alloy sheet is the result of the pioneering and innovative work undertaken by Super form Aluminium, which started production in Worcester, UK, in 1974, and Super form USA opened later at Riverside, California. The Super form plants produce many thousands of parts per annum from the Al alloys 5083, 2004, 7475 and 8090, with other alloys being shaped by diaphragm forming.^[48] The bulk of manufacture is from AA5083 and AA2004, with most parts being produced from the former material.

Many aerospace companies in the USA, Europe, Russia and China, have dedicated forming equipment, particularly for the production of parts in AA7475 (and Ti-6Al-4V alloy), while various subcontractors also have SPF manufacturing facilities. Aluminum alloy components produced by SPF are found in civil and military aircraft, helicopters, unmanned reconnaissance vehicles, air weaponry and space craft. The SP alloys 7475, 8090, 2004 clad and unclad, and 5083 are used to produce a wide range of parts, while the non-SP alloys 2014 and 2024 (Al-Cu-Mg-Si-Mn) and 6061 (Al-Mg-Si), find applications after diaphragm forming. AA 5083 can be used as a diaphragm because of its relatively low cost. All parts are subjected to heat treatment where appropriate.

On military aircraft parts range from leading edge components capable of withstanding bird strikes, access and inspection doors, and fairings (aerodynamic covers). For primary structures, AA7475 is used to produce two basic configurations. One is a waffle pan type structure where a built-up framework of extrusions and/or beams is replaced by a single piece super plastically formed pan. The pan is joined to an outer skin but the costly riveting involved in assembling the pan frame is eliminated. The pan would be produced by drape forming using back pressure. The second type of structure is the sine wave beam or spar (Fig. 23). This type of channel is used to construct a frame of high torsional rigidity and replaces built-up channels.

Applications of the waffle pan structure are found in many military aircraft and include the avionics and gun doors on the British Aerospace Hawk (Fig. 24) and the engine bay doors on the Typhoon (Eurofighter 2000). In

Fig. 23 Illustration of sine wave spar^[47]

Fig. 24 Access door components for British Aerospace Hawk aircraft; 7475. Courtesy of Superform Aluminium

the latter aircraft, sine wave spars of lengths up to 1.5 m are used in the construction of the tail fin. Chemical milling of formed parts is frequently used to reduce weight. In civil aircraft, the Lear Jet baggage bay door is a waffle pan structure produced in 7475 and the outer skin is joined to this by adhesive bonding. Other parts produced by SPF which find applications on civil and/or military

aircraft include avionics enclosures, access door frames, air intake skins, ejector seat panels, engine cowling and engine cowling stiffeners, window surrounds, hydraulic and mechanical equipment housings, wing and tail leading edge panels. Interior parts include ceiling lighting panels, cabin surfaces, floor panels, and door frames.

The rail market is important, particularly in Europe, where large numbers of parts produced from SP 5083 find external and internal applications on commuter trains. The interior fittings often replace plastics so reducing fire hazards. Examples of external parts include end panels fitted to more than 700 Underground trains (Fig. 25), roof canopies and double curvature transition panels, while internal fittings include window surrounds, door pillar panels, and ventilation, roof and door panels. More than 2500 seats comprising one piece seat shells produced by SPF and covered with fire resistant fabrics have been fitted to the Heathrow Express to Central London, one piece pillars ($2\text{ m} \times 0.25\text{ m}$) and window surrounds ($1.6\text{ m} \times 1.3\text{ m}$) are used on the Stockholm Metro, and equipment covers on the Bern Tram (Switzerland).

Architecture and building is a market which uses mainly 5083 and where products are used for external and internal cladding. The most frequent use is on external cladding systems where ribbed panels can enhance both the aesthetic and structural performance, and also be designed to function as a rain screen. Examples of clad buildings include the Financial Times print works in London, Gatwick Airport N. Terminal, and the roof of the Charlety Stadium, Paris, which makes use of around 4000 SP panels in 14 different sizes. Panels can be coated/colored using polymer-based paints. SPF components have been used successfully in applications such as ceiling panels, e.g. 2000 sq. m in the British Library, London, logo panels, display and shelving systems, and complex column cladding. Figure 26 shows applications of decorative and double curvature panels.

Numerous parts are formed from SP 5083 for specialist and prototype automobiles. These include the entire bodies of the Roadster and Esperante models produced for the American sports car maker Panoz. The UK sports car manufacturer Morgan has the wings on all of its models produced by SPF, and has replaced a 3-piece steel fabrication

Fig. 25 End panels for London Underground trains; 5083. Courtesy of Superform Aluminium

Fig. 26 (a) Decorative panel, Grady Hospital, Atlanta, USA; double curvature panels, Dorset House, Hong Kong (b) and Victoria Station Shopping Mall, London (c). Courtesy of Superform Aluminium

with a single component formed from a $3.2 \text{ m} \times 1.5 \text{ m}$ 5083 sheet (Fig. 27). Other components are the rear valance for the Aston Martin Vantage, and the radiator grill and the boot finisher for the Bentley Arnage. There is interest in the mass production automobile industries in SPF as a production tool and if this is maintained it could have an enormous impact on the field.

Other parts produced by SPF are used in medical diagnostic and test equipment and range from large diameter end

Fig. 27 Morgan sports car with wings produced by SPF; 5083. Courtesy of Superform Aluminium

plates for body scanners, to covers and finishing items with an aesthetic bias, and in communications include radar and satellite receiver dishes up to 2 m diameter. Deep formed parts are produced from 2004, and others with a lower forming strain from 5083. Figure 28(a) shows a defense computer housing produced from 2004 and 5083, and Fig. 28 (b) a 2.6 m (8 ft 6 in.) dingy formed from a single sheet of 5083.

POST-SPF MECHANICAL PROPERTIES

SPF of Al alloys leads to two effects which can degrade mechanical properties. Firstly, and potentially the most

Fig. 28 (a) Defense computer housing; 5083 and 2004; (b) sailing dingy; 5083. Courtesy of Superform Aluminium

serious, is that all Al alloys undergo cavitation during SP flow, and secondly, a combination of elevated temperature and SP strain can lead to an increase in grain size. This section will examine the effect of SPF, particularly strain and post-forming heat treatment, on tensile, fatigue, fatigue crack growth and corrosion data, where available, for 7475, 2004 and 5083 alloys, while noting that for some applications data on a wider range of properties may be required. A considerable amount of post-SPF property data was generated for Al-Li alloys during their development era. The subject has been reviewed by Partridge et al. and includes data on 8090.^[54]

Aluminum alloy 7475 sheet is used for the manufacture of primary structures for aerospace applications and it is essential to prevent cavitation, or to hold it at a low level, so as to avoid property degradation. This is achieved both by back pressure forming and not exceeding an equivalent

SP elongation of 150%. The optimum forming rate for 7475 is low, $\sim 2 \times 10^{-4} \text{ sec}^{-1}$, and, as a consequence, forming times can be up to 2h. To prevent cavitation during forming the condition $P > K\sigma_e/3$ [Eq. 11] must be fulfilled, where σ_e is dependent on strain rate and grain size. Static and strain enhanced grain growth will cause an increase in σ_e because of the low forming rate, so it is important that an increase in back pressure, or an decrease in strain rate within the optimum strain rate range, compensates for this.

A detailed study has been made of post-SPF material properties for back pressure formed material.^[55] Data shown in Fig. 29(a) is for room temperature tensile properties of 7475-T6 for test pieces lying parallel and transverse to the sheet rolling direction. It can be seen that neither YS nor UTS are affected by equivalent SP elongations up to 150%, although elongation shows a drop beyond 100%. Fatigue behavior shown in Fig. 29(b) for two orientations lies within

Fig. 29 Post-SPF properties of AA7475 at room temperature. Back pressure formed. T6 condition. (a) tensile properties; (b) fatigue strength^[55]

the cross-hatched band obtained for the non-SP formed parent sheet. For fatigue crack growth rate in air, no measurable effect was reported for equivalent SP elongations up to 150%. Resistance to stress corrosion cracking and exfoliation corrosion showed no deleterious effect of SP strain. However, the T76 temper provides for improved exfoliation and corrosion resistance over the T6 temper, although with some decrease in strength. Overall, it is seen that provided cavitation can be minimized then post-SPF properties should be similar to those for the parent metal sheet.

AA2004 is available in the form of sheet of thickness ranging from 1 mm to 6 mm, and is supplied in the unclad condition (SUPRAL 100), or is roll clad with a layer of commercially pure aluminum (SUPRAL 150) for use in aggressive environments. Clad alloys are weaker than unclad material because of the pure Al layer, and show enhanced levels of cavitation. The alloy is highly superplastic but

forming strains are generally limited to an equivalent SP elongation of $\sim 250\%$. It is not usually back pressure formed as it is not used for primary structures. However, the flow stress of the alloy is relatively high, $\sim 10\text{ MPa}$ at 460°C , at normal forming rates, $\sim 10^{-3}\text{ sec}^{-1}$, so this would require a high back pressure to eliminate cavitation. Both the unclad and clad materials may be used in the as-formed or fully heat-treated condition T6 condition.

Shakesheff^[56] has examined the effect of SPF on tensile properties, fatigue, and fatigue crack growth rates, of formed and fully heat treated 2004 alloys for equivalent strains up to 200%, and has related this data to the cavitation behavior of the materials. Further post-SPF mechanical property data is found on materials data sheets produced by Superform Aluminum. The room temperature tensile and fatigue properties for unclad material in the as-formed and fully heat-treated T6 conditions are shown in Fig. 30.

Fig. 30 Post-SPF properties of unclad AA2004 at room temperature. Tensile properties (a) as-formed; (b) T6 condition

Fig. 30 Post-SPF properties of unclad AA2004 at room temperature. Fatigue strength (c) as-formed; (d) T6 condition

At low equivalent SP elongations ($\sim 100\%$), the ductilities of the unclad (0.7 vol% cavities) and the clad (1.5% cavities) are similar but the PS and UTS are both $\sim 30\text{--}40\text{ MPa}$ lower for the clad alloy. A reduction in strength and ductility is observed with increasing SP strain up to 200% and, hence, increasing cavitation, with the effect being greater for the clad alloy (5/6 vol% cavities) than the unclad ($\sim 3\text{ vol\%}$ cavities).

The fatigue performance of unclad and clad alloys is little affected by SP strain provided the material is fully heat treated after forming [Fig. 30(d)]. However, fatigue crack growth rates are adversely affected by both strain and heat treatment. This is attributed to the influence of cavitation and to the increased strength from heat treatment which reduces fracture toughness. The corrosion resistance of unclad 2004 is similar to that of other copper containing aluminum alloys such as 2014 and 2024. Clad 2004 is designed to give good corrosion resistance. Environmental exposure tests at industrial and marine sites have shown that the material has a corrosion resistance equal to that of 99.8% pure Al sheet. In salt spray tests and acetic acid + salt spray tests clad 2004 performs as well as 99.8% pure aluminum.

AA5083 is available in the form of sheet of thickness ranging from 0.5 mm to 6 mm and is formed at $\sim 500^\circ\text{C}$. The forming strain is limited to about 100% equivalent SP elongation because the material does not have large reserves of superplasticity. However, the post-SPF properties shown in Fig. 31 cover a wider range of forming strains.^[26,57] For normal forming strains, the loss in strength and tensile ductility is relatively small although as the SP strain increases towards 200% elongation it can be seen that falls in these properties become quite significant [Fig. 31a]. The alloy does not show appreciable cavitation at small strains.

The fatigue strength of post-formed sheet is reduced but the fall is not catastrophic for an equivalent SP elongation of 100% [Fig. 31(b)]. The alloy is particularly resistant to

corrosion in seawater and tests have shown that weight losses after 4000h of salt spray exposure (3.5% NaCl) for parts formed by SPF are similar to those for non-formed sheet.

DIFFUSION BONDING OF SUPERPLASTIC ALLOYS

Introduction

Diffusion bonding (DB) is a joining process which involves minimal macroscopic distortion of the parts being bonded. Joining may occur entirely within the solid state or may involve isothermal melting and re-solidification of a thin interfacial region of transient liquid phase.^[58] The applied pressures tend to be relatively low so as to avoid macroscopic flow. To ensure reasonably short process times, bonding takes place at high homologous temperatures which usually correspond with those for optimum SP flow. It is important that grain growth is minimized during bonding so that the potential for subsequent SPF is not lost.

In solid state diffusion bonding two suitably prepared surfaces are brought into intimate contact at an appropriate temperature. Since the surfaces are not atomically flat there will be a finite number of contacting asperities which will undergo instantaneous plastic collapse on the application of pressure to give a planar array of interfacial voids. Diffusion and creep processes transport atoms to the void surfaces from adjacent areas so reducing the volume of interfacial voids until, with time, they are completely removed, and an atom to atom bond is formed across the original interface. In the absence of local melting, the microstructure of the bond is identical to that of regions remote from the bond and, as a consequence, has parent metal properties.

There have been several attempts, of varying refinement, to predict the time required to obtain 100% contact between surfaces of measured roughness, including

Fig. 31 Post-SPF properties of AA5083 at room temperature, (a) tensile properties; and (b) fatigue strength^[26,57]

models which assume DB to be analogous to pressure sintering.^[59] The actual bond is assumed to form instantaneously on contact. Several models assume that bonding occurs under plane strain conditions, although there is current interest in isostatic bonding. While the same physical processes will be involved in both cases, it has been predicted that the kinetics of the processes will differ such that the rate of void closure during isostatic bonding will be 2–3 times faster than for plane strain bonding.^[60]

DB/SPF Technology

In the context of superplasticity, DB can be used for the selective bonding of sheet materials into sandwich-like constructions. These can then be expanded by gas pressure to form cellular structures. The shape of a cellular structure depends on the number of sheets which make up the initial sandwich and the pattern of the bonded and non-bonded areas. These cellular structures have low overall densities and, if formed from high strength alloys, have extremely high torsional rigidity and high strength-to weight ratios.

DB/SPF technology is readily applicable to titanium alloys, e.g. Ti-6Al-4V, since the Ti lattice is capable of taking into solution the surface oxide and other contaminants which would normally prevent the formation of a metal-metal bond. It has been used for a number of years to manufacture a range of complex components, particularly for aerospace applications, and more recently for the construction of large heat exchangers. Figure 32 shows a 4-sheet cellular structure which has been produced by DB/SPF of Ti-Al-4V. There is considerable interest in extending the technology to other SP materials, particularly aluminum alloys.

However, Al alloys are difficult to bond because of their stable and tenacious surface oxide films which both inhibit the formation of a metal to metal contact and interfacial diffusion. Oxide films inevitably form on the surface of Al alloys when they are exposed to the atmosphere. The films are mainly composed of Al_2O_3 , which with a melting point of $> 2000^\circ\text{C}$, neither passes into solid solution, decomposes, nor evaporates at bonding temperatures. To achieve a sound DB joint it is necessary to remove the oxide films at least partially, or to disrupt their continuity. The DB of Al alloys has been extensively investigated.

Fig. 32 A 4-sheet cellular structure produced by DB/SPF of Ti-6Al-4V

Procedures used to produce diffusion bonds in SP aluminum alloys have been outlined by Partridge^[58] and Huang et al.^[61] Methods have included solid state bonding of uncoated surfaces using static compression or gas pressure; the use of a range of interlayers; the deposition of protective coatings on, or implantation in, sputter cleaned surfaces; the application of an organic solution to give a protective layer on an oxide-free surface obtained by mechanical cleaning, or roll cladding of transient liquid layers to the surfaces to be bonded. All of these procedures have been shown to be capable of developing high quality bonds on a laboratory scale, although in a number of cases a variability in bond strength was noted. However, several of the procedures outlined would be difficult to scale up to produce demonstrator or production parts

Testing of Diffusion Bonds

The quality of a diffusion bond can only be reliably assessed by comparing its mechanical properties/fracture characteristics with that of the parent metal subjected to the same heat treatment. Direct observation of the bond region using optical metallography and SEM is a useful procedure for identifying incomplete bonds, defects in the bond line and the extent of migration of grain boundaries across the original interface. Non-destructive evaluation using ultrasonics is useful for the detection of large disbands. However, this procedure would not be able to resolve bond line microvoids ($< 5 \mu\text{m}$) since the wavelength used ($\sim 200 \mu\text{m}$) is much greater than the defect size, and in thin sheets the transit times are very short.

For bonds produced in thick sections conventional tensile, rotating bend fatigue and impact test pieces can be readily produced and tested. In practice, parent metal tensile strengths are often achieved with more than 85% interfacial contact, while parent metal fatigue endurance normally requires a complete absence of interfacial voids. The most discriminating measure of bond quality is obtained by impact testing, when poor bonds which show complete interfacial contact may exhibit low impact strengths (58). Impact testing is not widely applicable because the majority of bonds are formed between sheet materials. In such cases, the room temperature fracture strength of the bond is measured using a constrained lap shear test.

In addition to good room temperature strength, it is particularly important that the bond should be capable of resisting peel during SPF after DB. For a 2-sheet structure it would be possible to constrain the bond during SPF by appropriate tool design. However, for producing 3-sheet structures, or a 4-sheet structure of the type illustrated in Fig. 32, the hot peel strength becomes critical, and the bond region must be able to withstand the pressures encountered during SPF. This is dependent on sheet thickness and SP flow stress. It is important to develop a high hot peel strength during bonding but at the same time

taking care not to increase the grain size and hence the flow stress of the SP alloy.

Selected Bonding Procedures

Two examples of industrially based projects illustrate the position with regard to DB/SPF of aluminum alloys. Firstly, one of the most successful attempts to produce high strength joints in AA7475 sheet is seen in the work of Kennedy.^[62] Bonding was carried out at the SPF temperature of 516°C, without the use of interlayers. The material was prepared for bonding by a proprietary technique and bonding was carried out using a relatively low pressure of argon [Fig. 33(a)]. The microstructure of a bond region is seen in Fig. 33(b) and, although there has been some boundary migration across the original interface, the bond line is clearly visible in places and is probably outlined by small amounts of the original surface oxide. Both tensile shear strength and peel strength at room temperature, and cyclic shear behavior of bonds given a T6 heat treatment were similar to those of the AA7475 base material (Fig. 34). It was also demonstrated that DB and SPF could be used to produce a two-sheet stiffened compression panel which exhibited superior buckling resistance compared with riveted built-up panels, although the bond was constrained during forming.

Fig. 33 AA7475. (a) Effect of pressure and time on bond shear strength (144 psi = 1 MPa); (b) microstructure of bond interface, T6 condition^[62]

Fig. 34 Cyclic shear strength of bonds in 7475; T6 condition (144 psi = 1 MPa)^[62]

Bonding of AA8090 has been carried out using a transient liquid phase based on the invariant reaction:^[63]

at a temperature of ~524°C. This was achieved by cladding 8090 with an Al alloy containing 7% Si (AA4343) and then electroplating with a thin layer of copper. Bonding was carried out at 540°C using 1 MPa for 0.5 h, which gave sufficient time for the solute atoms to diffuse away from the bond line. Hot peel strengths of 5/6 MPa at 520°C were developed with room temperature bond shear strengths > 150 MPa. The former were considered to be high enough to prevent peeling during SPF. The procedures were used to produce a 2-sheet demonstrator part, 220 mm × 220 mm, by subsequent SPF but the bond was constrained during forming.

It is clear from the literature that while procedures for producing bonds with good ambient mechanical properties and good hot peel strength appear to have been established, their suitability for producing 3-sheet structures by subsequent SPF remains to be tested.

CURRENT AND FUTURE DEVELOPMENTS

Introduction

A simplified view of the economics of sheet forming is shown schematically in Fig. 35 where relatively high materials costs and slow forming rates offset the benefit of relatively low tooling costs.^[48] This diagram indicates that the cost effective niche for SPF would involve the production of between 50 and 5000 parts of a given product. For a lower annual output a manufacturing route involving substantial hand fabrication could be more cost effective while at the higher end matched dies could be a less expensive option. For SPF to become a high volume production

Fig. 35 Economics of SP sheet forming. Schematic^[48]

process would require a reduction in materials costs and/or forming times. This points to the benefits of lower cost, faster forming alloys.

The market for products continues to grow but there are a number of factors which may limit this growth and need to be addressed. These have been outlined by Barnes,^[48] and include the existence of only a restricted range of qualified alloys, the relatively high cost of these alloys, the high cost of developing and qualifying new alloys, limited awareness by designers of the potential of SPF, need for an accurate thickness prediction modeling technique accessible to designers, and the integration of SPF parts into existing joining, assembly and finishing systems.

Research and development activity has largely concentrated on materials rather than the SPF process. It was noted by Sanders^[64] that while the number of research publications relating to superplasticity had been growing rapidly for several years, the number of parts produced by SPF had been increasing at a much slower rate.

Materials

Much effort has been devoted to the development of new and faster forming SP materials. This has led to the observation of high strain rate superplasticity (HSRS) which is defined in JISH7007 by the Japanese Standards Association as SP observed at strain rates $> 10^{-2} \text{ sec}^{-1}$.^[65] Most high strain rate SP materials are Al-based, either alloys or Al alloy composites containing ceramic or particulate reinforcement. Although HSRS was initially reported in the mid-1980s,^[66] it has been intensively studied in Al-base materials since about 1990. The subject has been reviewed by Mabuchi and Higashi.^[67]

It is recognized that HSRS is associated with an ultra-fine grain size and this is consistent with the predictions of Eq. 5. A combination of thermo mechanical processing and powder metallurgy has been used to produce alloys with grain sizes of $< 3 \mu\text{m}$. In addition the techniques of physical vapor deposition, mechanical alloying or consolidation of amorphous and nanocrystalline powders result in increasingly small sub-micron grain sizes, capable of giving SP strains to failure at increasingly high strain rates (up to 10^3 sec^{-1}). Data for Al alloys is summarized in Figs. 36 and 37.^[68,69]

Fig. 36 Variation of optimum strain rate for several Al alloys with different grain sizes produced by different processing routes^[68,69]

Fig. 37 Relation between elongation to failure and strain rate for several Al alloys produced by various processing routes^[68,69]

While some nano-phase microstructures show poor thermal stability, those produced by mechanical alloying such as IN9021 (wt% composition: Al-4.0 Cu-1.5 Mg-1.1 C-0.8 O₂) are stable at elevated temperatures because of the presence of about 5% volume of fine (~30 nm) dispersed carbides (Al₄C₃) and oxides (Al₂O₃ and MgO). For this alloy, and for many other HSRS materials, the optimum temperature for maximum SP elongation is above the solidus temperature, or above a temperature at which partial melting has occurred. It is believed that the liquid phase helps with the accommodation of grain boundary sliding, but a liquid phase is not always necessary for a material to exhibit HSRS.^[68]

Although the above materials are interesting and illustrate the importance of grain size on SP behavior, they have only been produced in relatively small amounts by expensive processing and are unlikely to be of significance in a commercial SPF context, at least in the near future.

A further procedure for producing very small grain sizes (~ 1 μm or less) involves equal-channel angular extrusion (ECAE).^[68,69] The principle of this process is illustrated in Fig. 38. A die is used which contains 2 channels of equal cross-section which intersect near the center of the die. A bar of material which fits the channels is pressed through the die to undergo straining by shear. By control of the rotation of the bar between successive passes, the deformation temperature and the number of passes, considerable strains can be developed leading to fine equiaxed recrystallized microstructures.

This redundant work procedure has been applied to several materials including SUPRAL 100 and a Russian SP Al-Mg-Li-Zr alloy (01420), giving grain sizes in the

Fig. 38 Principle of ECAE

range 1/2–1 μm.^[70] Although the resulting microstructures lacked thermal stability on heating to their normal SPF temperatures, they did exhibit HSRS at appreciably lower temperatures, e.g. 300°C for SUPRAL, with elongations of 500–1000%. However, at these lower temperatures flow stresses could be appreciably higher than conventional levels (Fig. 39). Grain refinement by ECAE has so far been applied to material of relatively small cross-section, ~ 10 mm diameter, but it may be possible for the technique to be scaled-up to process larger sections which could be rolled to produce ultra-fine grained sheet for subsequent SPF.

It has been noted that materials such as SUPRAL and Al-Li 8090, which develop SP microstructures by dynamic recrystallization during the early stages of hot forming, have smaller grain sizes, ~ 5 μm, than those processed by the static recrystallization route such as AA7475 and

Fig. 39 True stress versus strain for tensile tests on SUPRAL processed by ECAE^[70]

AA5083 (10–15 μm) and, as a consequence, have higher optimum strain rates for SP flow. To induce dynamic recrystallization it is necessary to prevent recovery and recrystallization during thermomechanical processing of the sheet material by the pinning action of very fine precipitates, e.g. ZrAl_3 . It has been demonstrated that AA7475–0.7Zr produced by powder metallurgy can be processed to develop a fine grain ($\sim 2\mu\text{m}$) microstructure by dynamic recrystallization during hot (SP) forming, and elongations of 500–1000% could be obtained at strain rates of 10^{-3} – 10^{-2} sec^{-1} .^[71]

Various attempts have been made to improve the SPF properties of AA5083 because of its commercial significance, and these have been summarized by Vetrano et al.^[24] It was shown that by applying a range of thermal treatments to Mn, Sc and Zr-containing Al-Mg alloys, the recrystallization behavior could be modified to create either fine, stable grains or a microstructure that was resistant to static recrystallization (i.e. dynamically recrystallizing). However, apart from the costs of producing and qualifying new or modified alloys, it should be noted that sheet producing industries are volume sensitive businesses and there are viable tonnages below which production is not worthwhile.

SPF Process

The production of a part by SPF initially requires the manufacture of a tool. The manufacturing process then involves several stages. These include the application of lubricant to the sheet blank/tool interface, the loading of the sheet into the press, clamping around the edge to ensure a gas tight seal, heating of the sheet to forming temperature, the forming of the part, opening of the press to allow the part to cool sufficiently to enable it to be removed

without distortion, and finally trimming. It is important to optimize all of these steps to ensure that overall costs are minimized.

Tooling is vital to the success of SPF as it has to operate at elevated temperatures without being degraded, contain the gas pressure and withstand the mechanical force applied. It must produce parts of high dimensional accuracy and good surface finish, which should be manufactured at minimum cost. The use of non-planar split clampline tooling can be utilized in female and drape forming to bend the sheet into a near-net shape before starting SPF in order to minimize SP strain levels and thickness variations.^[48] Where CAD data for a part is available, this can be used to produce tools of high quality from solid blocks in commercially competitive times by Computational Numerical Control (CNC) machining. Multiaxial CNC milling can be used to trim parts.

Continual refinement of currently available materials, tooling and forming equipment, will help to expand the cost-effective niche. However, a breakthrough in the development of an Al alloy of ultra-fine grain size and fast forming rate produced at low cost would help to transform SPF from its expanding niche into main stream manufacturing. The evidence so far is that lower cost and faster forming are mutually exclusive objectives.

Surface Chemistry of Adhesion to Aluminum

Margaret M. Hyland

University of Auckland, Auckland, New Zealand

Abstract

Understanding the microstructure and chemistry of the aluminum surface is the key to designing coating and structural bonding systems that endure. The focus of this article is the examination of concepts common to all polymer/aluminum bonding applications and to discuss some common surface treatments alter the surface chemistry and microstructure and how these treatments affect adhesion. Topics covered in this review include: discussion of the untreated aluminum surface, adhesion to aluminum surfaces, prevention of hydration of the bonded interface, and pretreatments,

Keywords: Anodizing; Bonding; Cleaning; Etching; Interfacial hydration; Pretreatments.

INTRODUCTION

Understanding the microstructure and chemistry of the aluminum surface is the key to designing coating and structural bonding systems that endure. In important practical applications, bonding of structural components in aircraft, lacquer systems in packaging, paint, and decorative coatings for architectural, automotive, and general engineering components, the adhesion is generally of a polymer to the aluminum surface. The polymer layer may be a phenol or epoxy structural adhesive, a polyethylene, or other polyolefin coating in flexible packaging systems, or a paint or lacquer. Examples of systems involving bonding of a polymer layer to an aluminum substrate are shown schematically in Fig. 1. In each case, the polymer and the aluminum substrate are linked through the oxide layer on the surface of the metal. This layer, which may be as thin as a few nanometers, plays a crucial role in determining the strength and endurance of the bonding system, and much effort is spent on designing and maintaining a pretreatment schedule which ensures that it is engineered to have the optimum composition and microstructure. The 'optimum' composition and microstructure will vary from system to system and will depend on the nature of the polymer layer, the mechanical requirements of the bond, and the environment it will be exposed to in service.

Surface treatments usually involve a number of steps carried out under strictly controlled conditions and times. They can be roughly broken down into a cleaning step — to remove oils, greases, and dirt, and a step in which the existing oxide is removed; in the same or a following step, a new, tailored oxide or conversion coating is formed. This may be followed by sealing or priming of the surface. Examples of surface preparations^[1–4] are given in Table 1. In general, the more demanding the environmental and/or mechanical performance required, the more extensive the pretreatment procedure. The requirements placed on a

structural bond in an aircraft, for example, will be significantly greater those that for a packaging laminate, and the pretreatment process reflects this. The focus of this chapter is to examine key concepts common to all polymer/aluminum bonding applications and to examine how some common surface treatments alter the surface chemistry and microstructure and effect adhesion.

THE UNTREATED ALUMINUM SURFACE

The surfaces of aluminum alloys after forming are not conducive to adhesion. They will be covered with an aluminum oxide of varying thickness and composition depending on the preceding forming steps. Oxides formed at low temperature, below about 375°C, are composed of a thin, 1–2nm amorphous γ - Al_2O_3 adjacent to the metal which is overlaid with progressively hydrated surface oxides and hydroxides.^[5] The low-temperature hydrated overlayer is typically composed of hydrated gel-like pseudoboehmite (AlOOH), crystalline boehmite, and/or trihydroxides, $\text{Al}(\text{OH})_3$, bayerite, or gibbsite depending on the relative humidity and exposure time,^[5–11] and the total oxide thickness may be between 2 and 60 nm.^[8,12–14] The thicker oxides, in particular, lack the microstructure, porosity, mechanical strength, and hydration resistance to form durable bonds with a coating or adhesive. If higher temperature treatments such as annealing/degreasing have taken place, then the oxide will also contain oxides or hydroxides of the alloying elements. Magnesium, Si, Li, Na, Mn, and Cu preferentially segregate to the surface, having detrimental effects on the hydration/corrosion resistance of the interface.^[15–19] Precipitates of intermetallics can also form, which, in the case of Fe intermetallics, reduce the interfacial hydration resistance or, in the case of Cu intermetallics, reduce the interfacial corrosion resistance.^[19,20]

Fig. 1 Schematic of the interface region for two polymer/aluminum systems

Table 1 Examples of surface treatments for coating and structural applications

Food packaging laminates[1]	Anneal 280°C
Structural bonding in aircraft components [2]	Vapor degrease or alkaline clean; vacublast (dry alumina); vapor degrease or alkaline clean; chromic/sulfuric etch; chromic acid anodize; chromate primer; bond with epoxy-based adhesive
Screen cloth [3]	Alkaline clean; rinse; phosphate/chromate conversion coat; rinse; dry; varnish/paint
Landing gear [3,4]	Clean in non-etching cleaner (alkaline); rinse; deoxidize with chromic/sulfuric etch; rinse; chromate conversion coat; rinse; apply primer; polyurethane topcoat

In addition to the oxide/hydroxide layer, the surface will be contaminated with hydrocarbon and silicone processing aids, lubricants, rolling oils, etc., which hamper wetting of the surface by the adherent.^[21] Below the oxide, a layer of deformed, micrograined metal will be present, especially in rolled, then heat-treated alloys. During rolling, surface oxides will become incorporated into this deformed substrate layer, which, researchers have shown, contributes to reduced corrosion resistance.^[22] Thus, pretreatments are designed to remove the organic contaminants, remove the existing oxide layer, and develop a tailored surface layer with the required microstructure and chemistry to promote bonding and resist environmental attack. However, once the desired surface structure has been obtained, it will still be susceptible to attack by moisture and should be used promptly, or stored under appropriate conditions to prevent a friable, hydrated oxide from reforming.

ADHESION TO ALUMINUM SUBSTRATES: GENERAL PRINCIPLES

Strong bonds between an aluminum surface, or, more correctly, between the oxide layer on the aluminum surface and an organic coating or adhesive, are generally acknowledged to be the result of both mechanical

interlocking and physicochemical bonding.^[23,24] Effective mechanical interlocking requires the surface oxide to be sufficiently rough to allow the coating/adhesive to key into the aluminum surface. The greater the interlocking, the more difficult it will be for a crack to propagate at the interface, and the greater the amount of plastic deformation the substrate and/or polymer must undergo for the bond to rupture, thereby increasing the energy needed to separate the interface. Surface roughness also increases the area of contact between the aluminum substrate and the polymer, maximizing the number of potential sites for physicochemical bonding. Treatments such as grit blasting and acid etching will increase the macroroughness of the surface by introducing surface features such as scallops and whiskers, but this can be increased much more by generating ‘microroughness,’ in other words, fine porosity, in the oxide layer itself. Figure 2 is a schematic of the macroroughness and microroughness generated by chromic acid etching and anodization. The oxides produced by anodization, particularly in phosphoric acid, contain such porosity in the form of channels extending from the outer surface almost to the surface of the metal. Anodization is the preferred surface treatment in the preparation of structurally bonded joints in aircraft because of the strength and durability of the bond formed. When the polymer can penetrate well into the surface oxide,

physicochemical bonding and mechanical interlocking are maximized, forming what is sometimes referred to as a *microcomposite*. Figure 3a shows an example of microcomposite formation in a structural bond.^[25] The image is a cross-section of a phosphoric acid anodized 2014 A aluminum alloy surface to which a waterborne epoxy primer was applied. The oxide layer (green) has clearly been infiltrated by the primer (blue).

For mechanical interlocking to be effective, the polymer must be in intimate contact with the surface oxide. In other words, the polymer must be able to wet the surface oxide, penetrate the pores, and displace air from the interface. The extent of pore penetration in a fixed time interval will depend on the viscosity of the organic, the size and shape of the pore, and the polymer/substrate contact angle.^[23] The contact angle is a measure of how well a liquid wets a solid or, for bonding to aluminum, how well a polymer coating or adhesive wets the surface oxide on an aluminum substrate. It is measured by placing a droplet on a substrate; as shown in Fig. 4, the smaller the angle, the greater the wetting. Aluminum oxide surfaces have high surface energies and are, generally speaking, more wettable than low surface energy surfaces like teflon,^[23] but the wettability of aluminum oxide is reduced when the surface is covered by contaminant hydrocarbon. The common water break test gives a measure of this. Where the aluminum surface is clean, the contact angle is small, and

water spreads across the surface freely. Where there is surface contamination (usually hydrocarbon), the contact angle is high, and the water droplets bead and do not spread. On a properly prepared aluminum surface, the polymer coating or adhesive should also spread across the surface, but it should be noted that a positive water bead test is not necessarily a good indicator of whether the polymer will also wet the surface. It signals the presence or absence of contaminant hydrocarbon, which will interfere with the wetting of the aluminum surface by water or the polymer coating or adhesive.

Kinloch et al. demonstrated the importance of wetting on bond strength and durability by comparing the fatigue behavior of adhesive joints prepared using a variety of metal pretreatments.^[25] Aluminum surfaces that had been degreased only prior to bonding exhibited voids at the adhesive/oxide interface indicative of poor adhesive/oxide wetting (Fig. 3). These joints had lower fracture energies and strain release rates in both dry and humid cyclic fatigue testing compared to chromic acid etched and phosphoric acid anodized surfaces, where the adhesive wetted the oxide surfaces. Voids at the interface will act as stress concentrators, reducing the mechanical strength of the interface. In addition, such unfilled pores at the interface will allow moisture to more readily penetrate the interface — moisture at the interface is one of the major causes of bond failure, as discussed in the following section.

Fig. 4 Schematic of droplet wetting a surface. The contact angle is θ , and γ_{LV} , γ_{SV} , and γ_{SL} are the interfacial tensions between the liquid–vapor, solid–vapor, and solid–liquid phases, respectively. When the contact angle is zero, the liquid spontaneously spreads at a rate determined by the liquid viscosity and surface roughness

Physicochemical bonds can range in strength from weak van der Waals interactions to acid–base interactions and covalent bond formation. The van der Waals forces are relatively weak and operate over extremely short distances — the strength of the interaction falling off as a function of distance to the sixth power.^[23] They are due to the presence of dipoles — unequal electron sharing between an electronegative atom, such as fluorine or chlorine, and a more electropositive atom, such as carbon, causing one atom to be slightly negative, the other slightly positive. Positive dipoles in the organic will interact with negative dipoles in the oxide (or vice versa). The dipole may be permanent, because of the polar nature of the atoms in the bond, or may be induced in non-polar systems by interaction with a permanent dipole or by interaction with another induced dipole. Thus, van der Waals interactions are usually subdivided into *dipole–dipole*, *dipole–induced dipole*, and *induced dipole–induced dipole* (also called *dispersion*) forces between atoms of the substrate and those of the polymer. Although this type of interaction is weak, dispersion forces, in particular, are ubiquitous, and will be significant when the substrate and polymer are in intimate contact and when the number of such bonds is large — i.e., when the contact area is high.^[23,24] Hydrocarbon polymers such as polyethylene and polypropylene that lack polar groups adhere to aluminum foil primarily through dispersive forces.

Acid–base interactions can take place at interfaces and play a role in adhesion: the work of adhesion increases when an acidic substrate is coupled with increasingly basic liquids or vice versa.^[23] A variety of spectroscopic techniques have shown that the organic compounds which contain nitrogen functionalities and which act as Lewis bases bond to the Lewis acid sites on the aluminum oxide surface.^[26,27] Amine cured epoxies will also be able to bond through this mechanism.

One rule of thumb^[23] for adhesive bonding is to choose an adhesive with the opposite acid/base character to that of the substrate. Unfortunately, determining the acid/base character of the oxide layer on an aluminum substrate is not straightforward, since the oxide is amphoteric.

The surfaces of aluminum oxides contain a variety of oxide, hydroxyl, and metal cation sites with acid or basic character depending on the bonding arrangement.^[5,28] The number and type of these groups, and therefore the net acid or basic character of the surface, will vary with the specific aluminum oxide or hydroxide phase present at the surface, degree of hydration of that phase,^[5,28] and the presence of oxides of alloy elements or impurities, such as magnesium or silicon.^[29,30] These, in turn, will be strongly dependent on the surface treatment regime. Thus, the precise role of acid–base interactions in adhesion to aluminum is not well understood, but the development of surface analytical techniques to measure the acido-basicity of aluminum surfaces offers promise.^[29–32] Oxygen binding energies from x-ray photoelectron spectroscopy (XPS) correlated well with other spectroscopic and wet analytical techniques to give a measure of the acid/base nature of the surfaces of aluminum alloys treated using common pretreatment methods. The acid/base nature is apparently quite dependent on the specific treatment and alloy — there are no obvious trends as a function of treatment type (acid etch, alkaline clean, anneal, corona discharge) or alloy.^[29–33] Nevertheless, changes in the surface acidity have been correlated with changes in bond strengths.^[32,33] The adhesive strength of amine cured epoxy and polyurethane primers, for example, has been shown to vary with the acid/base character of the oxide layer,^[32] moving from adhesive to cohesive failure as the surface became more basic. However, it would be unwise to generalize these results, since a number of contributing factors, such as surface morphology and chemical reactions in the polymer, also contribute to the measured strengths.

All other factors being equal, covalent bonding at the interface has the potential to generate the strongest interfacial bonds.^[23,24] One of the primary targets in the development of adhesive systems is to engineer the surface chemistry of the components to allow covalent bonds to form across the interface.^[23,34] The surface aluminum oxide has the potential to form covalent bonds with some organics, but direct evidence of such bond formation is not readily found in the literature with the exception of a few important systems, carboxylates and organosilanes. One of the few clear examples of direct chemical bond formation is the interaction of carboxylic acid groups with surface hydroxyls on aluminum oxide layers. The COO– functional group forms a monodentate bond with basic surface groups forming Al–O–C bonds, which can be evidenced directly by infrared spectroscopy.^[34–36] The incorporation of the carboxylate functional group through copolymerization,^[36] grafting,^[34,37] or plasma treatment^[38] has been used to enhance the adhesion of polyolefins to foil surfaces for flexible packaging applications.

The other well-studied example of covalent bonding at the aluminum interface is the silane coupling agent. Organosilanes hydrolyze in water, providing an OH group at one end of the molecule which will react with

the oxide surface, forming strong Si–O–Al bonds.^[39,40] The organic end of the molecule is compatible with the paint or primer, thus forming a link across the interface, increasing the adhesion strength in paint and structural bonding systems.^[41]

DURABILITY OF THE BOND — PREVENTING HYDRATION OF THE INTERFACE

These multilayered aluminum/aluminum oxide (or conversion coating)/polymer structures can fail within the polymer layer, within the oxide layer, or at the metal/oxide or oxide/polymer interfaces. A variety of test methods and geometries have been developed to measure the strength of the polymer/aluminum bond and its durability in humid or corrosive environments (see, for example, Ref. [42]). Detailed discussion of the methods is outside the scope of this review, but in addition to the numerical treatment of the data obtained from the tests, the fractured specimens are analyzed to determine the locus of failure. Failure within the polymer is termed *cohesive*, and any failure at or below the polymer/oxide interface is often referred to as *interfacial* or *adhesive*. Occasionally, a distinction is made between failures at the polymer/oxide interface (*adhesive failure*) and those at the oxide/metal interface (*interfacial*).^[41] In this chapter, interfacial will refer to any failure below the polymer/oxide interface.

Polymer/aluminum bonds are notoriously susceptible to water — ingress of moisture hydrates the interface, initiating interfacial failure. This is the major cause of bond failure in such systems. Analyses of the two sides of the failed bond show that the failure is often initially cohesive — that is, it takes place within the adhesive, but with exposure to humid atmospheres, the locus of failure moves to the coating–oxide interface (see, for example, Refs. [7,24,25,41]).

Generally speaking, water damages the interface in two ways: it disrupts the oxide/polymer chemical interactions and it changes the microstructure and chemistry of the oxide layer itself, thereby disrupting mechanical bonding.

In many cases, the oxide/polymer bond is thermodynamically unstable in the presence of moisture — particularly if the bond is based on weak secondary, van der Waals interactions. For example, the work of adhesion for aluminum oxide/epoxy interface has been calculated in the absence and presence of moisture. The bond is stable (work of adhesion is 178 mJ/m²) unless water is introduced, in which case the work of adhesion becomes negative (–137 mJ/m²).^[23] Both sides of the interface will react with water. X-ray photoelectron spectroscopy shows that with water exposure, carboxylate groups form in the epoxy and the aluminum oxide becomes increasingly hydroxylated.^[43]

The changes that take place within the oxide layer itself are equally destructive. These changes proceed in a manner similar to the reaction of aluminum surfaces

immersed in water.^[8] As described earlier, moisture at the interface initially converts the aluminum oxide to a gel-like pseudoboehmite, which progressively extends into the oxide layer. The outer oxide surface eventually converts to boehmite, crystalline boehmite, and/or one of the trihydroxides, gibbsite or bayerite. The hydrated oxide is reported to be mechanically weaker than the γ -Al₂O₃ formed from the surface treatments.^[21] The volume expansion that accompanies the phase transformations described may also contribute to bond failure by increasing internal stresses.^[17]

Water can diffuse into the interface through the polymer layer and via voids at the interface or in the oxide layer. Eliminating voids by wetting of the oxide by the polymer and intimate contact of the two can help to slow the rate of moisture ingress and improve bond durability.^[25,44,45] This is illustrated in Fig. 3,^[25] which shows cross-sections of aluminum/epoxy structural joints prepared by phosphoric acid anodization (PAA) and fatigue tested under dry and wet conditions. Where a water-based primer was used prior to application of the epoxy adhesive, energy filtered transmission electron microscopy (EFTEM) micrographs of cross-sections of the joint show that a microcomposite interphase, described earlier, is formed (Fig. 3a). With no primer, the adhesive fails to penetrate the porous oxide, as shown in the EFTEM micrograph (Fig. 3b). Although the two had similar initial fracture energies and similar threshold strain–energy release rates (G_{th}) when tested under dry conditions, the unprimed joint has a much lower G_{th} under wet fatigue testing. Transmission electron microscope images of the wet cyclic-fatigue-tested specimen (Fig. 3c) show that the oxide layer has undergone hydration. A dense oxide is visible at the interface between the PAA oxide and the adhesive, which would have disrupted oxide/polymer adhesion. In contrast, the primed oxide, lacking open porosity, showed no evidence of a dense hydrated oxide at the interface.

Impurities at the interface can also reduce bond strengths. Magnesium and lithium oxides or hydroxides at the surface have been shown in some systems to be detrimental to bond durability.^[12,15,16,19] These elements are concentrated at the surface, sometimes a thousand-fold over their bulk concentration, during annealing. Their hydroxides are soluble and will increase the local pH when water is introduced to the interface. This increase in pH enhances the solubility of aluminum oxide, disrupting the oxide layer.^[15] However, other studies have found that the presence of Mg oxides and hydroxides enhances bond stability.^[46,47] Other factors such as curing chemistry of the adhesive may play a role; amount and form of the magnesium may also play a role.^[47]

Fluoride ions at the surface, from insufficient rinsing or rinsing using fluoride containing tap water, can form soluble aluminum species and disrupt the oxide layer, which can be sufficiently extensive to dissolve the surface layer, altering surface topography.^[48]

A range of strategies are used to improve the water resistance of the interface: ensuring there is minimal porosity at the interface by maximizing oxide/polymer wetting; reducing the susceptibility of the polymer/oxide bond by designing for covalent bond formation between them (silane coupling agents); employing targeted cleaning steps to selectively remove detrimental impurities; reducing the rate of oxide hydration by using hydrophobic sealants or passive, insoluble chromate or phosphate conversion coatings.

COMMON PRETREATMENTS FOR ALUMINUM SUBSTRATES

A multitude of prebonding surface treatments procedures are available for aluminum. Critchlow and Brewis identify 41 individual pretreatments.^[49] The combination of pretreatment steps used for any particular application will depend on the mechanical requirement of the bond in service, the severity of the service environment, the alloy in question, and the polymer coating/adhesive. Details of pretreatment procedures for various applications can be found in Refs. [1,4,41,50,51]. The pretreatments may be divided into *mechanical*, *chemical*, and *electrochemical*.^[49] This section describes some of the common aluminum pretreatments from each of these categories and shows how these treatments alter the microstructural or chemical composition of the surface to improve the strength and environmental resistance of the aluminum/polymer interface. As a general rule, the order of bond strength and durability is electrochemical > chemical > mechanical. There will always be exceptions, and the quality of the preparation and the compatibility of the polymer with the surface oxide can change these relative orders.

Mechanical Pretreatments

Mechanical pretreatments are usually the first and occasionally the only stage in a pretreatment schedule. This category covers a broad range of processes, not all of which are strictly 'mechanical,' but have the common feature of generally being less sophisticated than the chemical and electrochemical treatments described later, both in the equipment required and in the changes they induce in the aluminum surface. This stage can fulfill multiple functions: removal of gross oxide layers, surface roughening, and degreasing; these may be carried out together or as separate steps. Common mechanical pretreatments include grit blasting, mechanical abrasion, solvent degreasing, and corona discharge/plasma.

Grit blasting, generally using silica or alumina particles, and *mechanical abrasion* physically remove gross surface contamination and some of the existing oxide and roughen the substrate, enabling mechanical keying. They are often followed by a degreasing step. Larger grit particles produce

greater surface roughness, and the resultant bonds are also apparently less durable^[46,52] than those on smoother surfaces. At the same time, grit blasting also changes the wettability of the surface — rougher surfaces (irrespective of grit type) have lower surface energies than smoother surfaces.^[52] This effect is due, in part, to the surface features such as asperities, which reduce wettability by preventing liquid flow and droplet spreading, but may also be related to Na and Mg impurities from residual grit. Grit blasting with finer grit leaves higher levels of these surface contaminants, which leaves the surface with a higher surface energy.^[52]

Solvent or vapor *degreasing* with solvents such as trichloroethylene, methylethyl ketone, or methylene dichloride is a cleaning step to remove hydrocarbons. This step does not affect the surface morphology (unless it is coupled with mechanical abrasion or ultrasonics) or surface chemistry of the oxide layer, nor does it remove adherent inorganic contaminants such as metal oxides and hydroxides of alloy elements. It is an important step because removal of mill oils, processing aids, etc., increases the wettability of the oxide, allowing the adhesive/coating to come into intimate contact with the oxide. Because the chemistry and morphology of the oxide are unchanged, this may not be sufficient to ensure strong bonding if this is the only treatment applied. More often, degreasing takes place prior to other processing steps such as alkaline clean or acid etch, and the improved surface wettability means that these solutions can evenly wet and uniformly act on the alloy. Acid and alkaline clean and etches will also remove surface hydrocarbons, but they are more effective if the surface is solvent degreased first.

Foils used for laminates in food packaging are degreased in the annealing step. At annealing temperatures, the hydrocarbons are oxidized, and their removal lowers the contact angle of the surface with water.^[53] In addition to the removal of hydrocarbon residues, the oxide layer thickens, and there is a significant change in the oxide composition, with the migration of alkali and alkaline earth elements such as Na and Mg to the surface.^[12,15–17] The oxide itself may be converted to boehmite.^[11]

Aluminum may also be pretreated by exposure to activated gases in corona discharge or plasma treatments.^[33,38,53] The reactive atmosphere, typically oxygen or nitrogen, oxidizes hydrocarbon residues, removing the surface contamination, increasing the number of surface acid and base groups, and reducing the water contact angle.^[33,53] The oxide layer thickens — the final depth depending on treatment time and energy.

Chemical Pretreatments

Acid/Alkaline Etches and Cleaning

Acid and alkaline cleaners and etches are frequently used to prepare the aluminum surface. They may be used as the final treatment (for example, chromic acid etches), or used

as part of a multistage process prior to conversion coating or anodizing. A degreasing step is generally carried out before acid/alkaline treatment; though these treatments can remove hydrocarbon contaminants, they are more effective if the surface has been degreased first. Acid and alkaline solutions act by chemical dissolution of the surface oxide and, to a greater or lesser extent, the metal as well. The distinction between 'cleaning' and 'etching' is therefore a matter of degree of aggressiveness and selectivity of attack. While both acid and alkaline treatments 'clean' the surface (aluminum oxide is soluble in either highly acidic or highly basic solutions), the resulting surface chemistries and textures differ, and therefore acid and alkaline treatments have different functions in a carefully tailored treatment process. For example, many pretreatment procedures employ alkaline solutions to remove the air-formed aluminum oxide, followed by an acid etch, its function being to remove oxides of alloying elements not dissolved in the alkaline treatment and/or develop a surface microstructure to enhance mechanical interlocking.

Alkaline Clean/Etch

Alkaline cleaners based on sodium carbonates or phosphates are less aggressive than sodium hydroxide, which tends to etch the metal significantly. Typical formulations of etching and non-etching alkaline treatments are given in Ref. [1]. Alkaline cleaners can be further inhibited by the addition of silicates, which form a protective film over the surface. Rinsing to remove the film and residual basic solution is important.

After alkaline cleaning, the surface oxide is considerably thinner than the native oxide — less than 10 nm.^[47] Alkaline cleaning and etching can leave the surface enriched in alloying elements, Si, Fe, Cu, Mg, Mn, Mg,^[1,18,19,54] and in capacitor foils, Pb.^[55] These may be as a uniform oxide or hydroxide layer, or as localized stains or 'smut.' An acid 'de-smut' treatment dissolves the residue, which, as discussed earlier, could otherwise have detrimental effects on the bond strength and corrosion resistance. Aside from this, little other information about the surface chemistry of the alkaline treated surface is available. Alkaline etched surfaces may develop a 'scalloped' structure.^[47,55,56] This treatment can be used to remove the micrograined structure that develops in cold rolled alloys and which has been implicated in their poor corrosion resistance after heat treatment.^[19]

Acid Etches

Acid etches are used for a variety of purposes: to remove the native aluminum oxide; to de-smut an alkaline cleaned surface; to develop a specific surface microstructure for bonding; and as a pretreatment for anodizing because the nature of the acid etch will affect the morphology of the anodized film. The most common acid treatments for

bonding applications are the chromic acid etches (CAE) — mixtures of chromic and sulfuric acids, although HF/HNO₃, HF/H₂SO₄, and chromic/phosphoric combinations are also employed. The drive to reduce the use of toxic, hexavalent chromium has led to the development of other etching systems — most notably the 'P2' etch and FeSO₄/H₂SO₄. Details of acid etch solutions and procedures can be found in Refs. [1,4].

Acid etching results in a thin, 5–40 nm thick oxide film.^[40,44,48,57] The microstructure of such oxides formed by P2 and chromic acid etching, in particular the Forest Product Laboratories (FPL) and modified FPL chromic acid etches, have been well characterized.^[25,40,44,48] A schematic of the morphology of the FPL etch is shown in Fig. 2a. The surface is covered with shallow scalloping, approximately 40 nm wide. Fine 'whiskers' protrude from the surface to a height of about 40 nm which are believed to be important in mechanical interlocking of coating/adhesives to the aluminum surface. The oxide is an amorphous Al₂O₃, and small quantities of ions of the treatment solutions are adsorbed onto the surface: Fe and sulfate in the case of the P2 etch, and Cr and F in the case of the FPL etch.^[44] The surfaces of FPL etched substrates are susceptible to damage by hydration and presence of impurities. Fluoride contamination, for example, causes the whiskers to be dissolved.^[48]

Even when acid etches are used as an intermediate step in the treatment process, they may still influence the chemistry and structure of the final bonding surface. Depending on whether an FPL or P2 etch is carried out prior to anodization, more 'open' or 'closed' pore morphologies, respectively, are observed.^[44] Acid de-smutting changes the surface chemistry by removing Mg, Si, Cu, Mn, and Fe oxides and hydroxides, which would otherwise remain at the bonding interface and degrade bond strength and durability.

Conversion Coatings

Conversion coatings are adherent layers of insoluble chromium oxides/hydroxides or Al, Cr, Zn, and Mn phosphates, which largely replace the aluminum oxide. They are typically used for surfaces that are to be lacquered or painted and enhance bond durability of the polymer coating to aluminum alloys by providing corrosion protection to the metal through formation of a passive layer and presentation of a surface that enhances polymer adhesion.

Chromate conversion coatings are amorphous passive layers of two common types: chromium phosphates or chromium oxide/hydroxides. These systems provide excellent corrosion resistance and are less expensive than anodizing, which is also used as a paint or lacquer base. However, hexavalent chromium is carcinogenic, and there are significant pressures to reduce or eliminate its use. Chromium-free alternatives are being actively sought. Twite and Bierwagen^[58] and Metroke et al.^[59] review

some of the alternative systems, which include cerium hydroxides (CEROX), silica, titania-silica, zirconia sol-gels, direct electrodeposition of coatings (e-coat), plasma polymerized coatings, and conducting polymer coatings.

Chromium oxide/hydroxide conversion solutions typically contain soluble Cr(VI), added as either CrO_3 or Na_2CrO_7 , fluoride ion, usually as NaF, and sometimes ferricyanide, $\text{Fe}(\text{CN})_6^{3-}$ accelerants, at pH 1–2. The fluoride activates the surface by dissolving the surface aluminum oxide. Once it is sufficiently thinned, reduction of Cr(VI) to Cr(III) can take place, and chromium oxide/hydroxide is deposited. The exact form of the oxyhydroxide is unclear, but it is variously represented as CrOOH ^[60] or hydrated chromium oxide, $\text{Cr}_2\text{O}_3 \cdot n\text{H}_2\text{O}$.^[61] Varying amounts of aluminum hydroxide will also be precipitated and incorporated into the growing chromate film.^[60] A thin aluminum oxide layer remains immediately adjacent to the aluminum surface overlaid with a thicker more porous layer, giving a total thickness typically between 60 and 200 nm.^[60,62] Fluoride,^[63] ferricyanide,^[64] and unreduced Cr(VI)^[65,66] are also found in the coating. Chromium (IV) is important for the ‘self-healing’ ability of these coatings. If the conversion coating is disrupted and the metal exposed, Cr(IV) can be reduced to Cr(III) oxide/hydroxide, reforming the passive layer. The pH of the chromating solution plays an important role in the quality of the coating. As the pH is reduced, thicker coatings can form,^[60,61] and more Cr(VI) is incorporated into the layer.^[65] At the same time, the coating becomes more porous and more permeable to ion transport.^[61] Chromating can also be done using alkaline solutions, hydroxyl serving the same function as fluoride, that is, to activate the surface by dissolving the residual oxide.

The uniformity of the coating is dependent on surface treatments prior to chromating and on the microstructure, in particular the presence on intermetallic precipitates.^[63,67–69] The chromium oxide/hydroxide forms as isolated deposits, which grow in size and number with the treatment time.^[62] Degreasing and uniform removal of the surface oxide (deoxidizing) by alkaline or acid etching are essential to ensure uniform wetting by the chromating solution and a uniform rate of deposition across the surface.

Chromium phosphate conversion coatings are formed in acidic solutions containing CrO_3 , F^- , and PO_4^{3-} . Like chromium oxide/hydroxide coatings, the existing surface oxide is thinned by fluoride, allowing electron tunneling and reduction of Cr(VI) to Cr(III), but in these solutions, CrPO_4 is deposited. The coating is duplex, having a more porous, amorphous overlayer with a dense layer at the metal interface.^[70] The dense layer contains less phosphate and relatively more Cr, O, Al, and especially F, which may be mixtures of Cr_2O_3 and AlF_3 .^[71] The overlayer is predominantly chromium phosphate, but also contains some Al and F.^[71] In the early stage of the deposition process, small nodules are formed, which agglomerate, forming filaments — the final texture being dependent on substrate chemistry and topography.^[69]

Zinc phosphate is used as a conversion coating prior to painting for parts where aluminum is combined with steel or galvanized steel.^[72] These treatments differ in several fundamental ways from the chromium coatings — they are crystalline and offer less corrosion resistance than the chromium-based conversion coatings. The crystalline structure provides a barrier layer to moisture and assists the mechanical keying of the polymer coating.

It is not clear how the chromate and phosphate coatings enhance adhesion. One suggestion is that the porosity of the layer allows penetration of the polymer coating/adhesive system,^[69] enhancing mechanical and van der Waals interactions. Stronger bonding interactions could also take place through the surface hydroxyl groups, which will be present on the oxide/hydroxide and phosphate surfaces. Hydroxyl groups, which may be acidic or basic in nature, may participate in hydrogen bonding or acid/base interactions with the polymer, just as they have been implicated in the adsorption of Cr(VI).

Electrochemical Pretreatments: Anodizing

Anodizing refers to the electrochemical formation of an oxide layer when aluminum is anodically polarized in (usually) aqueous solution. Anodizing of aluminum alloys is widely used to form a corrosion and abrasion resistant coating in its own right, as a base for paints, organic finishes, and adhesive bonding, and in countless specialist applications. The diversity of applications is a reflection of the range of oxide microstructures, thicknesses, and compositions that can be generated. These depend on the specific anodizing procedure — voltage, amperage, solution composition, time, alloy pretreatment — giving rise to a bewildering array of anodizing systems. Reviews of the structure and formation mechanism of anodized aluminum films can be found in Ref. [73] and descriptions of specific procedures and technologies in Refs. [1,72,74]. Fortunately, the resulting oxides can be broadly divided into the non-porous, barrier oxides and the porous films. It is the latter that are used in adhesive/coating applications; the two principal procedures for producing porous oxide films are chromic acid (CAA) and phosphoric acid anodization. Anodization is used extensively in the aerospace industry to prepare aluminum for structural bonding and painting.

Phosphoric Acid Anodization

Phosphoric acid anodization was developed to create surfaces amenable to structural bonding in aerospace applications. The surfaces are degreased, chromic/sulfuric etched, and then anodized in 10wt% H_2SO_4 at 10 V. Under these conditions, PAA films are typically 0.5–1 μm thick, with a thin (< 100 nm) barrier oxide adjacent to the metal underlying a distinctive pore structure.^[1,25,48] This is shown schematically in Fig. 2b. Film growth takes place at the

metal surface as aluminum is converted to oxide and the metal consumed. The vertical pores are hexagonal in cross-section and roughly 40 nm in width, with pore walls of 10 nm.^[48] The thickness of the pore wall increases with applied voltage, thus reducing the amount of open porosity.^[1] This open structure offers potential for significant mechanical interlocking and microcomposite formation, provided the adhesive/primer/coating wets the surface and penetrates the pores. The surface morphology depends on the pretreatment used. When the surfaces are FPL pretreated, the outer surface morphology is similar to the whisker-like FPL morphology, providing additional interlocking capacity.^[44,48] P2 etched specimens have been observed to have a denser, less open surface structure.^[44] The oxide is amorphous Al_2O_3 ,^[25] with phosphate incorporated in the outer sections.^[57,75] Davis has shown that the phosphate incorporated at the surface is in the form of a low solubility aluminum phosphate, which helps to seal the surface.^[76] Continued exposure to moisture will eventually dissolve the phosphate, and bond failure is correlated with the loss of phosphate at the interface allowing moisture to hydrate the aluminum oxide to boehmite and eventually bayerite.^[76]

Chromic Acid Anodization

Chromic acid anodized oxides are formed in electrolytes containing 2.5–10 wt% CrO_3 .^[72] Like PAA oxides, they are amorphous Al_2O_3 , with a columnar pore structure that grows from the aluminum surface into the metal. However, they have a thicker barrier layer, are thicker overall (1.5–7 μm),^[1,4,72] and denser than PAA oxide films, and few, if any, chromium ions are incorporated in the oxide.^[1,64] The pore structure is less regular than for PAA oxides and the cell walls thicker^[48] (Fig. 2c). The density contributes to the mechanical strength of these oxides and goes some way to slowing moisture ingress in the absence of a passive phosphate. It is expected that the less open structure hinders the interpenetration of adhesive/polymer, but this depends on the organic used — examples of microcomposite formation have been found.^[45] As with PAA oxides, the surface morphology can be altered by pre- and postanodization procedures (for example, Ref. [45]).

Abstract

This article presents some information related to the chemical conversion procedures applied onto Al and its alloys involving both classical hexavalent chromium-based solutions and the most recent ones involving transitional metals and/or rare earth compounds, as environmentally friendly alternatives. The main characteristics of the formed thin films, including appearance, composition, morphology, corrosion resistance, and performance, are also presented.

Keywords: Cerium conversion coating; Chemical conversion; Chromium-based conversion coating; Chromium-free conversion coating; Molybdate conversion coating; Surface modification of aluminum; Surface treatments.

INTRODUCTION

An important component of the surface finishing processes applied onto Al and its alloys is represented by the conversion coatings, defined as a process that removes the native oxide formed on a metallic surface while a new formed layer grows as a result of a reactions sequence, possessing certain characteristics. Usually, they are applied in order to provide a better corrosion protection, to improve the adhesion of paint systems, or to extend their decorative characteristics. The main attractions of chemical conversion coatings are the low required costs and the shorter process period associated with the possibility of application on a large range of metallic parts, using quite simple equipment as compared to electrochemical procedures. Moreover, these films may also assure a suitable temporary protection when relatively long storing periods are required.

Hexavalent, chromium-based conversion procedures are among the most developed and large scale applied ones, and the formed oxide layers provide the best corrosion protection for Al and its alloys.

Due to the safety and health-related concerns associated with the use of chromate-based solutions, many research efforts have focused on finding and developing viable alternative solutions that partially or entirely replace them. Therefore, conversion coatings involving Cr (VI)-free solutions, containing transitional metals (e.g., titanium, zirconium, molybdenum, tungsten, vanadium, trivalent

chromium), and/or rare earth compounds (e.g., cerium, lanthanum) are extensively investigated.

Several types of aluminum surface modifications developed in the past years involving chemical conversion procedures are reviewed in this article.

CHEMICAL CONVERSION LAYERS ONTO ALUMINUM-BASED SUBSTRATES GENERAL ASPECTS

Aluminum and its alloys are light metals largely used in various industries including automotive industry, aerospace sector, medical appliances, architecture, and electronic equipment. They are characterized by a relatively low cost, a low thermal expansion coefficient, and good wear resistance and strength-to-weight ratio.^[1,2]

A large range of surface treatments are applied onto Al and its alloys, being a major field of industrial finishing, in order to enhance their corrosion protection, improve the adhesion of paint systems, extend their decorative characteristics, and allow particular functional properties.^[2-5]

A significant part of the surface finishing processes is represented by the conversion coatings, defined as a process that removes the native oxide formed on a metallic surface and a new formed layer that grows as a result of a reactions sequence, possessing certain characteristics.^[2,6-9]

According to Wernick et al.,^[2] there are several properties the conversion coatings should possess:

- The coating layer should be continuous over the Al surface and impervious to liquids and gases.
- Preferably, the coating should be inert and almost insoluble in the conversion solution; in addition, it has to have a low environmental reactivity.
- The coating presence should not promote galvanic attack on the substrate.
- The coating should possess mechanical properties and self-healing characteristics.
- It should bond readily to the substrate and subsequently applied finishing coatings such as paint systems.
- The coating system has to be able to perform the desired function, such as decorative aspect or corrosion protection.

Usually, the conversion coating systems can be classified as follows:

- Coatings developed by hydrothermal treatment.
- Chromate-containing conversion coatings.
- Chromium-free conversion coatings.

During the process, a colored surface may be formed, ranging from colorless, light yellow to dark brown, even black. The color formation is due to the light interference in the semitransparent coating, so that it may also be a measure of the coating thickness. Generally, the darker the conversion layer the thicker it is, thereby providing a better protection.

The first category of coating systems is based on the immersion of Al metal in water at elevated temperatures, when various forms of alumina may be developed, such as boehmite and bayerite, depending on the operation parameters. This hydrothermal treatment is relatively specific to capacitors applications and to antireflective coatings fabrication to reduce the optical loss of a large range of optical devices.^[2,8,10,11] The total film thickness is of the order of several hundreds of nanometers.

Chromate-containing conversion coatings are among the most developed and large scale applied ones, and the formed oxide layers assure the best corrosion protection for Al and its alloys. Usually, these conversion solutions include additional compounds such as fluorides, phosphates, and silicates.^[2,12] In this case, the process involves both oxide formations associated with inhibitive action of the abovementioned anions.

However, due to the safety and health-related concerns associated with the use of chromate-based solutions, such conversion treatments need to be replaced by more environmentally friendly alternatives. Therefore, this research community is paying an increased attention to non-Cr(VI) conversion processes. Usually, non-chromate conversion coatings are based on elements having a similar chemistry to that of chromium.

The inorganic species considered for Cr (VI) replacement can be divided into the following categories:^[6,13–21]

- Cr(III) conversion coatings.
- Reducible hypervalent transition metals (compounds of Mo, Mn, V, W, and Tc). Like Cr, the high-valent oxoanions of these elements exist in aqueous solution.
- Difficult-to-reduce transition metal oxides (Zr, Ti, Y, Hf, Ta) and covalent oxides (oxides and mixed oxides of Si, Ge, P, and Te).
- Precipitated coatings including rare earth metals (REM) and hydrotalcite type coatings.

In the next sections, the main aspects related to the formation and characteristics of the chemical conversion coatings involving both chromates and other transitional metals and REM compounds will be discussed.

Chromate-Based Conversion Coatings

Chromate conversion coatings (CCCs) are still extensively applied onto Al-based metallic substrates due to their excellent corrosion resistance, including the self-healing ability. Moreover, they provide a very good adhesion of further applied coatings mainly based on painting. A large range of formulations have been proposed and developed since the beginning of the twentieth century. Usually, the conversion solutions contain hexavalent chromium ions, fluoride ions, and/or phosphate ions, with pH values in the range of 0.8–4.5.^[2,12,13,22–24] Table 1 briefly presents some examples of conversion solutions compositions as well as their operating parameters.

Based on surface analysis techniques, it has been suggested that the composition of the coatings involving chromate-phosphate-fluoride solutions mostly consisted of amorphous hydrated chromium phosphate ($\text{CrPO}_4 \cdot n\text{H}_2\text{O}$) and a small amount of hydrated chromium (III) oxide.^[13,22] Generally, the passive films are amorphous.^[27,28]

In order to increase the coating weight and shorten the coating formation time, the addition of several compounds acting as accelerators has been taken into consideration, as illustrated in Table 1.^[1,2,13,26] The predominant accelerator in current and commercial formulations is ferricyanide, $\text{Fe}(\text{CN})_6^{3-}$, which is added to chromate-fluoride solutions. Based on several studies investigating the role of $\text{Fe}(\text{CN})_6^{3-}$ in conversion coatings, it has been suggested that its presence facilitates the Cr^{6+} to Cr^{3+} reduction reaction through $\text{Fe}(\text{CN})_6^{3-}$ redox mediation.^[13,29] Other proposed accelerators are based on prusside compounds such as $\text{Na}_2[\text{Fe}(\text{CN})_5\text{NH}_3]$, $\text{Na}_3[\text{Fe}(\text{CN})_5\text{NH}_3]$, $\text{Na}_3[\text{Fe}(\text{CN})_5\text{H}_2\text{O}]$, and $\text{Na}_3[\text{Fe}(\text{CN})_5\text{NO}_2]$, added in amounts of 0.5–2 g/L, which allowed shorter treatment periods with about 10%–15% as compared to classical ones.^[30] The most applied conversion solutions commercially available are ALODINE and ALOCHROME.^[1,2,31]

Table 1 CCC processes conditions

Conversion solution type	Composition	Operating parameters	References
Chromate-phosphate-fluoride	CrO ₃ 0.06–0.2M	pH < 1.8	[13]

XANES and Raman spectroscopy studies^[32–35] on CCCs evidenced the presence of both Cr(III) and Cr(VI) species into the films, with possible formation of a mixed Cr(III)–Cr(VI) oxide.^[33,34]

Concerning the formation mechanism, Brown et al.^[28,36] suggested that the coating develops due to electron tunneling through the chemically thinned natural alumina film always present on Al surface. The rate of passive film growth depends on the rate of the chemical dissolution of the oxide by fluoride species. Reduction of Cr(VI) species to hydrated chromium oxide and hydrogen evolution may take place either via easy paths of electronic conduction associated with residual flaws in the oxide or by tunneling of electrons from the metal.^[34,35] Equilibrium between oxide dissolution, due to F⁻ ions attack, producing a scalloped shape of the metal/conversion layer interface,^[28] and coating growth that prevents further the solution ingress may be established. Thus, the surface may be seen to be formed by randomly distributed micro-areas, some of them covered by the coating and protected from fluoride attack, and others covered only by a thin oxide film. These latter regions would act as anodic sites that facilitate the continuation of the process with time by electron tunneling, allowing the growth of the conversion

film. This mechanism implies a cracked structure of the conversion layer, as confirmed by SEM pictures^[27] and observed also by us, as illustrated in Fig. 1. The presence of the accelerator in the conversion bath leads to a quicker attack of the initial oxide allowing also to deposit a thicker conversion layer.

The generally accepted model for CCCs formation is via a redox reaction between chromate ions in solution and aluminum, resulting in the formation of a hydrated chromium oxide gel on the surface of the metal.^[37] The overall formation reaction is as follows:

Al is subjected to the native oxide dissolution in the presence of fluoride ions in acidic chromate solutions, thus allowing electron tunneling with chromate reduction. Additionally, AlOOH is also dissolved by F⁻ so that the reaction of Cr⁶⁺ at the Al interface may continue, resulting in a further deposition of hydrated chromium oxide, up to the complete covering of the exposed metallic surface with the protective layer. The precise hydration state and speciation of Cr(III) and Al(III) in Eq. 1 depend on the

Fig. 1 SEM micrographs of CCCs on pure electropolished aluminum grown from a chromate-fluoride solution containing $K_3[Fe(CN)_6]$ as accelerator for (a) 2 min and (b) 5 min at 25°C

applied operation conditions, and the components in Eq. 1 are only one of several possibilities.

The corrosion performance of the CCCs is also due to the presence of a so-called “built-in inhibitor reservoir” that may provide additional protection beyond that provided by a thickened oxide layer.^[3,13,38] This built-in protection, also known as “active corrosion protection” (ACP) is distinct from “passive” corrosion protection, which is often produced by a barrier oxide film on a metal surface. ACP by conversion coatings is less important when the coating is used as a base for paints and primers that are good barriers and may contain soluble chromate inhibitors themselves.^[13]

ACP involves several discrete processes: release of chromate from the coating, its transport through solution, and its action at the site of damage (typically pits). In other words, chromate leaches from the coating and acts at incipient pits, prohibiting their propagation.^[39]

Chromium-Free Conversion Coatings

In spite of the robustness and performance of the CCCs, these types of conversion treatments need to be replaced by more environmentally friendly alternatives since Cr(VI) has been reported to be highly toxic and carcinogenic and provokes effluent disposal problems.^[40] In addition, European directives 2000/53/EC and 2002/95/EC for the automotive and electronics sectors regulate the use of Cr(VI). Although the aerospace industry was still exempt for safety concerns related to corrosion, it still has to comply with EU REACH regulation that stipulated the latest application date of Cr(VI) at 2016/2017.^[17]

In this section, several novel chemical conversion coatings will be presented, as alternatives to Cr(VI)-based treatments, able to provide an enhanced corrosion resistance of Al and its alloys as compared to bare metals.

Trivalent Chromium Conversion Coatings

A promising replacement for CCCs is that based on the use of Cr^{3+} chemistry. The so-called “Trivalent Chromium Process” (TCP) treatment, belonging to the fluorozirconate coatings family,^[41] recently has gained wide acceptance.

Pearlstein and Agarwala^[42] have developed for the first time a corrosion-resistant conversion coating on Al alloys involving aqueous solutions containing $Cr_2(SO_4)_3$, Na_2SiF_6 , or NaF. They proposed a composition consisting of 4 g/L $Cr_4(SO_4)_5(OH)_2$ and 0.4 g/L Na_2SiF_6 to which 20 mL/L of 0.5N NaOH has been added to increase the bath pH until precipitation of basic compound was evidenced. The obtained conversion layers exhibited different colors depending on the treatment time, ranging from tan tones after 10 min of immersion, violet films after 20 min up to blue ones after 40 min. An increase of the solution temperature up to 42°C allowed a reduction of the treatment time from about 5 up to 2 min and provided a corrosion performance similar to that of the formed films at 25°C for 5 min. The authors suggested a mechanism of formation involving a sol-gel process similar to Cr(VI) coatings. The films are mostly composed of a hydrated chromium hydroxide, and they passed 200 h salt mist tests with no signs of corrosion. The most corrosion-resistant films have been obtained involving a post-treatment based on the use of an oxidizer such as peroxide or permanganate. However, post-treatment in an oxidizing bath likely results in the formation of Cr(VI) species, which will violate regulations.

The zirconia-based TCP coatings, however, are quite different in nature and have improved properties. The TCP bath generally contains Cr^{3+} , ZrF_6^{2-} , and SO_4^{2-} as the main constituents in an aqueous solution with a pH of 3.8–4.0. The conversion process is performed at a temperature of 40°C–45°C, for treatment periods between 30 s and 5 min, sometimes longer when the solution temperature is lower. Modified TCP formulations include the addition of soluble thickeners (e.g., methyl cellulose, colloidal silica, clays) and surfactants (e.g., alkyl sulfate sodium salts, alkyl sulfoamides, dodecylphenyl polyethylene glycol ether).^[41]

TCP has been developed at NAVAIR, and it has been shown to provide excellent corrosion protection and paint adhesion in standardized tests.^[43,44] They are currently the only non-chromate products that have been qualified according to Class 1A of MIL SPEC MIL-DTL-5541F, Chemical Conversion Materials for Coating Aluminum

and Aluminum Alloys. TCP baths are similar to fluoro-zirconate/fluorotitanate baths, except that they contain Cr(III) species, which improve the properties. The film is similar to the Zr coating, but it is enriched in $\text{Cr}(\text{OH})_3$ and Cr_2O_3 .^[45,46]

The conversion layer is considered to be formed by precipitation of an outer chromium- and zirconium-rich layer due to an increase of pH at sites of the usual cathodic reactions:

At the same time, aluminum is oxidized, forming an inner alumina film across the aluminum surface, according to the reaction:

The alumina film dissolves by reaction with hydrofluoric acid as follows:^[47]

The dissolution is balanced by formation of fresh alumina at the aluminum/alumina interface. The relatively thin residual alumina film thickness permits electron tunneling to support the cathodic reactions.^[48,49]

The local increase of pH due to the cathodic reactions (2) and (3) facilitates the precipitation of a hydrated zirconia film on the surface along with hydrated chromium oxide, according to the following reactions:

It should be noted that the formation of TCP layers induced by the local pH increase is fundamentally different from the CCCs formation involving a redox reaction between chromate ions and the Al metallic substrate.^[33]

Based on complex surface analysis investigations and electrochemical measurements, Guo et al.^[45] suggested that TCP coating consists of a two-layered structure, with zirconium–chromium oxide in the outer layer and aluminum oxide or oxyfluoride at the metal/coating interface. The film thickness is in the range of 40–120 nm depending on the treatment period. No Cr(VI) species were found on the TCP surface, which supports its designation as an environmentally friendly replacement for CCC.

However, recent research investigations have reported that Cr(VI) species are present in the conversion layer

after aging in air or following a corrosion test in NaCl solution at room temperature.^[14,46,50] It was suggested that Cr(VI) may be produced through the oxidation of Cr(III) oxide by the locally produced hydrogen peroxide. The reduction reaction was proposed to occur at sufficiently thin regions of the alumina layer at the base of the coating, where tunneling of electrons can take place, or at flaw sites in the layer, associated with the influences on the film composition and morphology of impurities in the Al-based substrate.

Chemical Conversion Coatings Based on Transitional and Rare Earth Metals Compounds

Many of the metals that form oxo-metallates, including Mo, W, V, and Mn, have soluble high-valence oxo-anions that may be reduced to form insoluble oxides in the same way as Cr. Therefore, the use of hexavalent Mo and W compounds has taken into consideration, as simple combinations or polycbinations (e.g., iso- or heteropolyanions) with a general formula of $\text{X}_n\text{M}_m\text{O}_o$, where X = heteroelement, such as P and Si.^[51–56]

The interaction of *molybdates with Al* and its alloys surfaces was found to improve the pitting resistance, and there is a certain dependence on molybdate concentration into the solution. Several studies^[53,54] proposed Mo incorporated into the film and reduced to a Mo(IV) state, but the whole chemistry of such kind of modifications is not yet elucidated.

Breslin et al.^[57] proposed formation of Mo, Mo^{3+} , and MoO_2 species. The passivity ability of molybdate anion may depend on pH value of formation solution, being associated with its polymeric nature. Also, they took into consideration the formation of a mixed molybdenum and aluminum passive layer. Based on XPS and Raman investigations associated with EIS, Lopez-Garrity et al.^[56] suggested that the protective action of molybdate on AA2024-T3 alloy might follow a two-step process whereby molybdate is rapidly reduced to form $\text{MoO} \cdot (\text{OH})_2$ over the intermetallic particles and subsequently oxidized to intermediate molybdenum oxides in the presence of oxygen. This, in turn, may lead to a local acidification, promoting the condensation and polymerization of molybdate species in solution to form polymolybdate species ($\text{Mo}_7\text{O}_{24}^{6-}$ and $\text{Mo}_8\text{O}_{26}^{4-}$).

Lomakina et al.^[58] investigated some *conversion layers based on tungstates* and tungsten heteropolyanions, at higher temperatures, e.g., 90°C–250°C, proposing tungsten incorporated into oxide film as polytungstate complex interacting with active sites on the Al oxide surface. Zein El Abedin^[59] suggested that the adsorption of WO_4^{2-} anions at flawed areas and developing pits represents the main factor for the corrosion inhibition.

Table 2 shows some examples of molybdate- and tungstate-based conversion solutions compositions as well as their operating parameters.

Table 2 Molybdate- and tungstate-based conversion processes conditions

Chemical conversion type	Formation conditions		Reference
	Electrolyte composition	Working parameters	
Molybdate-based chemical conversion (CCMo)	Na ₂ MoO ₄ ·2 H ₂ O 0.1M Na ₂ SO ₄ ·10H ₂ O 0.05M	25°C–90°C pH 5.5–6.5 0.5–30 min	[60]

	H ₂ WO ₄ 10–20 g/L	pH 11–12 (with NH ₄ OH) 3–15 min	[65]
Tungstate-based chemical conversion (CCW)			

Chemical conversion layers using molybdate solutions are formed quite easily, with a good adherence to the metallic substrate and less dependence on the alloying elements percentage. Usually golden-yellow conversion layers are formed, for immersion periods between 30 s up to 20 min, for a solution temperature of 25°C–30°C. With immersion time increase, the golden tones are more intense and some reddish-bluish irisations have been evidenced. The increase of solution temperature to 40°C–60°C doesn't alter the surface appearance and the color changes to bronze tones. Solution temperatures in the range of 80°C–90°C facilitate the growth of golden-yellow up to dark brown-bronze passive films as a function of immersion periods from several minutes to more than 20 min.

The molybdate-based coating morphology is quite similar with that evidenced in the case of chromate chemical conversion layers, evidencing a cracked structure uniformly distributed on the entire metallic surface, as illustrated in Fig. 2. Based on EDX analysis, Mo content within the film was found to be around 6%–7%.^[60] In addition, a coating mass of about 600 mg/m² has been determined.^[64]

Usually, chemical conversion layers using tungstate-based solutions are light yellow regardless of the immersion period, between 1 and 30 min. Sometimes, these coatings exhibit a moderate adhesion to the Al metallic substrate, and an additional step consisting in a thermal treatment at 100°C–150°C for 30 min may be applied.^[60,64] A coating mass of about 100–200 mg/m² has been determined, lower as compared to molybdate-based conversion coatings.^[64,65] SEM micrographs of the tungstate-based conversion layers evidenced a relatively flat surface, with a precipitate-like appearance and very few cracks, as shown in Fig. 3.

The use of *rare earth compounds* as corrosion inhibitors has been proposed for the first time by Hinton and his co-workers in Australia,^[66] who involved Ce salts to protect Al-based substrates, thus providing an excellent resistance to the localized corrosion. The protection mechanism was suggested to be due to the alkaline precipitation of insoluble hydroxide/oxide layers. Other rare earth ions such as La, Pr, Nd, and Y were found to act in a similar way, and due to their low toxicity, they have been proposed as potential replacements for chromate-based

Fig. 2 SEM micrograph for a Mo-based chemical conversion coating formed onto Al 99.5% for 30 min at 50°C

Fig. 3 SEM micrographs of a tungstate-based chemical conversion coating formed onto Al 99.5% for 30 min at 80°C

formulations in metal finishing of Al alloys.^[67–71] In addition, Hinton group reported that the Ce deposition kinetics may be significantly increased by using Ce^{4+} -based solutions. Therefore, highly corrosion-resistant layers have been formed using a slightly acidic solution containing 1–10 g/L CeCl_3 and several wt% of H_2O_2 .^[72] Mixed Ce^{3+} - Ce^{4+} coatings have been formed for treatment periods of 6–10 min on several Al alloys types. These coatings exhibited excellent corrosion performance in both electrochemical and salt spray testing. Additional information on the lanthanide inhibitors can be found in Ref. [73].

Other investigations showed that cerium cations work well in conjunction with molybdates and hydrothermal treatment, thus growing quite compact films with a very good corrosion resistance.^[74] Hughes et al.^[6] investigated the generation of cerium- and molybdenum-containing

conversion coatings on Al alloy by a multistep process involving a treatment for 24 h in air saturated with water vapor at 100°C, followed by immersion in 10 mM $\text{Ce}(\text{NO}_3)_3$ for 2 h and then in 5 mM CeCl_3 for 2 h at 90°C–100°C and anodic polarization for 2 h in Na_2MoO_4 at 0.5 V vs. SCE. Based on SEM, XPS, and AES investigations, they found that the formed coating was predominantly a hydrated aluminum oxide incorporating cerium in a mixture of Ce^{3+} and Ce^{4+} oxidation states. Mo^{6+} has been detected around the intermetallic particles.

Kendig et al.^[75] analyzed the Ce and Mo roles in the global corrosion resistance evaluation, and based on the experimental results using EIS technique, they reported a protective capacity of chemical conversion coatings in the following order:

$$\text{CC Ce-Mo} > \text{CC Mo} > \text{CC Ce} > \text{Al untreated.}$$

These data suggested that Ce and Mo species have a synergistic action on attaining corrosion performance. According to Kendig's viewpoint, cerium forms insoluble oxides that increase the hydrated Al oxide film resistance, and the Mo oxidant species have an active inhibitor role.

Our own studies related to the comparative evaluation of corrosion performance of conversion coatings onto Al substrates involving Mo, W and respectively Ce-Mo, Ce-W systems^[64,76] also evidenced the enhanced protective characteristics of the binary ones, materialized by the halving of the corrosion current (e.g., values of about 0.11 $\mu\text{A}/\text{cm}^2$ for Ce-Mo coatings as compared to 0.2 $\mu\text{A}/\text{cm}^2$ for Mo-based ones in 0.5 M NaCl solution). Figure 4 exemplifies the evolution of surface modifications during salt mist test for AA2024 aluminum alloy.

As shown in Fig. 4, Ce-Mo chemical conversion coatings are characterized by the best corrosion performance. This phenomenon is in accordance with other literature data that have evidenced the remarkable effect of Ce-based conversion applied onto Al alloys.^[6,74,75] Additional cyclic damp heat tests for 56 cycles have not evidenced any significant appearance modifications, too.^[64]

Fig. 4 Corrosion evolution during salt mist test for chemical conversion coatings applied onto AA2024 aluminum alloy

CONCLUSIONS

A large range of surface modifications of aluminum and its alloys may be applied, some of them being commercially available, involving a huge diversity of formulations that are built to mainly provide corrosion inhibition but to promote adhesion of further treatments, mostly of painting systems, as well. This review briefly presented only a part of them. The interested reader may find additional information starting from the provided bibliography.

The problem of identifying suitable replacements for chromates has been a focus of the corrosion inhibition and protection community for decades, and their investigation during the last twenty years provided significant new insight into their mechanism. This knowledge, in fact, supported the development of the novel formulations under the general trend of using more environmentally friendly procedures.

There is still a lot of work to be performed to better understand the complex behavior of metal (alloy)/conversion coating interface during exposure to aggressive environments, strongly dependent on both film and alloy composition.

The deeper investigation of the available conversion systems will provide the required knowledge to further develop and commercialize more efficient conversion coatings that are economically viable and environmentally friendly, with no harm on human health.

Texture–Property Relationships in Aluminum Alloys: Simulations and Experiments

Dierk Raabe

Max Planck Institute for Iron Research, Düsseldorf, Germany

Abstract

Aluminum alloys provide a huge and increasing application spectrum for formed and cast products. This article texture and anisotropy of aluminum alloys. Topics covered include: experimental determination of surface strains, nanotextures and microtextures, constitutive laws for crystal plasticity finite element simulations and cellular automata for recrystallization, microscopic aspects of texture evolution during plastic deformation and recrystallization, relationship between texture, microstructure and surface properties, integration anisotropy into metal-forming simulations, and crystallographic approximation elastic-plastic anisotropy.

Keywords: Anisotropy; Finite element simulations; Plasticity; Polycrystal deformation; Texture.

INTRODUCTION

Modern well-tailored and optimized aluminum alloys provide a huge and steadily growing application spectrum to customers of formed and cast products. A good example is the 6xxx series aluminum alloys which gradually gain momentum in the automotive industry. The high demands with respect to mechanical properties and surface appearance faced by these materials increasingly require adequate quantitative characterization measures, simulation tools, and basic understanding to build a bridge between materials scientists, materials producers, and final product designers.

Current approaches for conducting simulations, for instance, of plastic deformation of aluminum and its alloys are usually based on solving large sets of differential equations associated with a well-posed forming problem by using finite element methods. Primary objectives of such simulations are the prediction of the material shape after forming, in particular, the thickness distribution, the minimization of material failure, the optimization of the material flow during forming, the simulation of the spring back effect, and the calculation of the final mechanical properties of the formed sample. Related essential applications are in the fields of optimizing tool designs, predicting pressing forces, and simulating the final surface appearance of the part. The latter aspect involves both macroscopical (e.g. wrinkling) as well as microstructural (e.g. ridging, strain localization, orange peel) mechanisms of surface changes during forming.

Rendering such continuum-type metal-forming simulations scientifically sound, predictive at the microstructure scale, in good accord with experiment, and

at the same time economically rewarding requires that the involved materials are properly specified in terms of their respective constitutive behavior. For this purpose, finite element approaches for advanced metal-forming simulations typically employ three sets of material input data covering strain hardening, failure behavior and forming limits, as well as texture and anisotropy (Fig. 1). The current chapter deals, in particular, with the latter aspect and consists of three parts. The first part presents an introduction to some of the employed experimental and theoretical methods. The second part reviews some microscopic aspects of texture development focusing on plastic deformation, primary static recrystallization, and the relationship between texture and surface properties. The third part reviews concepts for the integration of crystallographic texture and anisotropy into large-scale metal-forming simulations.

EXPERIMENTAL AND THEORETICAL METHODS

Experimental Determination of Surface Strains

Surface strains on plastically deformed samples can be experimentally determined using photogrammetry. This is a digital image analysis method which quantifies changes in surface patterns after straining.^[1,2] Both the natural characteristics of an unprepared sample surface or a stochastic color spray applied to a polished surface can provide an exploitable input pattern (Fig. 2). In order to measure the three-dimensional displacements at the surface, digital stereo pair images of the samples are acquired using two high-resolution CCD cameras. Pattern recognition is

Fig. 1 Modern finite element approaches for realistic metal-forming simulation typically require input data about strain hardening, forming limits, and anisotropy

Fig. 2 Plastic strain fields can be measured by photogrammetry. This is a digital image analysis method which is based on the recognition of changes in the gray scale distribution of natural or artificial surface patterns after a straining step^[1,2]

carried out by mapping a rectangular grid onto the image. The grid points are defined by three-dimensional coordinates and by the gray scale distribution in their proximity. After plastic straining, the distorted surface pattern is again determined. From the change in border coordinates containing the initial gray scale distribution around each grid point, the three-dimensional displacement gradient tensor field is determined with a lateral resolution given by the cameras and the grid point spacing. This pattern correlation method is based on the assumption that the gray scale

distribution changes its spatial arrangement around a lattice point but remains otherwise constant during straining. The displacement gradient data are used to calculate the surface components of the strain tensor at each grid point in the form of the first-order approximation of the standard polar decomposition. The strain resolution is below 1% since the method uses the match of the complete gray scale distribution before and after loading as a measure to determine the exact shift in border coordinates. This procedure provides a larger precision than the determination of the new border coordinates from discrete pixels. For aluminum, a fine white color spray usually provides sufficient contrast for obtaining good gray scale pattern on a polished sample surface.^[1,2]

Experimental Determination of Nanotextures and Microtextures

Nano- and microtexture evolution in aluminum is discussed in terms of crystal orientation maps of deformed and recrystallized samples. Orientation mapping is a technique for analyzing the two-dimensional topology of texture and grain boundaries in crystalline material. Local lattice orientations are measured on a regular grid by automated acquisition and processing of electron backscatter diffraction patterns (Kikuchi patterns) in a high-resolution scanning electron microscope (SEM). The microstructure can subsequently be reconstructed by coloring similar orientations on the measured grid with similar colors. In addition, the pattern quality of the Kikuchi patterns which is a measure for the local perfection of the crystal lattice is determined for each point.^[3–7] In the present investigations, the lateral resolution of the microtexture measurement lies between 20 nm and 15 μm.

Constitutive Laws for Crystal Plasticity Finite Element Simulations

In the large-strain constitutive crystal plasticity model^[8] modified for the present study,^[9,10] one assumes the stress response at each macroscopic continuum material point to be potentially given by one crystal or by a volume-averaged response of a set of grains comprising the respective material point. The latter assumption can be referred to as a local Taylor-type or local strain-rate homogenization assumption. In the case of a multi-grain description, the volume-averaged stress amounts to

$$\langle \mathbf{T} \rangle = \sum_{k=1}^N (\omega_k \mathbf{T}_k) \quad (1)$$

where N is the total number of individual orientations mapped onto an integration point using the Taylor assumption, ω_k the volume fraction of each single orientation, $\mathbf{T}_k$ the Cauchy stress produced by the k th individual orientation, and $\langle \mathbf{T} \rangle$ the volume-average stress produced by all orientations mapped at an integration point. The constitutive equation for the stress in each grain is then expressed in terms of

$$\mathbf{T}^* = \mathbf{C} \mathbf{E}^* \quad (2)$$

where $\mathbf{C}$ is the fourth-order elastic tensor, and $\mathbf{E}^*$ is an elastic strain measure obtained by polar decomposition

$$\mathbf{E}^* = \frac{1}{2} (\mathbf{F}^{*T} \mathbf{F}^* - \mathbf{I}) \quad (3)$$

which leads to a stress measure which is the elastic work conjugate to the strain measure $\mathbf{E}^*$,

$$\mathbf{T}^* = \mathbf{F}^{*-1} (\det(\mathbf{F}^*) \mathbf{T}) \mathbf{F}^{*-T} \quad (4)$$

where $\mathbf{T}$ is the symmetric Cauchy stress tensor in the grain, and $\mathbf{F}^*$ is a local elastic deformation gradient defined in terms of the local *total* deformation gradient $\mathbf{F}$ and the local *plastic* deformation gradient $\mathbf{F}^p$. The relation between the elastic and the plastic portion of $\mathbf{F}$ amounts to

$$\mathbf{F}^* = \mathbf{F} \mathbf{F}^{p-1}, \quad \det(\mathbf{F}^*) > 0, \quad \det(\mathbf{F}^p) = 1 \quad (5)$$

The plastic deformation gradient is given by the flow rule

$$\dot{\mathbf{F}}^p = \mathbf{L}^p \mathbf{F}^p \quad (6)$$

with its crystalline portion

$$\mathbf{L}^p = \sum_{k=1}^N \dot{\gamma}_k m_k, \quad m_k = \hat{b}_k \otimes \hat{n}_k \quad (7)$$

where m_k are the k th dyadic slip products of unit vectors $\hat{b}_k$ in the slip direction and $\hat{n}_k$ normal to the slip plane, and $\dot{\gamma}_k$

are the shear rates on these systems. The specific constitutive functions for the plastic shearing rates $\dot{\gamma}_k$ on the slip systems are taken as

$$\dot{\gamma}_k = \dot{\gamma}_0 \left| \frac{\tau_k}{\tau_{k,crit}} \right|^{1/m} \text{sign}(\tau_k) \quad (8)$$

where τ_k is the resolved shear stress for the slip system k , and $\tau_{k,crit}$ is the actual critical shear stress on the k th slip system. $\dot{\gamma}_0$ and m are material parameters representing shearing rate and the rate sensitivity of slip. $\tau_{k,crit}$ can be calculated by accounting for latent hardening through the use of a hardening matrix,

$$\dot{\tau}_{k,crit} = \sum_i h^{ki} |\dot{\gamma}^i|, \quad h^{ki} = q^i h^{(i)} \quad (9)$$

where h^{ki} is the rate of strain hardening on k th slip system due to a shearing on i th slip system, q^i the hardening matrix describing the latent hardening behavior of a crystallite, and $h^{(i)}$ is the hardening rate of a single-slip system i . In all simulations presented in this chapter 12 slip systems with crystallographic $\langle 110 \rangle$ slip directions and $\{111\}$ slip planes are used for the plastic deformation of aluminum. The matrix h^{ki} can be taken as

$$h^{ki} = \begin{bmatrix} A & qA & qA & qA \\ qA & A & qA & qA \\ qA & qA & A & qA \\ qA & qA & qA & A \end{bmatrix} \quad (10)$$

where q is the ratio of the latent hardening rate to the self-hardening rate, and A is a 3×3 matrix populated by ones. Using this constitutive description renders the finite element method an elegant tool for detailed joint simulation studies of texture and strain evolution under realistic boundary conditions.

Constitutive Laws of Cellular Automata for Recrystallization Simulations

The recrystallization simulations discussed in this chapter are based on a cellular automaton formulation with a probabilistic switching rule.^[11–15] Independent variables are time t and space $\mathbf{x} = (x_1, x_2, x_3)$. Space is discretized into an array of equally shaped quadratic cells. Each cell is characterized in terms of the dependent variables. These are scalar (mechanical, electromagnetic) and configurational (interfacial) contributions to the driving force and the crystal orientation $\mathbf{g} = \mathbf{g}(\varphi_1, \varphi_2)$, where $\mathbf{g}$ is the rotation matrix, and φ_1, φ_2 are the Euler angles. The driving force is the negative change in Gibbs enthalpy G_i per transformed cell. The starting data, i.e. the crystal orientation map and the spatial distribution of the driving force, can be provided by orientation imaging microscopy or by a crystal plasticity

finite element simulation. Grains or subgrains are mapped as regions of identical crystal orientation, but the driving force may vary inside these areas.

The kinetics of cellular automata result from changes in the state of the cells (cell switches). They occur in accord with a transformation rule which determines the individual switching probability of each cell as a function of its previous state and the state of its neighbor cells.^[16–19] The switching rule used in the simulations discussed in this chapter is designed for the simulation of primary static recrystallization. It reflects that the state of a non-recrystallized cell belonging to a deformed grain may change due to the expansion of a recrystallizing neighbor grain which grows according to the local driving force and boundary mobility. If such an expanding grain sweeps a non-recrystallized cell, the stored dislocation energy of that cell drops to 0 and a new orientation is assigned to it, namely that of the growing neighbor grain. To put this formally, the switching rule is cast in the form of a probabilistic analog of the linearized symmetric Turnbull rate equation which describes grain boundary motion in terms of isotropic single-atom diffusion processes perpendicular through a homogeneous planar grain boundary segment under the influence of a drop in Gibbs energy,^[20–22]

$$\dot{\mathbf{x}} = \mathbf{n} v_D \lambda_{gb} c \left\{ \exp \left(-\frac{\Delta G + \Delta G_i/2}{k_B T} \right) - \exp \left(-\frac{\Delta G - \Delta G_i/2}{k_B T} \right) \right\} \quad (11)$$

where $\dot{\mathbf{x}}$ is the grain boundary velocity, v_D the Debye frequency, λ_{gb} the jump width through the boundary, c the intrinsic concentration of grain boundary vacancies or shuffle sources, $\mathbf{n}$ the normal of the grain boundary segment, ΔG the Gibbs enthalpy of motion through in the interface, ΔG_i the Gibbs enthalpy associated with the transformation, k_B the Boltzmann constant, and T is the absolute temperature. Replacing the jump width by the burgers vector and the Gibbs enthalpy terms by the total entropy, ΔS , and total enthalpy, ΔH , leads to the linearized form

$$\dot{\mathbf{x}} \approx \mathbf{n} v_D b \exp \left(-\frac{\Delta S}{k_B} \right) \left(\frac{pV}{k_B T} \right) \exp \left(-\frac{\Delta H}{k_B T} \right) \quad (12)$$

where p is the driving force, and V the atomic volume which is of the order of b^3 , where b is the magnitude of the Burgers vector. Summarizing these terms reproduces Turnbull's expression

$$\dot{\mathbf{x}} = \mathbf{n} m p = \mathbf{n} m_0 \exp \left(-\frac{Q_{gb}}{k_B T} \right) p \quad (13)$$

where m is the mobility. The equations provide a well-known kinetic picture of grain boundary segment motion, where the atomistic processes are statistically described in terms of the pre-exponential factor of the

mobility $m_0 = m_0(\Delta \mathbf{g}, \mathbf{n})$ and the activation energy of grain boundary mobility $Q_{gb} = Q_{gb}(\Delta \mathbf{g}, \mathbf{n})$. For dealing with competing switches affecting the same cell, the deterministic rate equation, Eq. 13, can be replaced by a probabilistic analog which allows one to calculate switching probabilities. First, it is separated into a deterministic part, $\dot{\mathbf{x}}_0$, which depends weakly on temperature, and a probabilistic part, w , which depends strongly on temperature:

$$\dot{\mathbf{x}} = \dot{\mathbf{x}}_0 w = \mathbf{n} \frac{k_B T m_0}{V} \frac{pV}{k_B T} \exp \left(-\frac{Q_{gb}}{k_B T} \right) \quad (14)$$

with $\dot{\mathbf{x}}_0 = \mathbf{n} \frac{k_B T m_0}{V}$, $w = \frac{pV}{k_B T} \exp \left(-\frac{Q_{gb}}{k_B T} \right)$

The probability factor w represents the product of the linearized part $pV/(k_B T)$ and the non-linearized part $\exp(-Q_{gb}/(k_B T))$ of the original Boltzmann terms. According to Eq. 14, non-vanishing switching probabilities occur for cells which reveal neighbors with different orientation and a driving force which points in their direction. The automaton considers the first, second (2D), and third (3D) neighbor shells for the calculation of the total driving force acting on a cell. The local value of the switching probability depends on the crystallographic character of the boundary segment between such unlike cells.

The cellular automaton is usually applied to starting data which have a spatial resolution far above the atomic scale. This means that the automaton grid has some mesh size $\lambda_m \gg b$. If a moving boundary segment sweeps a cell, the grain, thus, grows (or shrinks) by λ_m^3 rather than b^3 . Since the net velocity of a boundary segment must be independent of the imposed value of λ_m , an increase of the jump width must lead to a corresponding decrease of the grid attack frequency, i.e. to an increase of the characteristic time step, and vice versa. For obtaining a scale-independent grain boundary velocity, the grid frequency must be chosen in a way to ensure that the attempted switch of a cell of length λ_m occurs with a frequency much below the atomic attack frequency which attempts to switch a cell of length b . Mapping Eq. 14 on a grid which has a scaling length λ_m leads to

$$\dot{\mathbf{x}} = \dot{\mathbf{x}}_0 w = \mathbf{n} (\lambda_m v) w \quad \text{with} \quad v = \frac{k_B T m_0}{V \lambda_m} \quad (15)$$

where v is the eigenfrequency of the chosen mesh characterized by the scaling length λ_m . The eigenfrequency given by this equation represents the attack frequency for one particular grain boundary with constant mobility. In order to use a whole *spectrum* of mobilities and driving forces in one simulation, it is necessary to normalize the equation by a common grid attack frequency v_0 rendering it into

$$\dot{\mathbf{x}} = \dot{\mathbf{x}}_0 w = \mathbf{n} \lambda_m v_0 \left(\frac{v}{v_0} \right) w = \hat{\mathbf{x}}_0 \left(\frac{v}{v_0} \right) w = \hat{\mathbf{x}}_0 \hat{w} \quad (16)$$

where the normalized switching probability amounts to

$$\hat{w} = \left(\frac{v}{v_0} \right) \frac{pV}{k_B T} \exp \left(-\frac{Q_{gb}}{k_B T} \right) = \frac{m_0 p}{\lambda_m v_0} \exp \left(-\frac{Q_{gb}}{k_B T} \right) \quad (17)$$

The value of the normalization (grid attack) frequency v_0 can be identified by using the assumption that the maximum occurring switching probability cannot be larger than 1

$$\hat{w}^{\max} = \frac{m_0^{\max} p^{\max}}{\lambda_m v_0^{\min}} \exp \left(-\frac{Q_{gb}^{\min}}{k_B T} \right) \leq 1 \quad (18)$$

where $m_0^{\max}$ is the maximum occurring pre-exponential factor of the mobility, $p^{\max}$ the maximum possible driving force, $v_0^{\min}$ the minimum allowed grid attack frequency, and $Q_{gb}^{\min}$ the minimum occurring activation energy. Assuming $\hat{w}^{\max} = 1$, one obtains the normalization frequency as a function of the upper bound input data.

$$v_0^{\min} = \frac{m_0^{\max} p^{\max}}{\lambda_m} \exp \left(-\frac{Q_{gb}^{\min}}{k_B T} \right) \quad (19)$$

This frequency and the local values of the mobility and the driving force change the switching equation into

$$\begin{aligned} \hat{w}^{\text{local}} &= \frac{m_0^{\text{local}} p^{\text{local}}}{\lambda_m v_0^{\min}} \exp \left(-\frac{Q_{gb}^{\text{local}}}{k_B T} \right) \\ &= \left(\frac{m_0^{\text{local}}}{m_0^{\max}} \right) \left(\frac{p^{\text{local}}}{p^{\max}} \right) \exp \left(-\frac{Q_{gb}^{\text{local}} - Q_{gb}^{\min}}{k_B T} \right) = \left(\frac{m^{\text{local}} p^{\text{local}}}{m^{\max} p^{\max}} \right) \end{aligned} \quad (20)$$

This expression is the central switching equation of the cellular automaton algorithm. It shows that the local switching probability can be quantified by the ratio of the local and the maximum mobility $m^{\text{local}}/m^{\max}$, which is a function of the grain boundary character and by the ratio of the local and the maximum driving pressure $p^{\text{local}}/p^{\max}$. The probability of the fastest occurring boundary segment (characterized by $m_0^{\text{local}} = m_0^{\max}$, $p^{\text{local}} = p^{\max}$, and $Q_{gb}^{\text{local}} = Q_{gb}^{\min}$) to realize a cell switch is equal to 1. The equation shows that the mesh size does not influence the switching probability but only the time step elapsing during an attempted switch. The characteristic time constant of the simulation Δt is $1/v_0^{\min}$. The switching probability can also be formulated in terms of the local time $t = \lambda_m / \dot{\mathbf{x}}$ required by a grain boundary with velocity x to cross the automaton cell of size λ_m

$$\hat{w}^{\text{local}} = \left(\frac{m^{\text{local}} p^{\text{local}}}{m^{\max} p^{\max}} \right) = \left(\frac{\dot{\mathbf{x}}^{\text{local}}}{\dot{\mathbf{x}}^{\max}} \right) = \left(\frac{t^{\max}}{t^{\text{local}}} \right) \quad (21)$$

Therefore, the local switching probability can also be regarded as the ratio of the distances that were swept by the local grain boundary and the grain boundary with maximum velocity, or as the number of time steps the local grain boundary needs to wait before crossing the encountered cell. This reformulates the same underlying problem, namely, that boundaries with different mobilities and driving forces cannot equally switch the state of the automaton within one common time step.

The above equations allow one to calculate the switching *probability* of a cell as a function of its previous state and the state of the neighbor cells. The actual *decision* about a switching event is made by a Monte Carlo step. The use of random sampling ensures that all cells are switched according to their statistical weight, i.e. according to the local driving force and grain boundary mobility between abutting cells. The simulation proceeds by first calculating the individual local switching probabilities $\hat{w}^{\text{local}}$ and then sampling them using a Monte Carlo algorithm. This means that for each cell the calculated switching probability is compared to a randomly generated number r which lies between 0 and 1. The switch is accepted if the random number is equal or smaller than the calculated switching probability. Otherwise, the switch is rejected

random number r between

$$0 \text{ and } 1 \begin{cases} \text{accept switch if } r \leq \left(\frac{m^{\text{local}} p^{\text{local}}}{m^{\max} p^{\max}} \right) \\ \text{reject switch if } r > \left(\frac{m^{\text{local}} p^{\text{local}}}{m^{\max} p^{\max}} \right) \end{cases} \quad (22)$$

Except for the probabilistic evaluation of the analytically calculated transformation probabilities, the approach is entirely deterministic. The use of realistic or experimental input data for the grain boundaries enables one to make predictions on a real time and space scale. The switching rule is scalable to any mesh and to any spectrum of boundary mobility and driving force data. The state update of all cells is made in synchrony. Related cellular automaton models which are suited to tackle recrystallization of aluminum alloys were also suggested by other authors.^[23–28]

MICROSCOPIC ASPECTS OF TEXTURE EVOLUTION DURING PLASTIC DEFORMATION AND RECRYSTALLIZATION

Bicrystal Deformation

Figure 3 shows a bicrystal which was plane strain deformed (30% engineering thickness reduction) in a channel die set-up using Teflon foil as a lubricant. The tilt angle grain boundary separating the two crystals amounted to 7°

Fig. 3 Measured and simulated spatial distribution of the von Mises strain in an aluminum bicrystal (small angle grain boundary, 7.75° tilt angle) which was plane strain deformed (30% engineering thickness reduction) in a channel die set-up. The right-hand side shows the measured and simulated {1 0 0} pole figures

Fig. 4 Measured and simulated spatial distribution of the von Mises strain in an aluminum bicrystal (high-angle grain boundary, 34.8° tilt angle) which was plane strain deformed (30% engineering thickness reduction) in a channel die set-up. The right-hand side shows the measured and simulated {1 0 0} pole figures

before deformation and to 11° after deformation. The figure shows the experimentally determined distribution of the von Mises strain in the two abutting crystals together with a corresponding crystal plasticity finite element simulation. Although the simulation does not exactly match the experiments, both data sets clearly show that the two crystals do

not deform as a micromechanical entity -as anticipated due to the small angle of the grain boundary between them - but deform as two mechanically individual grains. An additional experiment (Fig. 4) conducted on a second bicrystal with a large angle grain boundary (34.8° tilt boundary) between the two grains indeed shows a very similar

behavior as the deformation experiment conducted on the bicrystal with the small angle grain boundary. The surprising similarity between the micromechanical influence exerted by a small angle grain boundary and that exerted by a large angle grain boundary shows that -although similar slip systems are active on either side of the small angle boundary - the grain boundary clearly impedes slip continuity and thereby generates discontinuities in the accumulated plastic strain. Also, the strong localization effects occurring at the open surfaces along the extension direction of the sample (Fig. 3) indicate that the main influence of the small angle grain boundary could lie in acting as a source for generating instability rather than acting as a rigid border to the dislocation flux. It is well known from studies on in-grain deformation banding that tiny orientation fluctuations within one grain can create neighboring

areas with different slip system selection (the so-called differently deforming regions). This principle might help to explain the strain heterogeneity observed in Fig. 3 across the grain boundary. It is conceivable that it is energetically more favorable for a bicrystal to deform by the activation of different single-slip systems in each crystal in order to follow the exerted loading rather than to symmetrically co-deform both crystals.

Figures 5 and 6 show a more detailed high-resolution analysis of the orientation changes on either side of the small angle grain boundary shown in Fig. 3 and of the large angle grain boundary shown in Fig. 4. In both the cases, it can be seen that the orientation change in front of the interface, expressing the stored content of geometrically necessary dislocations, is not symmetric. In other words, one grain reveals an increasing net

Fig. 5 Measured orientation gradients on both sides of the small angle grain boundary (7.75° tilt angle) of the sample shown in Fig. 3. Note the orientation change in the crystal on the right-hand side indicating a substantial increase in the density of geometrically necessary dislocations

Fig. 6 Measured orientation gradients on both sides of the high angle grain boundary (34.8° tilt angle) of the sample shown in Fig. 4. Note the orientation change in the crystal on the right-hand side indicating a substantial increase in the density of geometrically necessary dislocations

Fig. 7 Distribution of the accumulated von Mises strain in a quasi-2D polycrystalline aluminum specimen after 3%, 8%, and 13% sample thickness reduction ($\Delta d/d$, where d is the sample extension along compression direction). The strain was determined using photogrammetry. The grain boundaries indicated by black lines were taken from microtexture measurements (EBSD in an SEM)

Fig. 8 Simulated strain distribution in the 8% deformed polycrystalline aluminum sample shown in Fig. 7; left: J2-continuum plasticity; right: crystal continuum plasticity. The finite element calculations were conducted using plane strain boundary conditions and a friction coefficient of $\mu=0.2$. The constitutive crystal plasticity law was implemented using 12 $\{1\ 1\ 1\}\langle 110\rangle$ slip systems and viscoplastic hardening. The details are given in Ref. [1,2]

orientation change when approaching the boundary and the other one does not.

Grain-Scale Heterogeneity of Polycrystal Deformation

In order to investigate strain heterogeneity during polycrystal deformation, an aluminum sample with a single layer of quasi-2D coarse grains was plastically deformed in a channel die plane strain set-up at ambient temperature and low strain rate. Lubrication was obtained by using a Teflon foil. The microtexture was determined by orientation mapping in the SEM. The distribution of the plastic microstrain at the sample surface was determined using photogrammetry. The microtexture was mapped onto a finite element mesh. J2 based* and crystal plasticity finite element simulations were conducted using boundary conditions which approximated those of the channel die experiments.^[1,2]

Figure 7 shows the in-plane distribution of the accumulated plastic von Mises strain in the specimen after 3%, 8%, and 13% sample thickness reduction (given by $\Delta d/d \cdot 100\%$, where d is the sample thickness in compression direction). The grain boundaries indicated by lines were taken from microtexture data. The measurements

reveal that some grains and grain portions show much higher accumulated plastic strain than others. For instance, in the 8% compressed sample, some of the grains have accumulated less than 1% von Mises strain while others show maximum strains beyond 15%, particularly close to the grain boundaries. Related to the total compressive strain of 8%, this establishes an enormous strain heterogeneity with deviations of nearly $\pm 90\%$ from the average value.^[1,2] The phenomenon can be qualitatively interpreted in terms of the different geometrical hardness (orientation factor) of the grains. However, the observed lateral strain variation strongly exceeds the spread expected from the orientation factors. At larger strains, it was found that grain-scale strain hardening gradually equilibrates initial hardness differences among the grains, i.e. grain-to-grain strain heterogeneity is less pronounced at larger loadings. These observations have important consequences for the interpretation of data obtained by constitutive modeling, recrystallization, and electron microscopy. The strong heterogeneity observed suggests that local phenomena must be interpreted in terms of the *local* rather than the *global* strain state. The experimental data shown in Fig. 7 were analyzed using continuum simulations (J2, crystal plasticity; Fig. 8). The calculations reveal two important

Fig. 9 Details of the strain (left) and texture (right) distribution at a triple point between two soft and a hard grain. The three nanotexture maps (right) show the orientation changes between the grain interior far away from the triple point and the triple point in the form of gray scales. Black color indicates orientation changes of 15° between grain interior and the triple point. It can be seen that the hard grain does not reveal substantial in-grain orientation changes between its interior and the triple point. The two soft grains show strong orientation changes when approaching the triple point. This detail suggests that triple points can be of importance at the early stages of strain localization and orientational in-grain subdivision

points. First, the macroscopic plastic strain path is not completely altered by the crystallographic texture, but *modulated* following soft crystals and avoiding hard crystals. Second, grain-scale mechanisms are strongly superimposed by effects arising from the macroscopic profile of strain.^[1,2] Figure 9 shows some strain and texture details at a triple point between two soft and a hard grain. The nanotexture maps show the orientation changes between the grain interior and the triple point in the form of gray scales. It can be seen that the hard grain does not reveal substantial in-grain orientation changes between its interior and the triple point. The two soft grains show strong orientation changes when approaching the triple point. This detail suggests that triple points can be of importance at the early stages of strain localization and orientational in-grain subdivision.

Plastic Grain Interaction and In-Grain Subdivision during Large-Strain Polycrystal Deformation

This section is about experiments and crystal plasticity simulations (plane strain) which address the dependence of in-grain orientation subdivision and deformation textures in aluminum polycrystals on grain interaction.^[1,2,29–35] The finite element simulations are conducted by statistically varying the spatial arrangement of the grains in a polycrystal so that they have different neighbor grains in each simulation (Fig. 10). Each grain contains eight integration

points. The orientation changes of the eight integration points in each grain are sampled for the different polycrystal arrangements. The influence of grain neighborhood on in-grain subdivision and texture is quantified by the use of a mean orientation concept which allows one to calculate the orientation spread among the eight originally identical in-grain orientation points after plastic straining for each crystal (Fig. 11).

An aluminum sample with commercial purity (99.9 mass% Al) was chosen for comparing the finite element predictions with experimental results. For preparing the sample, an aluminum block was forged in three mutually perpendicular directions several times with gradually decreasing thickness reductions. This procedure was conducted in order to produce fine grains and a random texture. After forging, the sample was cold rolled to 95% thickness reduction (engineering strain $\Delta d/d$, where d is the sheet thickness before rolling). The textures were examined by measuring four incomplete pole figures in Bragg back-reflection mode. From the experimental pole figures, the orientation distribution function was derived by the use of the series expansion method and subsequently ghost corrected using spherical Gauss functions (Fig. 11).

The study reveals five important points about the relationship between texture and grain interaction. First, the grain neighborhood has a significant influence on the reorientation of a grain (up to 20% in terms of its end orientation and its orientation density), but its own initial orientation is more important for its reorientation behavior

Fig. 10 Finite element model set-up for evaluating the influence of neighboring grains on the deformation texture

Fig. 11 Texture results obtained from nine crystal plasticity finite element simulations conducted by statistically varying the arrangement of the grains in a polycrystal. Each grain is represented by eight integration points and has different neighbor grains in each of the nine simulations. There are only small differences among the nine calculations which show that details of the grain neighborhood can be regarded as a scalable statistical factor for texture evolution: (a) α -fiber including major components $\{0\ 1\ 1\}\langle 100 \rangle$ (Goss-component, $\varphi_1 = 0^\circ$, $\phi = 45^\circ$, $\varphi_2 = 0^\circ$), $\{0\ 1\ 1\}\langle 211 \rangle$ (brass-component, $\varphi_1 = 35^\circ$, $\phi = 45^\circ$, $\varphi_2 = 0^\circ$), $\{0\ 1\ 1\}\langle 111 \rangle$, and $\{0\ 1\ 1\}\langle 011 \rangle$ (90° about the normal rotated Goss-component, $\varphi_1 = 90^\circ$, $\phi = 45^\circ$, $\varphi_2 = 0^\circ$); (b) β -skeleton line including major components $\{2\ 1\ 1\}\langle 111 \rangle$ (copper-component, $\varphi_1 = 90^\circ$, $\phi = 35^\circ$, $\varphi_2 = 45^\circ$), $\sim\{1\ 2\ 3\}\langle 6\ 3\ 4 \rangle$ (S-component, $\varphi_1 = 60^\circ$, $\phi = 32^\circ$, $\varphi_2 = 65^\circ$), and the brass-component $\{0\ 1\ 1\}\langle 211 \rangle$; and (c) coordinates of β -skeleton line

than the neighborhood. Second, the sharpness of the deformation texture is affected by grain interaction leading to an overall weaker texture when compared to predictions obtained without interaction. Third, the in-grain subdivision of formerly homogeneous grains occurring during straining is strongly dependent on their initial orientation (Fig. 12). For instance, some crystals build up in-grain orientation changes of more than 20° after 95% straining while others do practically not subdivide (Fig. 13).

Fourth, the dependence of in-grain subdivision on the neighbor grains is different for crystals with different initial orientation (cube or rotated Goss grains reveal strong subdivision). Fifth, the upper bound for the variation of texture due to changes in grain neighborhood amounts at most to 5% in terms of the positions of the main texture components. In terms of the overall orientation density, all predictions (using different neighborhood configurations) remain within a narrow tube with an orientation scatter of

Fig. 12 Accumulated in-grain crystalline misorientations in gray scale coding; 50% plane strain thickness reduction of initially uniformly oriented single grains; {111} pole figures; open squares show initial orientations; black dots show orientations of all integration points after deformation; left: body-centered crystal structure using 48 slip systems; right: face-centered crystal structure using 12 slip systems

Fig. 13 In-grain misorientation functions between a mean orientation and the orientations of eight integration points initially pertaining to the same grain (same finite element) for three crystal plasticity finite element simulations with different grain neighborhood. By using a Gauss approach, all misorientation results for the 936 different elements were mapped into Euler space according to their *initial* orientation position. The misorientation functions are normalized so that the contour lines indicate not the absolute but the relative tendency of grains to build up orientation scatter. Most orientations show a small tendency to undergo strong orientation subdivision. Some orientations (e.g. cube) generally reveal a strong tendency to subdivide, irrespective of neighborhood details. Some components (e.g., 90° rotated Goss) reveal a strong dependence in their subdivision behavior on neighborhood details. All results are for face-centered crystal structure with 12 slip systems

Fig. 14 Simulated kinetics and microstructure of recrystallization in a plastically strained aluminum single crystal (cellular automaton). The deformed crystal had a (0 1 1) [1 0 0] orientation and a uniform dislocation density of 10^{15} m^{-2} . Simulation parameter: site-saturated nucleation, lattice size: $10 \times 10 \times 10 \text{ } \mu\text{m}^3$, cell size: $0.1 \text{ } \mu\text{m}$, activation energy of large angle grain boundary mobility: 1.3 eV , pre-exponential factor of large angle boundary mobility: $m_0 = 6.2 \times 10^{-6} \text{ m}^3 / (\text{N} \cdot \text{s})$, temperature: 800 K , time constant: 0.35 sec

10% (β -fiber) to 20% (brass component, α -fiber) when the neighborhood changes.^[1,2,29,35,36]

Simulation of Primary Static Recrystallization and Comparison to Avrami Kinetics

Figure 14 shows the simulated kinetics and microstructures of a recrystallizing aluminum single crystal. The initial deformed crystal had a uniform Goss orientation (0 1 1)[1 0 0] and a dislocation density of 10^{15} m^{-2} . The driving force was due to the stored elastic energy provided

by the dislocations. In order to compare the predictions with analytical Avrami kinetics recovery and driving forces arising from local boundary curvature were not considered. The simulation used site-saturated nucleation conditions, i.e. the nuclei were at $t=0 \text{ sec}$ statistically distributed in physical space and orientation space. The grid size was $10 \times 10 \times 10 \text{ } \mu\text{m}^3$. The cell size was $0.1 \text{ } \mu\text{m}$. All grain boundaries had the same mobility using an activation energy of the grain boundary mobility of 1.3 eV and a pre-exponential factor of the boundary mobility of $m_0 = 6.2 \times 10^{-6} \text{ m}^3 / (\text{N} \cdot \text{s})$. Small angle grain boundaries had a mobility of 0. The temperature was 800 K . The time constant of the simulation was 0.35 sec .

Figure 15 shows the kinetics for a number of 3D recrystallization simulations with site-saturated nucleation conditions and identical mobility for all grain boundaries. The different curves correspond to different initial numbers of nuclei. The initial number of nuclei varied between 9624 (nucleation energy of 3.2 eV) and 165 (nucleation energy of 6.0 eV). The curves (Fig. 15a) all show a typical Avrami shape. The logarithmic plots (Fig. 15b) reveal Avrami exponents between 2.86 and 3.13 which is in good accord with the analytical value of 3.0 for site-saturated conditions. The simulations with a very high initial density of nuclei reveal a more pronounced deviation of the Avrami exponent with values around 2.7 during the beginning of recrystallization. This deviation from the analytical behavior is due to lattice effects. While the analytical derivation assumes a vanishing volume for newly formed nuclei, the cellular automaton has to assign one lattice point to each new nucleus. Figure 16 shows the effect of grain boundary mobility on growth selection.

While in Fig. 16a all boundaries have the same mobility, in Fig. 16b, one grain boundary has a larger mobility (activation energy of the mobility of 1.35 eV instead of 1.40 eV) and, consequently, grows faster than

Fig. 15 Simulated kinetics for various 3D recrystallization simulations with site-saturated nucleation conditions and identical mobility for all grain boundaries (cellular automaton). The different curves correspond to different initial numbers of nuclei. The initial number of nuclei varied between 9624 (nucleation energy of 3.2 eV) and 165 (nucleation energy of 6.0 eV); (a) Avrami diagrams; (b) logarithmic diagrams showing Avrami exponents between 2.86 and 3.13

Fig. 16 Effect of grain boundary mobility on growth selection. All grains grow into a deformed single crystal: (a) all grain boundaries have the same mobility; (b) one grain boundary has a larger mobility than the others (activation energy of the mobility of 1.35 eV instead of 1.40 eV) and grows faster than the neighboring grains (cellular automaton)

the neighboring grains which finally cease to grow. The grains in this simulation all grow into a heavily deformed single crystal.^[12–15]

Examples of Coupling Cellular Automata with Crystal Plasticity Finite Element Models for Predicting Recrystallization

Motivation for Coupling Texture Simulation Methods

Simulation approaches such as the crystal plasticity finite element method or cellular automata increasingly gain momentum as tools for the discrete prediction of microstructure and texture. The major advantage of such approaches is that they consider material *heterogeneity* as opposed to statistical approaches which assume material *homogeneity*. Although the average behavior of materials after deformation and heat treatment can sometimes be well described without accounting for local effects, many examples exist where material response can only be predicted when considering material heterogeneity. For instance, in the field of plasticity, the quantitative investigation of ridging and roping or related surface defects observed in sheet metals requires knowledge about local texture effects. In the field of heat treatment, the origin of the Goss texture in transformer steels, and the incipient stages of cube texture formation during recrystallization can hardly be predicted without knowing local characteristics of the material. Although spatially discrete microstructure simulations

have already profoundly enhanced our understanding of microstructure and texture evolution over the last decade, their potential is sometimes simply limited by an insufficient knowledge about the external boundary conditions which characterize the process and an insufficient knowledge about the internal starting conditions which are inherited from the preceding process steps. It is, thus, an important goal to improve the incorporation of both types of information into such simulations. External boundary conditions prescribed by real industrial processes are often spatially non-homogeneous. They can be investigated using experiments or process simulations which consider spatial resolution. Spatial heterogeneities in the internal starting conditions, i.e. in the microstructure and texture, can be obtained from experiments or microstructure simulations which include spatial resolution.

Coupling, Scaling, Nucleation, and Boundary Conditions

In the present example, the results obtained from a crystal plasticity finite element simulation are used to map a starting microstructure and texture for a subsequent recrystallization simulation. The finite element model is used to simulate a plane strain compression test conducted on aluminum with columnar grain structure to a total logarithmic strain of $\epsilon = -0.434$. The values of the state variables (dislocation density, crystal orientation) given at the integration points of the finite element mesh are mapped on the

regular lattice of a 2D cellular automaton. In the present example, the original size of the specimen which provides the input microstructure to the crystal plasticity finite element simulations give a lattice point spacing of λ_m 61.9 μm . The maximum driving force in the region arising from the stored dislocation density is about 1 MPa. The annealing temperature is 800 K. Large angle grain boundaries are characterized by an activation energy for the mobility of 1.3 eV. Small angle grain boundaries are assumed to be immobile.

The nucleation process during primary static recrystallization has been explained for pure aluminum in terms of discontinuous subgrain growth.^[22] According to this model, nucleation takes place in areas which reveal high misorientations among neighboring subgrains and a high local driving force for curvature-driven discontinuous subgrain coarsening. The present simulation works above the subgrain scale, i.e. it does not explicitly describe subgrain coarsening kinetics. Instead, it incorporates nucleation on a phenomenological basis using the kinetic and thermodynamic instability criteria known from the classical recrystallization theory.^[22] The kinetic instability criterion means that a successful nucleation process leads to the formation of a mobile large angle grain boundary which can sweep the surrounding deformed matrix. The thermodynamic instability criterion means that the stored energy changes across the newly formed large angle grain boundary providing a net driving force pushing it forward into deformed areas. Nucleation in this simulation is performed in accord with these two aspects, i.e. potential nucleation sites must fulfill both the instability criteria. This nucleation model does not create new orientations. At the beginning of the simulation, the thermodynamic criterion, i.e. the local value of the dislocation density is checked for all the lattice points. If it is larger than some critical value, the lattice point is spontaneously recrystallized without any orientation change, i.e. a dislocation density of 0 is assigned to it and the original crystal orientation is preserved. In the next step, the growth algorithm starts according to Eqs. 20–22. This means that the kinetic conditions for nucleation are checked by calculating the misorientations among all spontaneously recrystallized cells (preserving their original crystal orientation) and their neighbor cells. If any such pair of cells reveals a misorientation above 15°, the cell flip of the non-recrystallized cell is calculated according to its actual transformation probability. In the case of a successful cell flip, the orientation of the first recrystallized neighbor cell is assigned to the flipped cell.

Predictions and Interpretation

Figures 17 and 18 show simulated microstructures for site-saturated spontaneous nucleation in all cells with a dislocation density larger than 50% of the maximum value (Fig. 17) and larger than 70% of the maximum value

Fig. 17 Consecutive stages of a 2D prediction of primary static recrystallization in a deformed aluminum polycrystal on the basis of a crystal plasticity finite element simulation in conjunction with a cellular automaton. The figure shows the change in dislocation density (a and b) and in microtexture (c and d) as a function of the annealing time during isothermal recrystallization. The texture is given in terms of the magnitude of the Rodriguez orientation vector using the cube component as reference. The gray areas in the upper figures indicate a stored dislocation density of 0, i.e. these areas are recrystallized. The white lines indicate grain boundaries. The simulation parameters are: 800 K; thermodynamic instability criterion: site-saturated spontaneous nucleation in cells with at least 50% of the maximum occurring dislocation density (threshold value); kinetic instability criterion for further growth of such spontaneous nuclei: misorientation above 15°; activation energy of the grain boundary mobility: 1.46 eV pre-exponential factor of the grain boundary mobility: $m_0 = 8.3 \times 10^{-3} \text{ m}^3 / (\text{Ns})$; mesh size of the cellular automaton grid (scaling length): $\lambda_m = 61.9 \mu\text{m}$

(Fig. 18). Each figure shows a set of four subsequent microstructures during recrystallization. The upper graphs show the evolution of the stored dislocation densities. The gray areas are recrystallized, i.e. the stored dislocation content of the affected cells is dropped to 0. The lower graphs represent the microtexture images where each gray scale represents a specific crystal orientation. The fat lines indicate grain boundaries with misorientations above 15°. The thin lines indicate misorientations between 5° and 15°. The incipient stages of recrystallization in Fig. 17 (cells with 50% of the maximum occurring dislocation density undergo spontaneous nucleation without orientation change) reveal that nucleation is concentrated in areas with large accumulated local dislocation densities. As a consequence, the nuclei form clusters of similarly oriented new grains. Less deformed areas between the bands reveal a very small density of nuclei. Logically, the subsequent stages of recrystallization reveal that the nuclei do not sweep the surrounding deformation structure freely as described by

Fig. 18 Parameters as in Fig. 17, but site-saturated spontaneous nucleation occurred in all cells with at least 70% of the maximum occurring dislocation density

the Avrami-Johnson-Mehl theory but impinge upon each other and, thus, compete at an early stage of recrystallization. Figure 18 (using 70% of the maximum occurring dislocation density as threshold for spontaneous nucleation) also reveals strong nucleation clusters in areas with high dislocation densities. Owing to the higher threshold value for a spontaneous initial cell flip, nucleation outside of the deformation bands occurs very rarely. It also shows an increasing grain size as a consequence of the reduced nucleation density.

Both simulations reveal further that, in most areas where spontaneous nucleation occurs due to a certain dislocation density, the kinetic instability criterion is also fulfilled stimulating further growth of the recrystallized cells. This means that high dislocation densities and large local lattice curvatures typically occur in close neighborhood. Another observation is that the nucleation clusters are particularly concentrated in macroscopical deformation bands which were formed as diagonal through-thickness instabilities. Generic *intrinsic* nucleation inside heavily deformed grains, however, occurs rarely. Nucleation is often successful at former grain boundaries where orientation changes occur naturally. This means that there might be a transition from *extrinsic* nucleation such as inside bands or related large-scale instabilities to *intrinsic* nucleation inside grains or close to existing grain boundaries. Another important result is the partial recovery of deformed material. Figures 17d and 18d reveal small areas where moving large angle grain boundaries did not entirely sweep the deformed material. An analysis of the state variable values at these coordinates and of the grain boundaries involved shows that not insufficient *driving forces* but insufficient *misorientations* between the

deformed and the recrystallized areas – entailing a drop in grain boundary mobility – are responsible for this effect (orientation pinning). Details of the simulations are given in Refs. [12–15,37–39].

Relationships between Texture, Microstructure, and Surface Properties

This section presents a study about surface roughening in aluminum and its microstructural origin. Four aluminum sheets were solution heat treated and aged to T4 condition. All samples have the same chemical composition (6xxx) but different processing and surface quality. The tensile samples were cut parallel to the transverse direction of rolling. The joint experimental investigation for the determination of surface roughness and ridging comprised the following steps: First, the microtexture at the sample surfaces was determined using orientation mapping in the SEM. The step size was $15\mu\text{m}$ and the scanned area amounted to $4000\mu\text{m} \times 4000\mu\text{m}$. Second, the 3D surface topography was measured using a white-light confocal microscope. Third, tensile, bending, and drawing tests were conducted. After each deformation step, digital stereo image pairs of the sample surfaces were taken. Fourth, the 3D plastic displacement fields was calculated after each straining step using photogrammetry. The displacement field serves as input for deriving the surface components of the local strain tensor. After each deformation step, the surface pattern was acquired and the displacement field as well as the strain distribution was calculated. Using the experimental procedures described above, three sets of mappings were determined exactly at the same locations of each sample after each deformation step, namely, the surface topography, the microstrain distribution, and the microtexture. Figure 19 shows the surface topography of two of the four samples after tensile elongation of 7% parallel to the transverse direction (engineering strain). Before the deformation, all surfaces were polished to a mirror-finish. The gray scale code represents the local height. The presented topography maps are filtered with respect to sample bending and long range undulations. While the specimen in the upper row (sample A) shows a very heterogeneous distribution of the von Mises strain and pronounced banding of the cube orientation parallel to the rolling direction, the sample in the lower row (sample B) reveals a very good surface finish, homogeneous strain distribution and a fine grained distribution of the cube texture component without banding or related clustering effects. A comparison of the distribution of the Goss grains in the sheet plane between the two samples A and B does not give a very clear picture (Fig. 20). The overall volume fraction of grains with Goss orientation is very small. Sample A shows a somewhat more pronounced banding of the Goss grains while sample B shows a very homogeneous distribution. The wavelength of the Goss bands in sample A can be correlated

Fig. 19 Two 6xxx aluminum samples in T4 state with different surface quality. The sample presented in the lower row (sample B) reveals better surface quality. The data show: surface topography (left), microstrain distribution, von Mises (center), microtexture, distribution of the cube component (right)

with the spacing of the large bands found in the in-plane distribution of the von Mises strain (Fig. 19).

Although it reveals only a very small overall volume fraction, the Goss orientation is nonetheless a very interesting texture component in the context of ridging and surface roughening. This is due to its symmetry. Tensile tests conducted on flat specimens parallel to the rolling direction reveal less ridging when compared to those which are extended parallel to the transverse direction. In rolling direction, the Goss orientation has a similar Taylor factor and a similar reorientation rate as the cube orientation. However, when rotating the sample 90° about the sheet normal direction prior to testing, thereby turning also the Goss component into a Goss component rotated 90° about its normal direction, renders the Goss a highly unstable orientation with a very high Taylor factor close to 5 and a very high plastic spin.

Figure 21 shows the development of the surface roughness during sheet bending for the four different samples as a function of the bending angle. The measurements were conducted using confocal white-light microscopy. The curvature stemming from bending was corrected by a filter before analyzing the microscopic roughness. The diagram shows different behavior for the different samples. Three of the samples reveal a close to linear development of

surface roughness for bending angles below 30° . One of the specimens has a much more pronounced roughening behavior particularly above 40° . Changes in roughening occur in a transition regime between 30° and 40° which is also indicated by the data shown in Fig. 22 for one of the samples. The critical regime might indicate a change in mechanism, such as the transition from ridging to ridging plus orange peel.^[40]

INTEGRATION OF ANISOTROPY INTO METAL-FORMING SIMULATIONS

Introduction to Anisotropy Engineering

The anisotropy concepts to be reviewed in the following are empirical yield surface approximations, yield surface formulations based on crystallographic homogenization theory, and the recently introduced texture component crystal plasticity finite element method. The present state in anisotropy engineering is naturally different between industrial applications and basic science. The use of empirical or semi-empirical polynomials for yield surface approximations is the standard procedure in the industrial practice whereas the various crystal plasticity

Fig. 21 Development of surface roughness in four aluminum samples during bending as a function of the bending angle. The experimental set-up is presented in the upper left corner. The measurements were made using confocal white-light microscopy

finite element methods gradually become a standard in the basic material sciences. The importance of empirical approaches in the industrial practice is due to the fact that they provide short computation times and require only a small set of input data. An important weakness of empirical approaches lies in the absence of texture update. The prevalence of the crystal plasticity finite element method in basic research is essentially due to the natural incorporation of texture update. The major drawback of the crystal plasticity approach is the long calculation times which presently exceed those required for yield surface simulations by a factor of 50–100. An improvement in the speed of the crystal plasticity methods is attained by the recent introduction of the texture component crystal plasticity finite element method which exceeds the computation times of yield surface calculations only by a factor of 15–25. Overviews to the

Fig. 22 Example for the development of the surface roughness during bending as a function of the bending angle. The measurements were made using confocal white-light microscopy

fundamentals of anisotropy engineering are given in Refs. [38,41–43].

From Scalar to Tensorial Material Concepts

The yield surface represents the generalization of the yield point from uniaxial tensile testing to general stress states. Expanding the yield point into a closed yield surface is only required if the material under inspection shows elastic–plastic anisotropy, i.e. if it deforms differently in different directions. However, such behavior is the rule and not the exception in real materials. Aluminum polycrystals with random and therefore quasi-isotropic behavior do practically not occur in sheet metal-forming operations.

The physical nature of elastic–plastic anisotropy in metals is the crystalline arrangement of the atoms. Commercial aluminum usually occurs in polycrystalline form where each grain has a different crystallographic orientation, shape, and volume fraction. The distribution of the orientations in a polycrystalline aggregate is referred to as (crystallographic) texture. The anisotropy of the elastic tensor and the discrete nature of crystallographic slip along densely packed lattice directions on preferred crystal planes entail a highly anisotropic response of polycrystalline specimens to mechanical loading. While the elastic–plastic deformation of single aluminum crystals and bicrystals as a function of their orientation can nowadays be well predicted, plasticity of polycrystalline samples is less well understood. This is essentially due to the intricate elastic–plastic interactions occurring during co-deformation among the highly anisotropic individual grains. This interaction leads to strong heterogeneity in terms of strain, stress, and crystal orientation. Another difficulty in tackling the anisotropy of polycrystalline aluminum lies in the fact that the crystals rotate during forming, owing to the skew symmetric portion of the displacement gradients created by crystal slip. This means that texture and anisotropy gradually change during forming, even under constant strain path conditions. In this context, it must be underlined that crystallographic orientation changes are principally non-reversible owing to the orientation sensitivity of strain path changes and the orientation dependence of strain hardening. This means that -even in the case of very simple strain paths -mechanics and texture should be treated jointly due to the strong non-linearity of the problem. These aspects which show the complexity of texture and anisotropy during forming underline that, for an engineering purpose, one major aim of polycrystal research must lie in identifying adequate measures for mapping crystallographic anisotropy into classical mathematical methods for predicting large-strain plastic deformation. The second even more challenging aim lies in developing methods for predicting also the *change* of crystal anisotropy during forming on a sound physical basis.^[38,41–43]

The Physical Origin of Crystalline Elastic-Plastic Anisotropy

Elastic Anisotropy

The elastic anisotropy of crystalline matter departs from the directionality of the electronic bond and the resulting crystal lattice structure. For small deviations of the atoms from their equilibrium positions, the reversible elastic response to loads can be approximated by a linear relationship which is referred to as Hooke's law. In this framework, the linear elastic constants can be derived as the components of the second derivative of the electronic potential. The elastic constants can be written in the form of a fourth-rank elastic stiffness tensor C_{ijkl} or in the form of a fourth-rank elastic compliance tensor S_{ijkl} . According to

$$\sigma_{ij} = C_{ijkl} \varepsilon_{kl}, \quad \varepsilon_{ij} = S_{ijkl} \sigma_{kl} \quad (23)$$

symmetry and thermodynamic considerations reduce the 81 elastic constants to a set of three independent numbers ($C_{1111}, C_{1122}, C_{2323}$)** in the case of cubic crystal symmetry (e.g. Al, Fe, Cu) and to a set of five independent numbers ($C_{1111}, C_{1122}, C_{1133}, C_{3333}, C_{2323}$)† in the case of hexagonal crystal symmetry (e.g. Ti, Mg, Zn). The deviation from elastic isotropy can for cubic crystals be quantified by the so-called Zener anisotropy ratio

$$A = \frac{2C_{2323}}{C_{1111} - C_{1122}} \quad (24)$$

While aluminum has a relatively low elastic anisotropy with $A = 1.215$, iron has a larger Zener ratio of $A = 2.346$. Of all the cubic metals, tungsten has the lowest deviation from isotropy with a Zener ratio of $A \approx 1$ and lithium the largest with $A = 9.34$.

Plastic Anisotropy

The plastic anisotropy of crystalline matter also departs from the directionality of the electronic bond and the resulting crystal lattice structure. Both aspects determine which slip planes and which translation vectors (Burgers vectors) serve for the motion of lattice dislocations or the activation of plastically relevant athermal transformations. The main consequence of this anisotropy in the present context is that metals are deformed in a discrete rather than in a continuum fashion rendering plasticity an intrinsically anisotropic property of metals. Assuming that the normalized Burgers vectors b_j and the normalized slip plane normals n_i of the s different slip systems available in a particular crystal lattice are known, their orientation factors m_{ij} can be readily formulated as dyadic products according to

$$m_{ij}^s = n_i^s b_j^s \quad (25)$$

with the symmetric portion being

$$m_{ij}^{\text{sym},s} = \frac{1}{2} (n_i^s b_j^s + n_j^s b_i^s) \quad (\text{crystal coordinates}) \quad (26)$$

when given in crystal coordinates. One must note that all slip vectors are normalized. Transforming the latter equation into the sample coordinate system (Fig. 23) leads to

$$m_{kl}^{\text{sym},s} = \frac{1}{2} (a_{ki} n_i^s a_{lj} b_j^s + a_{ij} n_j^s a_{kl} b_i^s) \quad (27)$$

where a_{ki} and a_{ij} are the transformation matrices between the crystal coordinate system and the sample coordinate system. Using these s different orientation factors, $m_{kl}^{\text{sym},s}$ of the s different available slip systems for the transformation of an external load into the slip geometry provides a simple kinematic formulation for the yield surface of a single crystal, i.e.

$$\begin{aligned} m_{kl}^{\text{sym},s} \sigma_{kl} &= \tau_{\text{crit},+}^{s,\text{active}} \\ m_{kl}^{\text{sym},s} \sigma_{kl} &= \tau_{\text{crit},-}^{s,\text{active}} \end{aligned} \quad (28)$$

for the *active* slip systems, and

$$\begin{aligned} m_{kl}^{\text{sym},s} \sigma_{kl} &< \tau_{\text{crit},+}^{s,\text{non-active}} \\ m_{kl}^{\text{sym},s} \sigma_{kl} &< \tau_{\text{crit},-}^{s,\text{non-active}} \end{aligned} \quad (29)$$

for the *non-active* slip systems (Fig. 24). One must note that the Einstein summation rule applies in all equations in case not stated otherwise. The slip dyads of aluminum at room temperature typically contain $\langle 111 \rangle$ and $\langle 110 \rangle$ vectors.^[38,41–46]

Most points on the single crystal yield surface describe single-slip conditions. In the graphical representation of the yield surface, single slip generally takes place when the stress tensor (in vector transformation notation) points at a hyperplane rather than a hyperconus (Fig. 25). Note that the cubes placed in Fig. 25 indicate the changing orientation of the external reference system, i.e. of the stress state. Polyslip conditions, as usually required for polycrystal deformation owing to the satisfaction of strain-rate

Fig. 23 The plastic anisotropy of crystalline matter departs from the directionality of the electronic bond and the resulting crystal lattice structure. Both aspects determine the slip planes and translation vectors (Burgers vectors) on which lattice dislocations move during plastic deformation. The diagram shows the different coordinate system and the resulting geometrical transformation operations one has to consider in this context

Fig. 24 A simple Schmid-type formulation considering the different orientation factors of all available slip systems which essentially transform an external load into shear stresses acting on the slip systems provides a kinematic formulation for the yield surface of a single crystal. The yield surface shown in figure (a) was derived using the 12 $\{1\ 1\ 0\}\langle 111 \rangle$ slip systems. The yield surface shown in figure (b) was derived using the 12 $\{1\ 1\ 0\}\langle 111 \rangle$, 12 $\{1\ 1\ 2\}\langle 111 \rangle$, and 24 $\{1\ 2\ 3\}\langle 111 \rangle$ slip systems (body-centered cubic). The figure indicates that body-centered cubic alloys, therefore, behave plastically principally different from face-centered cubic alloys

compatibility among the grains, are characterized by hyperconus coordinates of the stress state (Fig. 26). The conus positions for the stress can be calculated using a conventional homogenization approach, for instance, the Taylor–Bishop–Hill theory (indicated by σ^{TBH} in Fig. 26). The corresponding multi-slip positions of the stress tensor, satisfying an externally imposed strain rate, are then denoted as Taylor positions. It must be noted in this context that the Taylor factor generally takes the form of a stress

Fig. 25 Most points on the single crystal yield surface describe single-slip conditions. In the graphical representation of the yield surface, single-slip generally takes place when the stress state (here given in vector notation) points at a hyperplane rather than a hyperconus. The strain-rate tensor is indicated by D and m is the Schmid factor, i.e. the dyadic product of the slip elements. The small cubes placed in the figure indicate the changing relative orientation between the external reference system and the crystal coordinate system

shape tensor for the crystal yield surface rather than that of a factor owing to its dependence on the strain-rate tensor. Its magnitude for a given strain rate determines the kinematic size of the yield surface in the corresponding stress direction characterizing the correct polyslip hyperconus and, thus, the kinematic portion of the corresponding stress state.

The symbols $D^{s=1}$ and $D^{s=2}$ in Fig. 26 indicate the single-slip strain states from slip systems 1 and 2. Using these two slip systems allows one to realize any strain-rate state in the respective conus by a linear combination of $D^{s=1}$ and $D^{s=2}$. For cubic crystals, the yield surface reveals four classes of Taylor states for polyslip and one for single slip.^[38,41–46] These yield states are referred to as

penta slip state (five active slip systems):

$${}^5M_{pq}^i \text{ (fcc, bcc(reduced)) : } i = 56$$

tetra slip (four active slip systems):

$${}^4M_{pq}^j \text{ (fcc, bcc(reduced)) : } j = 108$$

tri slip (three active slip systems):

$${}^3M_{pq}^k \text{ (fcc, bcc(reduced)) : } k = 135$$

bi slip (two active slip systems):

$${}^2M_{pq}^l \text{ (fcc, bcc(reduced)) : } l = 66$$

single slip (one active slip systems):

$${}^1M_{pq}^n \text{ (fcc, bcc(reduced)) : } n = 24$$

(30)

where *fcc* denotes *face-centered cubic* and *bcc* denotes *body-centered cubic* crystal structure. The term *reduced* indicates that only 12 $\{1\ 1\ 1\}\langle 110 \rangle$ bcc slip systems were considered. The number at the end of each row gives the

Fig. 26 Polycrystal deformation requires polyslip conditions in order to satisfy strain-rate compatibility among the grains. Polyslip states are crystallographically characterized by hyperconus coordinates of the stress state. The conus positions for the stress can be calculated using a conventional homogenization approach, for instance, the Taylor-Bishop–Hill theory (indicated by σ^{TBH}). The symbols $D^{s=1}$ and $D^{s=2}$ indicate the single-slip strain states from slip systems 1 and 2. Using these two slip systems allows one to realize any strain-rate state in the respective conus by a linear combination of $D^{s=1}$ and $D^{s=2}$

Fig. 27 The Taylor stress state for a polycrystalline aggregate can for a given external strain-rate state be integrated as a volume weighted sum of all Taylor factors derived separately for each grain for the respective boundary condition. In this figure, M is the Taylor tensor, D is the strain rate, and w is the volume fraction. The counter k sums over all crystals in the aggregate

number of different conus cases (and single-slip cases) for the respective Taylor state. The total Taylor stress state for a polycrystalline aggregate can for a given external strain-rate state then be integrated as a volume weighted sum of all Taylor tensors derived separately for each grain for this boundary condition (Fig. 27).

$$\sigma_{\lambda}^T = \left\{ \frac{1}{\sqrt{6}} (2\sigma_{33} - \sigma_{11} - \sigma_{22}), \frac{1}{\sqrt{2}} (\sigma_{22} - \sigma_{11}), \sqrt{2}\sigma_{23}, \sqrt{2}\sigma_{13}, \sqrt{2}\sigma_{12} \right\} \quad (31)$$

Empirical Approximations of the Yield Surface

The first empirical mathematical description of an anisotropic plastic yield surface was suggested in 1928 by von Mises in the form of a quadratic function.^[47] This approach which was originally designed to approximate the plastic anisotropy of single crystals was in 1948 rendered by Hill^[48] into a generalized form using the Huber-Mises-Hencky approach:

$$f(\sigma_{ij}) = (F(\sigma_{22} - \sigma_{33})^2 + G(\sigma_{33} - \sigma_{11})^2 + H(\sigma_{11} - \sigma_{22})^2 + 2L\sigma_{23}^2 + 2M\sigma_{13}^2 + 2N\sigma_{12}^2)^{1/2} \quad (32)$$

where F , G , H , L , M , and N are anisotropy coefficients. The above equation can be rewritten as

$$f(S_{ij}) = ((G + H)S_{11}^2 + (F + H)S_{22}^2 + (F + G)S_{33}^2 - 2HS_{11}S_{22} - 2GS_{11}S_{33} - 2FS_{22}S_{33} + 2LS_{23}^2 + 2MS_{13}^2 + 2NS_{12}^2)^{1/2} \quad (33)$$

where S_{ij} are the deviatoric stress components. The shape coefficients of Hill's quadratic yield function can be fitted from experimentally obtained mechanical data such as the Lankford values taken in different directions of a specimen. Scaling can be provided by the yield stress obtained from uniaxial tensile testing. While the Lankford coefficients and the yield stress can be determined from tensile testing, the direct measurement of mechanical response under complex loads is an intricate task. Although Hill-based anisotropy simulations (referring to the Hill 1948 model) provide decent approximations at least of the initial plastic anisotropy in the case of certain iron textures and a number of textures in interstitial free steels, they typically fail to predict the yield shape of most aluminum alloys, high strength steels, austenitic steels, copper, or hexagonal materials. Typical examples where the Hill 1948 yield criterion is not applicable are cup drawing operations of aluminum crystals with sixfold slip symmetry, i.e. with a crystal $\{1\ 1\ 1\}$ plane parallel to the sheet surface. In this case, six slip systems have identical Schmid factor relative to the surface which cannot be modeled by the Hill polynomial owing to its quadratic form. Due to this principle shortcoming, a number of optimized empirical anisotropic yield surface concepts with higher-order polynomial forms have been proposed in the last decade, such as those introduced later by Hill^[49] and by Barlat^[50] which are better suited for face-centered cubic alloys and many body-centered cubic steels. In the last years, various authors have presented improved empirical yield surface approaches where the yield function can be fitted using both mechanically obtained and texture-based data.

The chief advantage of using an empirical anisotropic yield surface function as a constitutive law in metal-forming finite element simulations is time efficiency and the simple

mechanical methods with which it can be derived. The dominant limitation of yield surface functions is that the anisotropy of polycrystals generally changes during forming owing to the change of texture. This evolution of anisotropy is not mapped by a corresponding change of the shape of the yield surface. In other words, the same yield surface shape is used throughout one finite element simulation without making a physically meaningful update of its steadily changing shape. Although empirical constitutive laws can be used to gradually change the yield surface shape during forming, their capability is typically constrained by a lack of physical information about the actual development of the crystallographic texture during forming.

Crystallographic Approximations of Elastic-Plastic Anisotropy

Approximation of Elastic Anisotropy Using Polycrystal Homogenization Theory

A typical problem in the field of anisotropy engineering is the approximation of the integral elastic response of a polycrystalline sample under an external load. Although various aspects can principally contribute to the anisotropy of the overall elastic stiffness, we concentrate in the following on the influence of the crystallographic texture. The macroscopic elastic properties of a textured polycrystal can be calculated by formulating appropriate volume-weighted means of the individual elastic single crystal tensor, rotated parallel to the respective local coordinate system of each individual crystal. This average value of the integral elastic tensor must therefore take into account all individual orientations of the grains which are described by the orientation distribution function.

An early homogenization approach for the elastic response under an external load was suggested by Voigt, who assumed that in the case of a macroscopically prescribed strain-rate state, each material portion is in the same strain-rate state as the entire sample, irrespective of its spatial position in the specimen. The strain rate would then be homogeneous throughout the sample. However, in a polycrystalline sample, the elastic response typically varies from grain to grain, due to the spatially changing crystal orientation. Since in the Voigt model the prescribed strain rate is the same everywhere in the sample, the stress must vary. The Voigt limit for the elastic response of a polycrystalline sample can, thus, be calculated by weighting the tensor of the elastic stiffness as a function of orientation with the orientation distribution function. A different approach to treating the homogenization problem in an elastically loaded polycrystalline sample was suggested by Reuss. He suggested that in the case of a macroscopically prescribed stress state each material portion is in the same stress state irrespective of its spatial position in the specimen. The stress would then be homogeneous throughout

the specimen. The elastic response may then vary from grain to grain, in accord with the local orientation of the crystal. Since, in the Reuss model, the prescribed external stress is constant throughout the specimen, the strain must vary according to the local grain orientation. Consequently, the elastic Reuss limit can be calculated for a polycrystal by weighting the tensor of the elastic compliance as a function of orientation with the orientation distribution function. Since neither the Voigt nor the Reuss prediction provides reliable approximations to the elastic modulus of a polycrystal, Hill defined an average modulus which consists of the equally weighted results of both above models.

Approximation of the Yield Surface Using Polycrystal Homogenization Theory

Polycrystalline alloys subject to metal-forming operations typically develop or inherit morphological textures as well as crystallographic textures. While the former are often less relevant in typical commercial sheet material, the latter strongly determine the overall anisotropy. In the following, we will hence concentrate on texture effects on yield anisotropy. Orientation distributions can directly serve as input data for the calculation of the crystallographically determined portion of the yield surface shape using Taylor–Bishop–Hill or self-consistent type approaches.^[41–43,51,52] This applies for a single crystal yield surface as well as for the homogenization bounds of the polycrystal yield surface (Fig. 28). The major spirit and advantage of the crystallographic yield surface over empirical concepts consists in the fact that it reduces the individual anisotropic behavior of large sets of individual grains comprising a polycrystalline aggregate (10^6 – 10^{12} grains for a typical large scale forming operation) to a simple crystallographic shape function. It is, thus, an ideal example of a scale-bridging simulation approach which reduces the tremendous complexity inherent in real microstructures to a simple anisotropic function. Since texture-based yield surface approximations use the complete crystallographic anisotropy information of a specimen, they are often superior to empirical approaches which are fitted only to a small set of mechanical parameters. Modern approaches for the approximation of the yield surface typically use both, texture-based and mechanical data to fit the complete anisotropy function.

More complex yield surface functions incorporate kinematic and kinetic plasticity effects. In this context, it must be noted that the crystallographic texture only gives the respective anisotropic *shape* function for a particular polycrystalline sample, but the texture dependence of the *internal stress* and the individual hardness of the different grains are typically ignored by the constitutive laws employed in homogenization approaches. However, it is principally feasible to generalize the crystallographic yield surface concept by enriching it with the individual

Fig. 28 Some examples of yield functions for different materials calculated by use of the homogenization bounds for their respective polycrystal yield surface. The figure shows yield surface sections for aluminum and steel

strength of each grain. This leads to a formulation of the following kind:

$$f(S_{ij}) = \frac{1}{V} \int_V M_{ij}(\mathbf{g}, D_{ij}) \tau_{\text{crit}}(D_{ij}, \mathbf{g}) dV \approx \sum_{k=1}^N M_{ij}^k \tau_{\text{crit}}^k w^k \quad (34)$$

where $f(S_{ij})$ is the yield surface, V the sample volume, M_{ij} the Taylor shape function obtained by the homogenization theory as a function of strain rate D_{ij} and rotation matrix $\mathbf{g}$, τ_{crit} the flow stress of each individual grain, and w the volume fraction of each grain. An example where kinetic information about the local texture-dependent hardness of the various grains has been used to approximate a yield surface is given in Fig. 29.^[38,53] The left diagram shows a portion of the yield surface as it anisotropically shrinks during partial recrystallization of aluminum. The right-hand side shows three subsequent time steps of a coupled crystal plasticity FEM–cellular automaton simulation where the upper figure gives the texture in terms of the magnitude of the Rodriguez vector and the lower figure the strength in terms of the dislocation density (black areas are recrystallized). The data from this discrete simulation served as an input to the kinematic-kinetic yield surface model.

A Texture Component Crystal Plasticity Finite Element Method for Scalable Large-Strain Anisotropy Simulations

The Basic Challenge of Constitutive Anisotropy Modeling

Aluminum polycrystals typically have crystallographic textures which form and inherit during processing. The intrinsic elastic and plastic anisotropy of crystalline matter

Fig. 29 Calculation of the yield surface of a recrystallizing aluminum sample. The simulations were performed using a crystal plasticity finite element simulation in conjunction with a cellular automaton

entails an overall anisotropic response of such specimens when mechanically loaded. This behavior imposes two basic requirements in the context of forming simulations. The first one is the mapping of the *initial* anisotropy into mathematical formulations for predicting large-strain deformation. The second even more demanding goal is the description of the *change* of crystalline anisotropy during forming. This is necessary since the crystals rotate during deformation owing to the antisymmetry of the crystalline displacement gradients. The first problem can be solved using adequate yield surface functions. The second problem cannot be solved in a straightforward fashion by the use of a statistical constitutive law since each crystal can take an individual reorientation path during forming. Translating this into the yield surface concept means that any constitutive evolution law for the shape function of the yield surface depends on the individual behavior of at least 10^3 possible discrete texture components as a function of their path-dependent local stress and strain-rate states. For solving this problem a new efficient and physically rooted prediction polycrystal plasticity simulation method has recently been developed which accounts for these two crystallographic aspects.^[9,10] It is based on directly feeding discrete orientation components onto the integration points of a crystal plasticity finite element model. The

texture components can be extracted from experimental data, such as pole figures stemming from x-ray or electron diffraction.

Using Texture Components in Crystal Plasticity FE Constitutive Models

As outlined above, the main issue of large-strain, large-specimen crystal plasticity metal-forming simulations is to tackle both the anisotropy due to the starting texture and due to texture evolution. One method could be to assign each grain orientation to one integration point. However, such a brute force approach is not feasible when simulating larger parts containing $\sim 10^{10}$ grains (e.g. automotive parts made of 6xxx aluminum). This essential limitation suggests the use of a more compact mathematical form to map and update textures of large parts properly during metal-forming simulations. Crystal plasticity finite element approaches which update the texture require a *discrete* representation of the orientation distribution function or a portion of it at each integration point. Mapping such a discrete portion of the global texture requires the reduction of the information content to a level at which complex deformation processes can be simulated at reasonable computation costs. Such a form is offered by the

Fig. 30 Schematic sketch of a spherical texture component c with a preferred orientation g^c and scatter width b^c . $f^c(g)$ only depends on $\tilde{\omega}^c = \tilde{\omega}(g^c, g)$, i.e. it is independent of the rotation axis $\vec{n}^c$ [55,56]

texture component method. It approximates the orientation distribution function by a superposition of sets of simple standard functions with individual coordinates, orientation density, and scatter in orientation space. Such a representation of a preferred orientation is referred to as a texture component. In contrast to the use of global symmetric Wigner functions, for instance, in the Fourier-type series expansion methods, the texture component method is based on using spherical, normalized, localized standard functions. [54–56] The superposition can be expressed by

$$f(g) = F + \sum_{c=0}^C I^c f^c(g) = \sum_{c=0}^C I^c f^c(g), \quad (35)$$

where $I^0 = F, f^0(g) = 1$

where g is the orientation, $f(g)$ the orientation distribution function, F the volume portion of all randomly oriented crystals (random texture component), and I^c the volume portion of all crystals which belong to the texture component c (Fig. 30). [56] The orientation distribution function is defined by

$$f(g)dg = 8\pi^2 \frac{dV_g}{V} \text{ which implies } f(g) \geq 0 \quad (36)$$

where V is the sample volume, and dV_g the volume of all crystals with an orientation g within the orientation portion $dg = \sin(\phi) d\phi d\varphi_1 d\varphi_2$. Normalization requires

$$\oint f^c(g)dg = 1 \text{ which implies } \sum_{c=0}^C I^c = 1 \quad (37)$$

As a rule, texture components require positivity, i.e.,

$$f^c(g) \geq 0 \quad \text{for all } g \in G \text{ and } I^c > 0 \quad (38)$$

where G is the orientation space. Distribution functions which have a maximum at a preferred orientation g^c and decrease with increasing orientation distance $\tilde{\omega}^c = \tilde{\omega}(g^c, g)$ are referred to as central functions. Such functions,

Fig. 31 Basic set-up of the texture component crystal plasticity finite element method [9,10]

including corresponding pole figures, can be generally represented in the form of series expansions of χ functions or, respectively, Legendre polynomials. More practical approximations of texture component have been introduced on the basis of spherical Gauß- and Lorentz-functions. [9,10,54–56] Although these functions are not exactly in accord with the central limit theorem, they can be represented in an analytically closed form. In most cases, ordinary spherical Gauß functions are well suited to decompose a texture (Fig. 31). The texture component method provides a small set of compact functions which are characterized by simple parameters of physical significance (Euler angles, scatter, volume fraction). Usually, only a few texture components are required for representing textures of aluminum in a precise mathematical form. The most important texture components in aluminum are the cube-component ($\{0\ 0\ 1\} \langle 100 \rangle$, $\varphi_1 = 0^\circ, \phi = 0^\circ, \varphi_2 = 0^\circ$), the Goss-component ($\{0\ 1\ 1\} \langle 100 \rangle$, $\varphi_1 = 0^\circ, \phi = 45^\circ, \varphi_2 = 0^\circ$), the brass-component ($\{0\ 1\ 1\} \langle 211 \rangle$, $\varphi_1 = 35^\circ, \phi = 45^\circ, \varphi_2 = 0^\circ$), the copper-component ($\{21\ 1\} \langle 111 \rangle$, $\varphi_1 = 90^\circ, \phi = 35^\circ, \varphi_2 = 45^\circ$), and the S-component ($\sim \{1\ 2\ 3\} \langle 634 \rangle$, $\varphi_1 = 60^\circ, \phi = 32^\circ, \varphi_2 = 65^\circ$).

The texture components are extracted from experimentally obtained pole figures (x-ray diffraction, neutron diffraction) or single orientation data sets (electron diffraction) by identifying the main texture maxima and the suggested scatter width and by minimizing the deviation between the original (experimental) texture and the one created by the texture component functions in an iterative fashion. Depending on the experience in interpreting crystallographic textures, the user can specify the position, height, and scatter of the texture components within certain bounds during the minimization. This makes sense, when the number of texture components initially prescribed to match an experimental texture is small or when a certain scatter width of the components should not be exceeded. Subsequently, the so-extracted texture components must be mapped onto the integration points of a finite element mesh. This is conducted in two steps. First, the discrete preferred (center) orientation of each texture component is assigned in terms of its respective Euler

Fig. 32 Simulation (left, right) and experiment (center) of cup drawing of aluminum. Left: the gray scale indicates the sheet thickness. Right: the gray scale indicates the orientation change during drawing

triple $(\varphi_1, \phi, \varphi_2)$ onto each integration point. It is important in this context that the use of the Taylor assumption locally allows one to map more than one texture component on an integration point. Second, all preferred orientations of the components that were initially assigned to the integration points are rotated in a fashion that the resulting distribution of all the rotated orientations deviating from the initial preferred orientation reproduces exactly the desired texture component function. This means that the scatter which was originally only given in orientation space is now matched by an equivalent scatter both in real space and in orientation space. Figures 32 and 33 show some results of the texture component crystal plasticity finite element method.

Thermal Analysis of Aluminum Alloys

Daniel Larouche

Department of Mining, Metallurgy and Materials Engineering, Université Laval, Québec, Canada

Abstract

Thermal analysis is applied on aluminum alloys by researchers to investigate mainly phase transformations, while it is regularly used for quality control purposes in industry. Techniques like cooling curve analysis, differential thermal analysis, differential scanning calorimetry, and isothermal calorimetry are amongst those most frequently used by scientists and engineers. These techniques will be described, and a mathematical description of the results will be developed. State-of-the-art quantification methods applied on aluminum alloys will be presented and criticized based on specific examples taken from the literature.

Keywords: Calorimetry; Cooling curve analysis; Thermal analysis; Phase transformation.

INTRODUCTION

Temperature is a fundamental variable in physics, which can be considered as a measure of the average kinetic energy of the elementary constituents of matter. As such, temperature has a direct impact on the properties of matter, and the set of methods dedicated to quantify the change of material properties with temperature is called thermal analysis. In the aluminum industry, thermal analysis has mainly been used to assess the microstructural transformation, which modifies the properties of the alloys as they are processed or used. In this article dedicated to the thermal analysis of aluminum alloys, we will focus on the methods developed to quantify parameters such as thermal arrests, grain size, level of eutectic modification, the dendrite coherency point (DCP), latent heat, kinetic parameters of phase transformation, fraction of phases, heat capacity, etc. Cooling curve analysis (CCA), differential thermal analysis (DTA), differential scanning calorimetry, and isothermal calorimetry are the methods that will be described and discussed. Emphasis will be put on the mathematical description of the methods enabling quantification of the parameters mentioned earlier and not on a systematic literature review of all contributions made on the characterization of aluminum alloys via thermal analysis. The intention of the author is to present a comprehensive description of thermal analysis applied to the metallurgy of aluminum alloys and to highlight the most relevant methods of quantification.

COOLING CURVE ANALYSIS

Among the techniques used to analyze the phase transformations occurring during the processing of an alloy, the

CCA is the simplest to perform. It consists of recording the evolution of the temperature of a hot specimen during the time it is cooled by the environment. Considering its simplicity, CCA is recognized as a low-cost technique to perform quality control on the shop floor. It is mainly used by foundries because of its efficiency to investigate the solidification path of alloys. To perform this control, one or two thermocouple junctions are immersed in a small sample of liquid metal contained in a cup having the smallest possible heat capacity. For aluminum alloys, it is recommended to use a crucible made of thin steel sheet having the following dimensions: 40–70 mm diameter, 50–120 mm height, and 0.1–0.2 mm wall thickness.^[1] Sampling of the liquid metal must be done in a consistent manner since the cooling curve is affected by the mass of the sample, the pouring temperature, and the oxidation level of the metal.^[2] Figure 1 presents a commercially available stand using one thermocouple to perform the thermal analysis of aluminum alloys. Other configurations can be used as those using two thermocouples to perform the so-called Fourier analysis. An example of such a configuration is presented in Fig. 2, where pressurized air can be used to adjust the cooling rate. This setup was used by Kamga et al.^[3] for the thermal analysis of 206-type alloys. Depending on the inlet air pressure, cooling rates between 1 and 4 K/s can be established just before the onset of solidification.

Thermal Arrests

Figure 3 presents a typical cooling curve obtained on a 206-type alloy with the setup shown in Fig. 2. One can easily see three thermal arrests on this cooling curve, while the last one, occurring at around 510°C, is better visualized by the examination of the curve dT_c/dt versus T_c (Fig. 4).

Fig. 1 Commercial stand (Meltlab) dedicated to the thermal analysis of aluminum alloys. The picture is a courtesy of David Sparkman

These curves give valuable information about the microstructure that is resulting from the solidification of this alloy. Since there are four thermal arrests, there are four reactions giving at least four different solid phases. It is not clear however to say, without any other means, what are these reactions. An examination of the microstructure obtained is a prerequisite to know the phases obtained. Figure 5 presents the as-cast microstructure. Most of the secondary phases are compounds close to θ - Al_2Cu , β - $\text{Al}_7\text{Cu}_2\text{Fe}$ or $\beta(\text{FeCu})$, and Mg_2Si . Frequently, the compounds made of high melting point elements come

Fig. 2 Thermal analysis setup used by Kamga et al.^[3]

first after the primary Al-rich phase, followed by those made with lower melting point elements.

Based on this simple rule, one can guess that peaks 2, 3, and 4 are, respectively, associated with $\beta(\text{FeCu})$, θ - Al_2Cu , and Mg_2Si . To validate the solidification path, one can use the Scheil module of Thermo-Calc^[4] to calculate the evolution of the apparent specific heat capacity (Fig. 6).

It is clear from the Scheil model that the four thermal arrests recorded by the cooling curve analysis come from the following reactions:

1. LIQUID $\rightarrow$ FCC_A1 + LIQUID.
2. LIQUID $\rightarrow$ FCC_A1 + $\text{Al}_7\text{Cu}_2\text{M}$ + LIQUID.
3. LIQUID $\rightarrow$ FCC_A1 + $\text{Al}_7\text{Cu}_2\text{M}$ + Al_2Cu + LIQUID.
4. LIQUID $\rightarrow$ FCC_A1 + $\text{Al}_7\text{Cu}_2\text{M}$ + Al_2Cu + Mg_2Si + LIQUID.

Fig. 3 Cooling curve obtained with the alloy $\text{Al}-4.64\text{Cu}-0.23\text{Mn}-0.25\text{Mg}-0.27\text{Fe}-0.10\text{Si}-0.02\text{Ti}$ (wt%)

Fig. 4 Cooling curve derivative obtained with the alloy Al–4.64Cu–0.23Mn–0.25Mg–0.27Fe–0.10Si–0.02Ti (wt%)

Fig. 5 As-cast microstructure of the alloy Al–4.64Cu–0.23Mn–0.25Mg–0.27Fe–0.10Si–0.02Ti (wt%)

The onset temperatures and the microstructure are in close agreement with the model except for the nonappearance of the Al_6Mn phase. Since there was no trace of a thermal arrest associated with this phase, one can conclude that the conditions for the nucleation and growth of this phase were not favorable. This illustrates the utility of the cooling curve analysis. It can substitute the metallographic examination if one has a good knowledge of the system or can predict the phases present in the microstructure by using a computational thermodynamic application. Starting from this point, the foundrymen can use the cooling curve analysis to assess the thermal signature of the ideal alloy composition and use further analysis to address any deviation from this curve. Compositions out of specifications or a certain amount of impurities can modify the onset temperatures or activate new reactions. To determine precisely the onset temperature of a reaction, some authors recommended using the second derivative of the cooling curve.^[5,6] Figure 7 presents a good example where the second derivative is used to determine the nucleation

temperature T_N of the primary dendritic Al phase in a near eutectic Al–Si–Cu–Fe alloy.

Sparkman^[7] suggests using higher-order derivatives, especially for complex phases making a very weak perturbation on the cooling curve. A complex phase can be defined as a phase made of at least two solute elements having dissimilar properties (coefficient of diffusion, activity, etc.), which imposes constraints to the migration of the interface. Beta crystals (Al_5FeSi and $\text{Al}_7\text{Cu}_2\text{Fe}$) and many other Fe intermetallic particles belong to that category of phases. The growth kinetics of these phases is complex and unclear. To understand the utility of using higher-order derivatives, one can imagine that a thermal arrest cause a deviation of the cooling curve, and it can be given as follows:

$$\Delta T(t) = u(t) \cdot \left[1 - \exp\left(-\beta(t - t_0)^n\right) \right] \quad (1)$$

where $u(t) = 0$ for $t < t_0$ and $u(t)$ remains constant for $t \geq t_0$. Figure 8 illustrates the impact of the exponent n on the cooling curve and its derivatives. In this example, the onset temperature is 580°C , and the reaction starts at time $t_0 = 1$ s in both cases. If the kinetic exponent $n = 3$, the first derivative shows a marked deviation at $t = 1$ s. But if the kinetic exponent $n = 6$, only the fifth derivative shows a marked deviation at $t = 1$ s. From its second derivative, one would estimate that the onset time is around 1.2 s instead of 1 s, giving an onset temperature of 579.2°C instead of 580°C . The error is small but one has to recall that the utility of the thermal analysis is to detect small deviations from batches to batches. It is interesting to notice that when the kinetic exponent is higher, one obtains a larger deviation from the constant cooling rate curve (dotted lines) but at a later time. This exemplifies the care we have to take when it is time to discuss the kinetics of a reaction from a cooling curve.

Fig. 6 Apparent specific heat capacity calculated with the Scheil Module of Thermo-Calc

Fig. 7 Thermal arrest associated to the nucleation of the primary dendritic phase in a near eutectic Al-Si-Cu-Fe alloy containing Bi^[6]

The challenge to obtain higher derivatives of cooling curves is the noise on the raw data. Even the second-order derivative can be very noisy if no precaution is taken to smooth the data, as this was demonstrated by Ibarra.^[8] Sparkman recommends using several noise suppression techniques, a 16-bit industrial grade analog-to-digital converter, and appropriate smoothing techniques in order to work with the fifth-order derivative in cooling curve analysis.^[9]

Microstructure Validation

During solidification, the growth rate of solid phases in Al castings depends on a number of factors like the cooling rate, the number density of primary phase nuclei, and the mobility of the interfaces. The impact of cooling rate on solidification characteristics has been studied extensively in many Al alloys, and it is generally accepted that it affects principally the secondary dendrite arm spacing.

Fig. 8 Impact of the kinetic exponent on the cooling curve and its derivatives

Grain size may also depend on the cooling rate, but not too much if grain refiners are added at the optimum level.^[10] In practice, cooling curve analysis is carried out under similar cooling conditions, and so, basically, microstructure validation is done via a verification of the efficiency of grain refiners and eutectic modifiers. These have a direct impact on the number density of primary phase nuclei and the growth kinetics of eutectic phases. Many authors have confirmed that grain size prediction is possible from the analysis of the thermal arrest associated with the nucleation of the primary^[11–20] solid phase. Considering the parameters characterizing the thermal arrest (see Fig. 9), Charbonnier^[12] showed that the time interval t_1 should give a better correlation with the grain size than ΔT , and this was confirmed by many authors.^[14–18]

Ibarra^[8] explained that the duration of recalescence (t_1) is related to the growth of the primary grains. The longer this time is and the larger the grains are. The evolution of fraction solid that can be deduced from the liquid peak area (shaded area in Fig. 9) gives also an excellent correlation with the grain size as demonstrated by Yen et al.,^[13] the latter calling this area the liquid peak parameter (LPP). It is likely that the fraction solid advance

Fig. 9 Temperature and time parameters characterizing a thermal arrest with undercooling

during t_1 can provide a better comparison basis when the cooling rate is not well controlled. Figure 10 presents the correspondence obtained by Yen and coworkers between LPP and the grain size with a commercial SAE 331 Al–Si–Cu alloy.

Fig. 10 Plot of nominal grain size versus liquidus peak parameter for a commercial SAE 331 Al-Si-Cu alloy^[13]

In spite of these excellent demonstrations, it seems that no real prediction of grain size can be made before a good correlation is established for a given setup and alloy. For that reason, cooling curve analysis remains a qualitative mean to estimate the grain size.

Cooling curve analysis can also reveal the level of modification of the eutectic microconstituent in Al-Si alloys. Modifiers are elements like, Na, Sb, and Sr, which are added in the melt to change the morphology of the eutectic silicon from acicular to fibrous.^[21] The modification increases notably the ductility and the machinability of the Al-Si alloys.^[22] The effect of modifiers on the eutectic thermal arrest is schematized in Fig. 11. The most significant impact is the depression of the eutectic temperature (ΔT_E), which increases as the level of modification increases.^[11,12,23] As an example, $\Delta T_E \approx 6-8$ K between the unmodified and the fully modified state of the A356 alloy.^[21] Amongst the other parameters that can be deduced from the cooling curve, ΔT_E is recognized as the most suitable for the evaluation of the modification

Fig. 11 Impact of the modifiers on the eutectic thermal arrest

level and has been endorsed by recent contributions.^[24-27] It is worthwhile to mention that the eutectic recalescence temperature interval (ΔT_M) can also be used to evaluate the modification level as this was shown by Shabestari et al.^[28] These authors found with their 319 alloy that ΔT_E and ΔT_M vary in a similar way with the Sr content. The problem with recalescence is that it can be very small when cooling rates and thermal gradients are high in the sample cup.

Dendrite Coherency

During the growth of the primary phase, there is a point from which the dendrites form a 3D network, capable of sustaining some stress. This precise moment is called the DCP. Solidification proceeds thereafter principally by the lateral growth and Ostwald ripening of the secondary dendrite arms. The determination of this point from a cooling curve has been explained and demonstrated by Backerud et al.^[29] These authors used the cooling curves recorded by two thermocouples, the first providing the temperature in the center of the sample (T_c) and the second providing the temperature near the wall of the sample cup (T_w). They argue that the difference between T_c and T_w reaches a maximum value at the DCP, to decrease thereafter during the thickening of the dendrite arms. According to these authors, the radial thermal gradient increases during the time the dendrites are growing toward the center of the sample because of the latent heat released in front of the advancing tips. Consequently, the largest difference between T_c and T_w occurs when the dendrites meet in the center. Figure 12 presents the evolution of $\Delta T = T_w - T_c$ and the derivatives of the cooling curves obtained for the case presented in Figs. 3 and 4.

In this example, the DCP occurs at 38 s according to the minimum obtained for $T_w - T_c$ (a maximum in absolute value). It is interesting to notice that the two time derivatives dT_c/dt and dT_w/dt intersect at this time, and that we have a local minimum in the second-order time derivative of T_c . These apparent coincidences are in perfect agreement with those previously observed by Jiang et al.^[30] on 319 and 356 base alloys. First of all, it is obvious that the minimum of $T_w - T_c$ occurs when $dT_w/dt = dT_c/dt$ since $d\Delta T/dt = 0$ at this time. It is less obvious however to explain the correspondence between the minimum of d^2T_c/dt^2 and ΔT . Jiang et al.^[30] have explained this correspondence by the fact that the acceleration of the cooling rate before DCP should result from an increase in the thermal conductivity of the semisolid alloy produced by the formation of the dendritic network, the solid phase having a larger thermal conductivity than the liquid phase. After the DCP, the acceleration of the cooling rate should then be decreased by slowing down of the thermal conductivity increasing rate. This results in an inflection of d^2T_c/dt^2 versus time at the DCP. Their explanation is based on the premise that an acceleration of the cooling rate is necessarily caused by an increase of the heat losses at the

Fig. 12 Evolution of $\Delta T = T_w - T_c$ and the derivatives of the cooling curves recorded during the solidification of the alloy Al-4.64 Cu-0.23 Mn-0.25 Mg-0.27 Fe-0.10 Si-0.02 Ti (wt%)

periphery, otherwise one could not obtain a larger thermal gradient ΔT while having a higher thermal conductivity. An alternative explanation can be put forward on the premise that the acceleration of the cooling rate is not caused by the increase of heat losses, but by a reduction of the rate of latent heat generated when approaching the DCP. Examination of the curve dT_c/dt versus time shown in Fig. 12 shows that the cooling rate in the center is almost equal to zero during the dendrite growth until $t = 25$ s. This period of very low cooling rate, which is called a thermal arrest, is undoubtedly caused by the latent heat released. It is reasonable to say that, if there is a slow increase of dT_c/dt after $t = 25$ s, it is much likely caused by a reduction of the rate of latent heat released at this stage. Indeed, latent heat is generated at the solid-liquid interface, and it is likely that the surface area of the latter does not increase at the same rate when the dendritic structure is closed to the DCP. Once the DCP is reached, the rate of latent heat released decreases because the fraction solid increases then essentially by the thickening of the dendrites, which is a slower process of heat generation. So, after the DCP, dT_c/dt increases at a slower pace, giving an inflection point in the plot of dT_c/dt versus time. Moreover, $T_c = 644^\circ\text{C}$ at $t = 25$ s, and according to Fig. 6, this corresponds to the highest peak of the apparent heat capacity. So, as soon as T_c is getting below this temperature, the rate of latent heat released is diminishing accordingly. These explanations are more in phase with the explanation given originally by Backerud et al.,^[29] except that the latter did not discuss about the local minimum occurring on the curve d^2T_c/dt^2 versus time.

Evolution of Latent Heat and Fraction Solid

An estimate of the latent heat evolution is possible from a cooling curve if one accepts a certain number

of assumptions and approximations. When only one thermocouple is used, the heat balance can be written globally, and the heat losses have to be estimated from the external boundary condition. This is the Newton type of analysis for which the heat balance can be written as follows:^[31,32]

$$\rho \cdot V \cdot c_p \frac{dT_c}{dt} = -\dot{\lambda} - UA(T_c - T_o) \quad (2)$$

(Rate of increase of internal energy) = (rate of heat released by phase transformation) – (rate of heat losses)

where V is the volume of metal, ρ the density of metal, c_p the specific heat capacity of metal, T_c the temperature measured in the center of the sample, t the time, $\dot{\lambda} = d\lambda/dt$ the rate of heat absorbed by the transformation, U the global heat transfer coefficient, A the effective surface area, and T_o the ambient temperature. Outside the solidification interval, there is no latent heat released, and in this case we have:

$$UA(T_c - T_o) = -\rho \cdot V \cdot c_p \left(\frac{dT_c}{dt} \right)_{zc} \quad (3)$$

The variable $(dT_c/dt)_{zc}$ represents the time derivative of the zero cooling curve that would prevail in the absence of latent heat. It is assumed that this curve can be extrapolated in the solidification interval to calculate the latent heat. Inserting Eq. 3 into 2 one obtains:

$$\dot{\lambda} = -\rho \cdot V \cdot c_p \left[\frac{dT_c}{dt} - \left(\frac{dT_c}{dt} \right)_{zc} \right] \quad (4)$$

The heat of phase transformation at time t will therefore be given by:

$$\int_0^t \dot{\lambda} dt = \Delta\lambda(t) = -\rho \cdot V \cdot c_p \int_0^t \left[\frac{dT_c}{dt} - \left(\frac{dT_c}{dt} \right)_{zc} \right] dt \quad (5)$$

If L is the latent heat of phase transformation, then

$$L = -\frac{\Delta\lambda(t_c)}{\rho \cdot V} \quad (6)$$

where t_c is the time required for a complete transformation. The latent heat can therefore be estimated by:

$$L = c_p \cdot \left[\text{Area between the curves } dT_c/dt \text{ and } \left(dT_c/dt \right)_{zc} \text{ vs time} \right] \quad (7)$$

The main approximations are those needed for the determination of the zero curve $(dT_c/dt)_{zc}$. The simplest approach considers that the global heat transfer coefficient and all material properties appearing in Eq. 3 are constant. Under these conditions, one can deduct from Eq. 3 that:

$$\left(\frac{dT_c}{dt} \right)_{zc} = a \cdot \exp(-b \cdot t) \quad (8)$$

For the case studied before, one obtains the plots shown in Fig. 13.

The evolution of latent heat calculated from Fig. 13 is compared in Fig. 14 with the one obtained from the Scheil module of Thermo-Calc. At the end of the transformation, the total latent heat released calculated by the cooling curve analysis is 313 J/g, while the value calculated by the Scheil module of Thermo-Calc is 337 J/g. Notice that an average value of $c_p = 1.11 \text{ J} \cdot \text{g}^{-1} \cdot \text{K}^{-1}$ was used with

Fig. 14 Evolution of latent heat released as calculated from the Scheil module of Thermo-Calc and from the cooling curve analysis for the alloy Al-4.64 Cu-0.23 Mn-0.25 Mg-0.27 Fe-0.10 Si-0.02 Ti (wt%)

Eq. 7. This value was taken as an average value of the specific heat capacities calculated by Thermo-Calc just before liquidus and after solidus.

The agreement between the two curves is quite good considering the high level of simplifications made. Some authors have proposed alternative methods of baseline determination in order to improve the accuracy of the Newtonian analysis.^[33–35]

Another method, proposed originally by Frasn et al.,^[36] uses two thermocouples embedded in the melt to estimate the heat losses. This method is called the Fourier analysis because it is based on the heat conduction between the two thermocouples. By performing a heat balance on a cylindrical volume element having an average volume thermal conductivity, one obtains the following equation:

$$\dot{Q} = c_p \left(\frac{\partial T}{\partial t} - \alpha \nabla^2 T \right) \quad (9)$$

Fig. 13 Plots of the cooling curve time derivative and the zero cooling curve time derivative for the alloy Al-4.64 Cu-0.23 Mn-0.25 Mg-0.27 Fe-0.10 Si-0.02 Ti (wt%)

(Rate of heat generated by phase transformation) = (rate of increase of internal energy) – (rate of heat losses by conduction). The units are in W/g.

The latent heat of phase transformation at time t will therefore be given by:

$$\int_0^t \dot{\lambda} dt = \Delta\lambda(t) = c_p \cdot \int_0^t \left(\frac{\partial T}{\partial t} - \alpha \nabla^2 T \right) dt \quad (10)$$

This equation is similar to Eq. 5 except that the zero curve is now given by the term $\alpha \nabla^2 T$. In the absence of latent heat, we have from Eq. 9:

$$\alpha = \frac{\partial T / \partial t}{\nabla^2 T} \quad (11)$$

A simple expression for $\nabla^2 T$ can be obtained by assuming a parabolic temperature distribution in the cylindrical sample. If r is the radial coordinate, one can therefore use the following expression:

$$T = Ar^2 + B \quad (12)$$

to find that:

$$\nabla^2 T = \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial T}{\partial r} \right) = 4A \quad (13)$$

The variable A can be estimated from Eq. 12 using the temperatures T_1 and T_2 measured, respectively, at radii R_1 and R_2 . Inserting the result in Eq. 13, one obtains:

$$\nabla^2 T = \frac{4(T_2 - T_1)}{R_2^2 - R_1^2} \quad (14)$$

The main difficulty of the Fourier analysis is the evaluation of the thermal diffusivity α in the solidification interval. The extremum values of α can be obtained with Eqs. 11 and 14 using the experimental data before the liquidus and after the solidus. These will correspond to the diffusivity of the liquid phase (α_l) and the diffusivity of the solid phase (α_s). These values are quite different in general, so a rule of mixture must be applied to interpolate the evolution of α between the liquids and the solidus. Finally, the evolution of latent heat is calculated by iteration using the following equations:

$$f_s(t) = \frac{\Delta\Omega(t)}{L} \quad (15)$$

$$\alpha = f_s \cdot \alpha_s + (1 - f_s) \cdot \alpha_l \quad (16)$$

$$c_p = f_s \cdot c_{ps} + (1 - f_s) \cdot c_{pl} \quad (17)$$

where f_s is the fraction solid, c_{ps} and c_{pl} are, respectively, the specific heat capacity of the liquid and solid phases,

and L is the total latent heat. Since this method removes the difficulty of working with a global heat transfer in order to get a better determination of the zero curve, some authors rated the Fourier analysis as more accurate than the Newton analysis.^[33,37] There are, however, many drawbacks with the Fourier analysis. First, the calculation of $\Delta\Omega(t)$ depends on the fraction solid of the phases and particularly on the validity of Eq. 15. But this equation is truly valid only if the difference between the enthalpy of the liquid and solid phases is constant throughout the solidification interval. This is not true in general since the composition of the phases varies significantly as the solidification proceeds.^[38] Moreover, more than one solid phase can nucleate and grow in multicomponent alloys, and the enthalpy difference between the liquid and solid phases may change rapidly, particularly when eutectic phases are involved. Second, it is almost impossible to get an accurate rule of mixture to evaluate the diffusivity in the solidification interval. According to Eq. 16, the thermal resistance of the liquid and solid phases is assumed to be connected in parallel. But one can assume that they are connected in series, so the rule of mixture should be

$$\frac{1}{\alpha} = \frac{f_s}{\alpha_s} + \frac{(1 - f_s)}{\alpha_l} \quad (18)$$

The reality is more complex than Eqs. 16 and 18, so a rough approximation is required. If α_s and α_l would have similar values, the error would not be significant. The problem is that α_s is two to three times the value of α_l in general, so one can say that the exact evolution of $\alpha \nabla^2 T$ is not known. The Fourier analysis also requires two thermocouples, and one has to ensure that most of the heat losses are in the radial direction. If axial and radial losses are comparable, the evaluation of $\nabla^2 T$ with Eq. 14 will be wrong. Supposing that heat losses are equal in all directions (spherical symmetry), then a factor 6 should be used instead of 4 in Eq. 14. This indicates that a long cylindrical cup should be used when a slow cooling rate is wanted because it is difficult to eliminate completely heat losses in the axial direction.

DIFFERENTIAL THERMAL ANALYSIS

The operational principle of DTA is to measure and compare the temperature evolutions of a specimen and an inert reference material under controlled heating or cooling conditions. Figure 15 presents a schematic illustration of a DTA setup.

A very good mathematical description of the DTA has been given by Gray.^[39] The theory that will be developed in “Differential Thermal Analysis” and “Differential Scanning Calorimeters” sections is largely inspired by his simple generalized model. The sample and reference cells

Fig. 15 Schematic of a differential thermal analyzer (DTA)

of the DTA are equally heated by a furnace, which is controlled via the temperature T_f measured by a thermocouple inserted near the heaters. If R is the total heat resistance between the furnace and the cells, the heat transferred to the sample cell can be written as follows:

$$q_{sc} = \frac{T_f - T_{sc}}{R} \quad (19)$$

Assuming that there is no temperature difference between the materials and their container, the heat transferred to the sample cell will change its temperature at a rate, which can be deduced from the following equation:

$$q_{sc} = C_{sc} \frac{dT_{sc}}{dt} + \dot{\lambda} \quad (20)$$

where C_{sc} is the heat capacity of the sample cell, and $\dot{\lambda}$ is the rate of heat absorbed by the sample due to a phase transformation. Notice that the unit of C_{sc} is J/K, since it combined the mass and the specific heat capacities of the sample and its container. Combining Eqs. 19 and 20, one obtains

$$T_f - T_{sc} = R \cdot \dot{\lambda} + R \cdot C_{sc} \frac{dT_{sc}}{dt} \quad (21)$$

A similar equation can be written for the reference cell, except that $\dot{\lambda} = 0$ in this case:

$$T_f - T_{rc} = R \cdot C_{rc} \frac{dT_{rc}}{dt} \quad (22)$$

Subtracting Eq. 22 from 21 and rearranging the terms, one obtains:

$$\Delta T(t) = T_{sc} - T_{rc} = R \cdot C_{rc} \frac{dT_{rc}}{dt} - R \cdot C_{sc} \frac{dT_{sc}}{dt} - R \cdot \dot{\lambda} \quad (23)$$

Generally, a constant cooling or heating rate is applied. As a first-order approximation, we will assume that the heat transferred to the inert material is constant when $dT_f/dt = \dot{T}_f$

is constant, so that $dT_{rc}/dt \approx \dot{T}_f$. As long as there is no phase transformation, $\dot{\lambda} = 0$ and $dT_{sc}/dt \approx dT_{rc}/dt = \dot{T}_f$, so one can write as follows:

$$\text{For } t \leq 0: \Delta T(0) = R(C_{rc} - C_{sc})\dot{T}_f \quad (24)$$

If the sample is made of a pure substance, a transformation starts at $T_{sc} = T_{crit}$ and then $dT_{sc}/dt = 0$ during the transformation. The evolution of ΔT deduced from Eq. 23 gives in this case the following relation:

$$\text{For } t \geq 0: \Delta T(t) = R \cdot C_{rc} \dot{T}_f - R \cdot \dot{\lambda} \quad (25)$$

Since T_{sc} is a constant and T_{rc} increases linearly with time at a constant rate $\dot{T}_f$, the evolution of $\Delta T(t)$ after the onset of the transformation will be given as follows:

$$\text{For } t \geq 0: \Delta T(t) - \Delta T(0) = \dot{T}_f \cdot t \quad (26)$$

Inserting Eqs. 24 and 25 into Eq. 26, one obtains:

$$\dot{\lambda} = \left(C_{sc} + \frac{t}{R} \right) \dot{T}_f \quad (27)$$

The integration of $\dot{\lambda}$ from the beginning ($t = 0$) to the end ($t = t_{\max}$) of the transformation gives the latent heat $\Delta\lambda$:

$$\int_0^{t_{\max}} \dot{\lambda} dt = \Delta\lambda = \int_0^{t_{\max}} \left(C_{sc} + \frac{t}{R} \right) \dot{T}_f dt = \left(C_{sc} t_{\max} + \frac{t_{\max}^2}{2R} \right) \dot{T}_f \quad (28)$$

Solving for $t_{\max}$, one obtains:

$$t_{\max} = RC_{sc} \left[-1 + \sqrt{1 + \frac{2\Delta\lambda}{RC_{sc}^2 \dot{T}_f}} \right] \quad (29)$$

Once the transformation is finished, $\dot{\lambda} = 0$ and Eq. 23 becomes:

$$\Delta T(t) - \Delta T(0) = -R \cdot C_{sc} \frac{d\Delta T}{dt} \quad (30)$$

Imposing the initial condition at $t_{\max}$, one can obtain:

$$\Delta T(t_{\max}) - \Delta T(0) = \Delta T_{\max} = \dot{T}_f \cdot t_{\max} \quad (31)$$

The solution of Eq. 30 is:

$$\Delta T(t) - \Delta T(0) = \Delta T_{\max} \exp\left(-\frac{t - t_{\max}}{R \cdot C_{sc}}\right) \quad (32)$$

Figure 16 presents the time evolution of $\Delta T(t)$ when the pure substance is undergoing a phase transformation.

The main limitation of DTA comes from the fact that the magnitude of the signal $\Delta T_{\max}$ is proportional to $t_{\max}$, the latter increasing with the thermal resistance R .

Fig. 16 Theoretical DTA curve for the phase transformation of a pure substance

If the magnitude of the signal increases with R , its width also increases with R as this is illustrated in Fig. 17.

The ideal analyzer should produce a sharp and intense peak for a phase transformation occurring in a narrow temperature interval. To get a sharp signal, the DTA should have a low thermal resistance. Unfortunately, a low thermal resistance reduces the magnitude of the peak and a compromise must be chosen. It is possible to evaluate the latent heat of the phase transformation from a DTA peak. Combining Eqs. 28 and 31, one obtains:

$$R\Delta\lambda = \frac{\Delta T_{\max} \cdot t_{\max}}{2} + R C_{sc} \Delta T_{\max} \quad (33)$$

The first term of Eq. 33 represents the area of region “A” shown in Fig. 16, while the second represents the area of region “B.” This means that the peak area is equal to $R\Delta\lambda$, and that a precise knowledge of R would permit to get an accurate determination of $\Delta\lambda$. A good instrument should therefore minimize the variation of R with temperature and sample size. Moreover, the thermal resistance between the sample and its container should be negligible in comparison to the thermal resistance between the furnace and the cell; otherwise, the onset temperature measured by the DTA would be offset from the real T_{crit} . The theory

Fig. 17 Impact of the thermal resistance on peak height and area for a sharp transition with a DTA

described earlier should also be upgraded by taking into account two other thermal resistances, one for the sample–container interface and another for the reference–container interface. In every circumstance, a precise calibration of the thermal resistance is mandatory to make quantitative estimations of the latent heat with a DTA.

DIFFERENTIAL SCANNING CALORIMETERS

There are two types of differential scanning calorimeters, the first one is the heat flux DSC (HF-DSC) and the second one is the power-compensated DSC (PC-DSC). These instruments differ in the way they measure the differential heat flow rates between the sample and the reference cells subjected to the same temperature variation. Since both types were used to study phase transformations in aluminum alloys, we will describe their principles of operation and give some examples of analysis made with them in the section entitled “Differential Scanning Calorimetric Analysis of Aluminum Alloys”.

Heat Flux DSC

HF-DSC may have a cylindrical-type arrangement, similar to the schematic DTA presented before, or a disk-type arrangement. When a cylindrical-type DTA includes a system converting ΔT to heat flux, the instrument can be considered as an HF-DSC, and the theory presented in “Differential Thermal Analysis” section can be applied to describe the principle of operation of such an instrument. Another arrangement is the disk-type HF-DSC, in which the two cells are positioned symmetrically on a disk of good thermal conductivity as illustrated in Fig. 18. The theory developed in the following paragraphs for this type of DSC was inspired from^[40] and^[41] The heat flux exchanged between the two cells is given by

$$q_{sr} = \frac{T_{sc} - T_{rc}}{r} \quad (34)$$

Fig. 18 Schematic of a disk-type heat flux DSC

where r is the thermal resistance between the two cells. Assuming that the thermal resistance between the furnace and the cells are equal on both sides, one can write:

$$q_{fs} = \frac{T_f - T_{sc}}{R} \quad (35)$$

$$q_{fr} = \frac{T_f - T_{rc}}{R} \quad (36)$$

Heat balance imposes that:

$$q_{sc} = C_{sc} \frac{dT_{sc}}{dt} + \dot{\lambda} = q_{fs} - q_{sr} \quad (37)$$

$$q_{rc} = C_{rc} \frac{dT_{rc}}{dt} = q_{fr} + q_{sr} \quad (38)$$

Combining Eqs. 34–38, one obtains

$$\Delta T(t) = T_{sc} - T_{rc} = R_e \cdot C_{rc} \frac{dT_{rc}}{dt} - R_e \cdot C_{sc} \frac{dT_{sc}}{dt} - R_e \cdot \dot{\lambda} \quad (39)$$

where

$$\frac{1}{R_e} = \frac{1}{R} + \frac{2}{r} \quad (40)$$

As one can see, Equ. 39 is identical to Equ. 23 if one substitutes R_e by R . Since the two cells are connected *via* a disk of high thermal conductivity, the value of r is very small and so is the value of R_e . This ensures that the DSC has a fast response time, knowing that its time constant $\tau = R_e \cdot C_{sc}$.

Power-Compensated DSC

In the disk-type HF-DSC, it was shown that the time constant of the instrument is reduced if the thermal resistance r between the two cells is small. But what happens if this thermal resistance $\rightarrow 0$? This can be achieved by compensating heat losses in order to maintain the temperature of the cells at the same value, except for the small error signal required for the control. This is the principle behind the concept of the PC-DSC. Figure 19 shows a schematic of the PC-DSC, where one can see that the cells are connected to a pan, which provides a heat flow rate to the cell located above.

Fig. 19 Schematic of a power compensated DSC. The temperature of the pans (T_p) is monitored with a Pt thermistor (1) and is controlled via a heating resistor (2)

The power is delivered independently to the cells (q_s and q_r) in order to obtain the same target temperature (T_p) for the sample and the reference pans. Notice that the theory presented later was previously presented by Larouche et al.,^[38,42] the latter having modified the simple generalized model of Gray.^[39]

If one assumes that the heat flow rate delivered to the sample and reference materials is proportional to the power delivered by the heating resistors and is measured via a calibration procedure, then one can write

$$q_s = \frac{(T_p - T_s)}{R_s} \quad (41)$$

where T_s is the temperature of the sample, and R_s is the thermal resistance between the thermistor and the sample. If m_s is the mass of the sample, one can write

$$q_s = \frac{m_s (T_p - T_s)}{z_s} \quad (42)$$

where z_s is the specific thermal resistance between the sample and the thermistor. Since the temperature of the sample is explicitly included in this analysis, one can use the heat balance equation

$$q_s = m_s \cdot \frac{dh}{dt} = m_s \cdot \Gamma_s \cdot \frac{dT_s}{dt} \quad (43)$$

where Γ_s is the apparent specific heat capacity of the sample. The latter is given by

$$\Gamma_s = \frac{dh}{dT_s} \quad (44)$$

where h is the enthalpy of the sample. The time derivative of Eq. 42 can be inserted into Eq. 43, which gives the following first-order differential equation:

$$z_s \cdot \Gamma_s \cdot \frac{dq_s}{dt} + \left(1 + \Gamma_s \cdot \frac{dz_s}{dt}\right) q_s = m_s \cdot \frac{dT_p}{dt} \cdot \Gamma_s \quad (45)$$

For the reference material, we will assume that the heat flow rate variations are very small when $dT_p/\dot{T}_p$ remains constant, so one can write

$$q_r = m_r \cdot c_r \cdot \frac{dT_r}{dt} \quad (46)$$

where c_r is the specific heat capacity of the reference material. Since q_r is nearly constant when $\dot{T}_p$ is constant, we will focus our attention on q_s . It is worth mentioning that most analyses made with a PC-DSC are conducted with an empty reference cell, so that $m_r = 0$ and $q_r = 0$. To simplify the notation, the variables T , q , m , Γ , and z will be associated with the sample instead of T_s , q_s , m_s , Γ_s , and z_s . If we

assume that the thermal resistance between the sample and the thermistor is constant, then Eq. 45 becomes:

$$\frac{dq}{dt} + \frac{q}{z\Gamma} = \frac{m}{z} \dot{T}_p \quad (47)$$

When there is no phase transition, $dq/dt \approx 0$ and then

$$q \approx m \cdot \Gamma \cdot \dot{T}_p = m \cdot c \cdot \dot{T}_p \quad (48)$$

where c is the specific heat capacity of the sample. Notice that in such a case, $\dot{T}_p \approx \dot{T}$. But, when the enthalpy of the sample changes abruptly because of a sharp phase transition occurring at time $t = 0$, Γ becomes very high and then Eq. 47 becomes:

$$\frac{dq}{dt} \approx \frac{m}{z} \dot{T}_p \quad (49)$$

The heat flow rate increases linearly with the furnace heating rate until the end of the phase transformation at $t = t_{\max}$:

$$\text{For } 0 \leq t \leq t_{\max}: \quad q = m \cdot c \cdot \dot{T}_p + \frac{m \cdot \dot{T}_p \cdot t}{z} \quad (50)$$

From Eqs. 43 and 50, we also have until $t = t_{\max}$ that:

$$\dot{h} = c \cdot \dot{T}_p + \frac{\dot{T}_p \cdot t}{z} \quad (51)$$

The integration of $\dot{h}$ from the beginning ($t = 0$) to the end ($t = t_{\max}$) of the transformation gives the latent heat Δh :

$$\Delta h = \int_0^{t_{\max}} \left(c \cdot \dot{T}_p + \frac{\dot{T}_p \cdot t}{z} \right) dt = \frac{\dot{T}_p \cdot t_{\max}}{z} \left(zc + \frac{t_{\max}}{2} \right) \quad (52)$$

Solving for $t_{\max}$, one obtains:

$$t_{\max} = z \cdot c \left[-1 + \sqrt{1 + \frac{2\Delta h}{z \cdot c^2 \dot{T}_p}} \right] \quad (53)$$

Once the transformation is finished, $\Gamma = c$ and the solution of Eq. 47 is

$$\text{For } t \geq t_{\max}: \quad q - m \cdot c \cdot \dot{T}_p = \Delta q_{\max} \exp\left(-\frac{t - t_{\max}}{zc}\right) \quad (54)$$

where $\Delta q_{\max}$ is given by

$$\Delta q_{\max} = \frac{m \cdot \dot{T}_p \cdot t_{\max}}{z} \quad (55)$$

Figure 20 presents the time evolution of q when the pure substance is undergoing a phase transformation.

Fig. 20 PC-DSC peak associated to a sharp transition

The area $A + B$ gives the latent heat according to Eqs. 52, 54, and 55:

$$\begin{aligned} A + B &= \frac{\Delta q_{\max} \cdot t_{\max}}{2} + \int_{t_{\max}}^{\infty} \Delta q_{\max} \exp\left(-\frac{t - t_{\max}}{zc}\right) dt \\ &= \Delta q_{\max} \left(zc + \frac{t_{\max}}{2} \right) = m\Delta h \end{aligned} \quad (56)$$

What is remarkable with the PC-DSC is that the area between the curve and the baseline is independent of the thermal resistance z and gives precisely the latent heat. Figure 21 presents how the thermal resistance impacts the peak produced by a sharp transition in such a DSC. Since the area under the curves is the same for all value of z , it is not necessary to calibrate this parameter to measure the latent heat of the transformation. This is a major difference with the DTA or HF-DSC, both needing a calibration of the thermal resistances to obtain the same value. This stems from the fact that a PC-DSC is a true heat-measuring device, while DTA and HF-DSC are temperature measuring devices. An ideal calorimeter should have the smallest value of z possible. However, the most important thing to consider is the stability of this value during a phase transformation. During a solid-liquid phase transition, one can expect that z does not remain constant since the thermal contact between the sample and the cell

Fig. 21 Impact of the thermal resistance on peak height and width for a sharp transition with a PC-DSC

is likely determined by the fraction liquid in contact with the cell. This problem arises also with the HF-DSC but to take this into account, one has to develop a second-order approximation of the HF-DSC. The theory of the HF-DSC presented earlier can be considered as a first-order approximation. The inclusion of a thermal resistance between the cell and the sample would be upgrading the theory to a second-order approximation.

This means that the theory presented earlier for the PC-DSC is equivalent to a second-order analysis of an HF-DSC. It is why the PC-DSC is recognized as being an instrument having a higher sensitivity and a higher resolution.

HF-DSC requires extensive calibration procedures but can operate at temperatures above 700°C, which is the maximum test temperature for PC-DSC. But the latter type is more accurate and is now the preferred instrument to study phase transformations in aluminum alloys.

DIFFERENTIAL SCANNING CALORIMETRIC ANALYSIS OF ALUMINUM ALLOYS

Determination of Thermodynamic Variables

Aluminum alloys have been studied extensively with the different types of DSC, including DTA. An excellent review on the subject has been published in 2004 by Starink.^[43] DSC analysis can provide accurate measurements of the following thermodynamic variables:

- Critical temperature of reactions.
- Heat of transformation.
- Heat capacity.

The determination of the first two variables has been discussed in “Cooling Curve Analysis”, “Differential Thermal Analysis”, “Differential Scanning Calorimeters” sections. Heat capacity measurements can be made when the main reactions are not started or when the microstructure is in a metastable or stable state. Using a DTA or an HF-DSC, one can use Eq. 24 providing that the thermal resistance R has been calibrated and that the heat capacity of the reference material is accurately known. With a PC-DSC, it is advised to use pure aluminum as the reference material for heat capacity measurements,^[44] even though Eq. 48 should be sufficient in theory to give a measured value of the heat capacity without a reference material. With a reference material, the following equation will have to be used to extract the specific heat capacity of the sample:

$$c = \frac{1}{m} \left(\frac{q}{\dot{T}_p} + m_r \cdot c_r \right) \quad (57)$$

A special calibration procedure using a sapphire specimen must be done with a PC-DSC prior to the determination of heat capacities.

Determination of Kinetic Parameters in Solid Phase Transformation

Beyond the determination of the three thermodynamic variables mentioned earlier, a considerable amount of research has been done in order to estimate the evolution of the phase fractions during a temperature scan. But since DSC instruments measure temperature or heat only, there is no direct way of getting the rate of phase transformations from a plot of q versus T . A kinetic model translating the rate of heat absorbed or released to the rate of phase transformation must be used, and consequently, many assumptions are required. Among the different types of models proposed in the literature, the generic analysis models using relatively simple expressions that provide the fraction transformed as a function of time are particularly suited for thermal analysis since they are not specific to a given process and can be used for all. Moreover, these methods can potentially describe the progress of a reaction regardless of whether the heat treatment is isothermal or not. The generic model that will be presented in the next paragraph will be developed for the nucleation and growth of β -precipitates in an oversaturated matrix. The model could have been developed for the progression of recrystallization, but we will keep the example of precipitation knowing that the mathematical treatment for recrystallization would be similar. When a new precipitate β is growing, its volume increases according to the following equation:

$$V_\beta = A_1 (v \cdot t)^{n-1} \quad (58)$$

where v is the velocity of the interface, while t is the time. For a growing spherical precipitate, $A_1 = 4\pi/3$ and $n = 4$. The volume transformed due to one nucleation event occurring at time τ is given by:

$$V_{\beta(\tau)} = A_1 [v \cdot (t - \tau)]^{n-1} \quad (59)$$

We can suppose that the volume is divided as a collection of cells of volume V_{cell} , each one containing one precipitate. In this mean field approach, we suppose that the cell is composed of a matrix and a precipitate having the composition prescribed by the equilibrium. The rest of the volume, still not included in a cell, is the oversaturated matrix at nominal composition where nucleation is possible. The cell and its precipitate grow in proportion, so that the volume fraction V_β/V_{cell} remains constant. The volume fraction of β in a cell is determined by the phase diagram (lever rule). Though the diffusion of atoms allowing the growth of the precipitate is not explicitly modeled, the growth of cells and their precipitates occurs and is driven by the difference in chemical potentials existing between the oversaturated matrix and the cell. The cells do not exchange atoms, Ostwald ripening being neglected, and the average composition of each cell remains the same. The precipitates are

not overlapping, and it is the boundary of the cells that will impinge together when the total system will reach equilibrium. For a given time t , we have^[45]

$$\frac{dg_\beta}{d\tau} = I \cdot V_{\beta(\tau)} \quad (60)$$

where g_β is the volume fraction of precipitate, τ is the time of nucleation, and I is the rate of nucleation per unit volume. In the cellular model described earlier, nucleation can only occur in the oversaturated matrix. If I_0 is the nucleation rate per unit volume of oversaturated matrix, then the nucleation rate will decrease in proportion of the volume fraction of the oversaturated matrix, so one can write

$$I = I_0 \left(1 - g_\beta / g_\beta^{eq}\right) \quad (61)$$

where g_β^{eq} is the volume fraction of precipitate at equilibrium. The term $(1 - g_\beta / g_\beta^{eq})$ represents the impingement factor of nucleation. Since the growth of precipitates is driven by the gradient in chemical potentials, which gradually decreases as the transformation progresses, we will assume that the velocity of the interface v varies accordingly. One can choose the following relationship to describe the evolution of this parameter:

$$v = v_0 \left(1 - g_\beta / g_\beta^{eq}\right)^{\frac{c}{n-1}} \quad (62)$$

where v_0 is the interface velocity at the start of the transformation, and c is the growth impingement exponent. Inserting Eqs. 59, 61, and 62 into Eq. 63, one obtains:

$$\frac{dg_\beta}{\left(1 - g_\beta / g_\beta^{eq}\right)^{1+c}} = A_1 \cdot I_0 \cdot \left[v_0 \cdot (t - \tau)\right]^{n-1} d\tau \quad (63)$$

Integrating both sides of Eq. 63 gives:

$$\frac{g_\beta^{eq}}{c \left(1 - g_\beta / g_\beta^{eq}\right)^c} \Bigg|_0^{f_\beta} = -A_1 \cdot I_0 \cdot v_0^{n-1} \frac{(t - \tau)^n}{n} \Bigg|_0^t \quad (64)$$

Introducing the fraction transformed $\alpha = g_\beta / g_\beta^{eq}$, one obtains

$$\alpha = 1 - \left[1 + c \cdot (k \cdot t)^n\right]^{-1/c} \quad (65)$$

where

$$k^n = \frac{A_1 \cdot I_0 \cdot v_0^{n-1}}{g_\beta^{eq} \cdot n} \quad (66)$$

Equation 65 is the kinetic equation proposed by Lee and Kim^[46] and Starink and Zahra^[47] (LKSZ), which encompasses the Austin–Rickett (AR) kinetics ($c = 1$) and the

generalized Johnson–Mehl–Avrami–Kolmogorov (JMAK) kinetics ($c = 0$). The JMAK kinetics equation can be obtained by integrating Eq. 63 after setting $c = 0$. The solution found is:

$$\alpha = 1 - \exp\left[-(k \cdot t)^n\right] \quad (67)$$

The rate equations can be determined by differentiating Eqs. 65 or 67 with respect to time:

$$\text{LKSZ}(c \neq 0): \frac{d\alpha}{dt} = k \cdot n \cdot \left[\frac{(1 - \alpha)^{-c} - 1}{c}\right]^{\frac{n-1}{n}} (1 - \alpha)^{1+c} \quad (68)$$

$$\text{JMAK}(c = 0): \frac{d\alpha}{dt} = k \cdot n \cdot (1 - \alpha) \left[-\ln(1 - \alpha)\right]^{\frac{n-1}{n}} \quad (69)$$

Nucleation rate, interface velocity, and the equilibrium volume fraction of precipitate are parameters that are influenced by the temperature. These parameters are all included in the expression defining k . Equations 68 or 69 can thus be rewritten as follows:

$$\frac{d\alpha}{dt} = k(T) \cdot f(\alpha) \quad (70)$$

where $f(\alpha)$ depends on the kinetic equation used. An analogy can be made between phase transformation and the filling of a bottle. In this analogy, $1/f(\alpha)$ represents the cross section of the bottle at height α , $k(T)$ represents the volumetric flow rate of liquid, and da/dt is the rising speed of the liquid-free surface in the bottle. This analogy helps to understand why $f(\alpha)$ is independent of the temperature. Indeed, the variable α is an independent variable in $f(\alpha)$ because α represents the heights coordinate in this function.

In a single-stage reaction model, one may assume that k has an Arrhenius-type dependency with temperature:

$$k = k_0 \exp\left(-\frac{E}{RT}\right) \quad (71)$$

The progression of the transformation could thus be described if k_0 , E , and the function $f(\alpha)$ are determined. Although the kinetic equations describe an isothermal transformation, non-isothermal calorimetric analysis can help to determine the kinetic triplet *via* the concept of the state variable defined as follows:^[48,49]

$$\omega = \int_0^{\alpha(t)} \frac{d\alpha}{f(\alpha)} = \int_0^t k_0 \exp\left(-\frac{E}{RT}\right) dt = \int_0^t k dt \quad (72)$$

For an isothermal transformation, k remains constant and so $\omega = k \cdot t$. The kinetic equations can therefore be written as follows:

$$\text{LKSZ}(c \neq 0): \alpha = 1 - \left[1 + c \cdot \omega^n\right]^{-1/c} \quad (73)$$

$$\text{JMAK}(c = 0): \alpha = 1 - \exp[-\omega^n] \quad (74)$$

For a non-isothermal reaction, the state variable is given by:

$$\omega = \int_0^t k_0 \exp\left(-\frac{E}{RT}\right) dt \quad (75)$$

For a constant heating rate $\dot{T}$, the integral can be transformed, so that

$$\begin{aligned} \omega &= \int_0^t k_0 \exp\left(-\frac{E}{RT(t)}\right) dt = \frac{E}{R\dot{T}} \int_{y_s}^{y_s} \frac{k_0 \exp(-y) dy}{y^2} \\ &= \frac{E}{R\dot{T}} \left[\int_{\infty}^{y_s} \frac{k_0 \exp(-y) dy}{y^2} - \int_{\infty}^y \frac{k_0 \exp(-y) dy}{y^2} \right] \end{aligned} \quad (76)$$

where $y = E/RT$. The subscript s refers to the temperature T_s at the start of the transformation. For a temperature lower than T_s , the energy barrier for the migration of atoms is such that the transformation is almost impeded. As one can see in Fig. 22, the values of $\exp(-y)/y^2$ are very small for $y > y_s$, compared to those for $y < y_s$.

This implies that the integral $[y_s, \infty]$ is negligible in comparison to the integral $[y, \infty]$. Consequently, one can rewrite Eq. 76 as:

$$\omega \equiv \frac{E}{R\dot{T}} \int_y^{\infty} \frac{k_0 \exp(-y) dy}{y^2} = \frac{E \cdot k_0}{R\dot{T}} p(y) \quad (77)$$

For reactions involved in aluminum alloys, $y > 15$, and the integral function $p(y)$ can be approximated by^[50]:

$$p(y) \approx \frac{\exp(-Ay + B)}{y^\kappa} \quad (78)$$

Very good accuracy can be achieved using $A = 1$, $B = 0$, and $\kappa = 2$; $A = 1$, $B = -0.235$, and $\kappa = 1.95$; or $A = 1.0008$, $B = -0.312$, and $\kappa = 1.92$.^[51] Using the first set of values, one obtains after insertion of Eq. 78 in Eq. 77

$$\omega \equiv k_0 \frac{RT^2}{E\dot{T}} \exp\left(-\frac{E}{RT}\right) \quad (79)$$

Fig. 22 Plot of $\exp(-y)/y^2$ versus y

Mittemeijer et al.^[49] proposed to use the so-called Kissinger method to extract the activation energy from a series of DSC scans made at different constant heating rates. To do so, one has to determine a temperature T_f corresponding to a fixed state of transformation ω_f . The latter is given by

$$\omega_f = \int_0^{\alpha_f} \frac{d\alpha}{f(\alpha)} \quad (80)$$

Taking the natural logarithm of both sides of Eq. 79 with $T = T_f$ and $\omega = \omega_f$, one obtains

$$\ln\left[\frac{T_f^2}{\dot{T}}\right] = \frac{E}{RT_f} - C_f \quad (81)$$

where C_f is a constant given by

$$C_f = \ln\left(\frac{R \cdot k_0}{E \cdot \omega_f}\right) \quad (82)$$

A plot of $\ln(T_f^2/\dot{T})$ against $1/T_f$ gives a straight line with a slope from which the activation energy can be obtained. Mittemeijer and coworkers^[49] showed, using Eq. 79, that the maximum of the transformation rate $d\alpha/dt$ occurs at the same value of ω for any value of $\dot{T}$. The temperature at the maximum of a DSC peak can therefore be considered as a fixed state of conversion since it corresponds to the maximum rate of conversion. The temperature at peak can therefore be used as T_f . Moreover, the maximum rate of conversion occurs at $\omega = 1$ for the JMAK and LKSZ kinetic equations, independently of the values of n and c . At the maximum rate of conversion, one can therefore set $\omega_f = 1$ in Eq. 82, which permits to obtain the value of k_0 from the intercept of the straight line with the axis $1/T_f$. Alternatively, one can use the average of all k_0 values calculated with Eq. 79 at T_f for each heating rates.

The other kinetic parameters n and c can be determined by comparing their effect on the shape of the curve $d\alpha/dt$, the latter impacting directly the shape of the DSC peak. According to Mittemeijer,^[48] the fraction transformed at a given time can be determined if a physical property p is known at this time, at the beginning (p_0), and at the end of the transformation (p_1). This can be written as follows:

$$\alpha = \frac{p - p_0}{p_1 - p_0} \quad (83)$$

Notice that this relation is not strictly equivalent to the ratio g_β/g_β^{eq} that we used to obtain the kinetic equations JMAK and LKSZ. Equation 83 is consistent with our definition of α only if we accept that the physical property can be well estimated using a volumetric rule of

mixture. For a thermodynamic property like enthalpy, this is acceptable if the difference of enthalpy between the reacting phases remains constant during the transformation. The solid phases must also have similar molar volumes, which is the case for most phases in aluminum alloys. Accepting these assumptions and considering that enthalpy is a state variable, Eq. 83 can be put in integral form:

$$\int_0^\alpha d\alpha = \frac{\int_{T_{\text{start}}}^{T_{\text{end}}} \Gamma \cdot dT}{\int_{T_{\text{start}}}^{T_{\text{end}}} \Gamma \cdot dT} = \frac{1}{\Delta h} \int_{T_{\text{start}}}^T dh$$

$$= \frac{\text{Heat absorbed from } T_{\text{start}} \text{ to } T}{\text{Total heat absorbed during the transformation}} \quad (84)$$

Since the area under a DSC peak is proportional to the latent heat, one can write as follows:

$$\int_0^\alpha d\alpha = \frac{1}{\Delta h} \int_0^t (q - q_0) \cdot dt \quad (85)$$

where q_0 is the baseline of the DSC. This equation is valid if the thermal lag is negligible, an assumption that most researchers accept for solid state reactions occurring a low heating rates. It is worthwhile to recall that for the melting of a pure substance at a given heating rate, the actual end of the transformation does not occur at the end of the DSC peak (see “Differential Thermal Analysis” section). But for solid state reactions, one can say that the end of the DSC peak occurs approximately at the finish time of the transformation when the thermal lag is negligible. Writing Eq. 85 in differential form, one obtains

$$\frac{d\alpha}{dt} = \frac{1}{\Delta h} (q - q_0) \quad (86)$$

So, accepting the approximations described earlier, one can conclude that there is a direct proportionality between the rate of transformation $d\alpha/dt$ and the heat flow $(q - q_0)$ measured by a DSC. Figure 23 shows the impact of the parameter c on the shape of the $d\alpha/dt$ peak.

As one can see, the value of c does not impact the beginning of the peak. This comes from the fact that for small t , or small ω , we have $\alpha \approx \omega^n$. Therefore, we have

$$\dot{\alpha} = \frac{d\alpha}{dt} = n \cdot \omega^{n-1} \cdot \frac{d\omega}{dt} = n \cdot k \cdot \omega^{n-1} \quad (87)$$

The value of n can be evaluated following a method proposed by Starink.^[43] Taking the logarithm of the last equation, with ω given by Eq. 79, one obtains

Fig. 23 Impact of the growth impingement exponent c on the rate of transformation

$$\ln(\dot{\alpha}) = -n \cdot \frac{E}{RT} + 2(n-1) \cdot \ln(T) + C \quad (88)$$

where C is a constant. The slope of $\ln(\dot{\alpha})$ against $1/T$ is:

$$\frac{d \ln(\dot{\alpha})}{d(1/T)} = -n \frac{E}{R} - 2(n-1)T = -n \left(\frac{E}{R} + 2T \right) + 2T \quad (89)$$

Since $\dot{\alpha}$ can be replaced by the heat flow of the DSC, the value of n can be calculated near the beginning of the DSC peak from the slope of the curve $\ln(dh/dt)$ against $1/T$. The last kinetic parameter to find is the growth impingement exponent c . As one can see in Fig. 23, the c exponent has for effect to change the deceleration rate near the end of the transformation. If the values for E , k_0 , and n are known, it is possible, similarly to the method proposed by Starink for n , to evaluate c by finding an expression for $d \ln(q - q_0)/d(1/T)$ using Eqs. 73 and 79, and comparing the value calculated at a temperature near the end of the transformation to the value of $d \ln(q - q_0)/d(1/T)$ obtained experimentally at the same temperature. Alternatively, one can find the right value of n and c by trials and error in order to obtain a good fit between the experimental and theoretical peaks.

One of the main difficulties in determining the kinetic parameters for aluminum alloys is the fact that, most of the time, different transformation processes occur simultaneously, especially at low temperatures, where many metastable phases can coexist. This makes it impossible to determine the parameters n and c with the method proposed by Starink, since this method requires the accurate determination of dq/dT produced by one process only. Fortunately, the temperature at maximal conversion rate (T_p) of each process partially overlapped can still be determined with accuracy since one can use the second derivative of the DSC signal to locate more precisely the maximum of each peak. The value of E and k_0 of each process can then be determined and used in a deconvolution procedure from which the other parameters can be obtained by optimization of the fit between theoretical and experimental signals. Let N be the number of partially superimposed transformation processes occurring and producing heat at a rate

proportional to the conversion rate of each process. In a mathematical form, this can be written as follows:

$$\frac{dh}{dt} = \sum_i^N \frac{dh_i}{dt} \tag{90}$$

Adapting Eqs. 84–86 to the situation depicted by Eq. 90, one can show that:

$$q - q_0 = \sum_i^N \Delta h_i \frac{d\alpha_i}{dt} \tag{91}$$

The fit between both sides of Eq. 91 can be optimized using a nonlinear method of minimization of least squares error. Such a procedure was used by Chen and coworkers^[52] to analyze the precipitation kinetics in alloy 6061. The heat flow they measured with a PC-DSC at different scanning rates revealed four peaks (A, B, C, and D) occurring in the interval 20°C–530°C. Peak B was found to be a doublet. The authors used the JMAK model for their analysis. For the purpose of providing a good application example of the analytical method described earlier, we will perform the analysis of peaks B and C but, instead of using the JMAK model, we will use the LKSZ model and see how the choice of the model may impact the value obtained for the exponent n . Table 1 presents the peak temperatures as a function of the heating rates.

The plots shown in Fig. 24 were made with the data presented in Table 1.

The value of E and k_0 for peak B₁ were not realistic with the peak temperatures reported by Chen and coworkers on the alloy 6061. But according to the peak temperatures observed on the composite 6061 matrix + Al₂O₃,^[52] one obtains $E = 112.5$ kJ/mol and $k_0 = 7.152 \times 10^9$ s^{−1} for peak B₁. The other kinetic parameters (n and c) can be found using a fitting procedure. Chen and coworkers^[52] provided the DSC trace ($q - q_0$) obtained at a heating rate of 5 K/min on alloy 6061 showing peaks in the 180°C–320°C interval (see their Fig. 2). This trace is reproduced in Fig. 25 with the three deconvoluted peaks obtained by adjusting Δh_i and some of the kinetic parameters of the LKSZ equation to optimize the fit. The final values of these parameters are presented in Table 2.

Table 1 PC-DSC peak temperatures T_f (°C) obtained at different heating rates $\dot{T}$ on 6061 aluminum alloy. Samples were previously solution heat treated at 530°C for 1 h in air and water quenched at 12°C^[52]

Heating rate (K/min)	Peak B ₂	Peak C
5	233.6	285.5
10	242.8	298.2
20	253.5	308.8
40	266.3	324.2

Fig. 24 Kissinger diagram obtained from the peak temperatures T_f and heating rates $\dot{T}$ presented in Table 1

Fig. 25 DSC trace ($q - q_0$) and deconvoluted peaks adjusted to optimize the fit between ($q - q_0$) and the sum of the heat produced by the three phase transformations causing peaks B₁, B₂, and C. The DSC trace was reproduced from^[52]

Table 2 Parameters found at the end of the fitting procedure

Peak	E (kJ/mol)	k_0 (s ^{−1})	n	c	Δh_i (mJ)
B ₁	92.50	2.664E+07	3.5	0.5	−65.0
B ₂	135.6	4.292E+11	2.0	0.4	−216
C	133.9	1.672E+10	2.5	0.4	−255

The fit between the DSC trace and the theoretical curve is really excellent everywhere in the interval 180°C–320°C. Peak C is the most isolated peak, and it is interesting to notice that the E and k_0 parameters given by the Kissinger method produced an excellent fit with the appropriate values of n and c . It is worth to mention that the latter could be found without any ambiguity for peak C because of the very small overlap. For peaks B₁ and B₂, there was more latitude in the choice of k_0 , n , and Δh_i to

obtain an acceptable fit. The final choice was guided by the following principles:

1. The value of E obtained with the Kissinger method should be used without any adjustment.
2. The value of k_0 can be adjusted a little bit from the value obtained with the Kissinger method to get a better matching of the crests.
3. The fit must be done under the constraint that $\Sigma\Delta h_i =$ latent heat released.
4. The fit must be good everywhere when there are enough adjustable parameters to obtain a near perfect agreement.

The value of E for peak B₁ was taken from^[52] since we could not obtain accurate values from the Kissinger method with the data provided in the paper. In spite of the fact that the values obtained for k_0 can be subject to large extrapolation errors,^[48] one has to use a value of k_0 not so far from the value obtained by the Kissinger method otherwise one would not get a consistent evaluation of $k = k_0 \exp(-E/RT)$. Obviously, a small error on E may cause a large error on k_0 , but the error made on the value of k will be small since $\Delta k/k = -\Delta E/RT$. Considering the approximations made in the development of the model, one can argue that the relationship between $\ln(T_f^2/\dot{T})$ and $1/T_f$ is likely not perfectly linear. So, accepting a small nonlinearity on this relationship makes acceptable that some freedom can be taken in the choice of k_0 . Chen and coworkers obtained values close to 1 for the exponent n . For peak B₂ they obtained a value of $n < 1$. Such a value for n is possible only if there is no continuous nucleation. Indeed, one can show that under the assumption of saturated site nucleation (the number of sites does not increase in time), the exponent n in the kinetic equations is in fact equal to the exponent $(n - 1)$ appearing in Eq. 59. So, if $n < 1$, the nucleation sites are saturated otherwise the size of the nuclei would decrease with time. For the same peak, we found a value of $n = 2$, and this illustrates how the accuracy of this exponent depends on the kinetic model used and the care taken in the fitting procedure. The fit between a DSC trace and a kinetic model depends also on the right determination of the number of transformation processes occurring in a given interval. For the first peaks occurring at low temperature, it is difficult to know exactly all processes occurring simultaneously because of the nature of the precipitates and the concentration of defects like vacancies and dislocations. This may impair the possibility of finding one value of n that will give a perfect fit between theory and experiment. If no value of n gives a satisfactory fit, one may conclude that two or more processes are occurring simultaneously. From the very good agreement obtained between theory and experiment for peak C, one can conclude that peak C results from only one process or from many perfectly conjugated processes. This is an important fact that quantitative thermal analysis can reveal.

Determination of Fraction of Phases during Solidification

Although solidification of aluminum alloys has been extensively studied by thermal analysis, there are a rather limited number of contributions which used quantitative methods to determine, from DTA or DSC scans, the evolution of fraction of phases. Some researchers^[53,54] applied the simplistic rule assuming that the fraction solid is equal to the partial area under the DSC curve divided by the total area below the solidification peak. The problem with this approach is that it ignores completely the impact of thermal lag, which is significant in solidification, even at cooling rates as low as 5 K/min. A much better approach is to retrieve the evolution of the rate of latent heat release from the DTA or DSC curves, which is referred as desmearing.^[40] This approach has notably been followed by Chen et al.^[55,56] and Fernandez-Calvo et al.^[57] on DTA curves, by Mirković and Schmid-Fetzer,^[58] Sabau and Porter,^[59] and Rady^[60] on HF-DSC curves and by Chen et al.^[61] and Birol^[62] on PC-DSC curves. We will apply this method on the PC-DSC model presented in “Power-Compensated DSC” section. First, we have to express the specific apparent heat capacity as follows:

$$\Gamma = c_p + \frac{d\lambda}{dT} \quad (92)$$

where c_p is the specific heat capacity, and $d\lambda/dT$ is the rate of heat absorbed by the phase transformation per Kelvin degree. Inserting Eqs. 92 into 45, one obtains:

$$z c_p \frac{dq}{dt} + q + q \cdot c_p \cdot \frac{dz}{dt} = m c_p \dot{T}_p + \frac{d\lambda}{dT} \left(m \dot{T}_p - z \frac{dq}{dt} - q \cdot \frac{dz}{dt} \right) \quad (93)$$

The term inside brackets is $m\dot{T}$ according to the time derivative of Eq. 42. After substitution, one finally obtains

$$\frac{d\lambda}{dt} = q' - c_p \dot{T}_p + z c_p \frac{dq'}{dt} + q' \cdot c_p \cdot \frac{dz}{dt} \quad (94)$$

where $q' = q/m$. This equation is similar to the one developed by Birol,^[62] except that the thermal resistance was not assumed constant in Eq. 94. Upon calibration of the thermal resistance for a particular set of conditions, one can plot $d\lambda/dt$ as a function of t or alternatively, $d\lambda/dT$ as a function of T , the latter being estimated by: $T = T_p - z \cdot q/m$. In an alloy containing up to N solid phases ϕ , $d\lambda/dT$ is related to the fractions of phase by the following equation:^[42]

$$\begin{aligned} \frac{d\lambda}{dT} &= \frac{dh}{dT} - c_p = \sum_{\phi=0}^N \frac{d(f_\phi h_\phi)}{dT} - \sum_{\phi=0}^N f_\phi \frac{\partial h_\phi}{\partial T} \\ &= \sum_{\phi=0}^N h_\phi \frac{\partial f_\phi}{\partial T} + \sum_{\phi=0}^N \sum_{i=1}^{I-1} \frac{\partial(f_\phi h_\phi)}{\partial w_i^\phi} \frac{dw_i^\phi}{dT} \end{aligned} \quad (95)$$

where I is the number of species. By convention, $\phi = 0$ represents the liquid phase. Notice that the last term was ignored by almost all authors. It represents the change of enthalpy related to the change of composition of the different phases. Even if we ignore this term, it is not easy to calculate the fraction of each phase considering that the enthalpy h_ϕ is a function of temperature and composition. If one simplifies the problem by considering the alloy as a liquid–solid system, each phase having a constant enthalpy, then one can estimate the fraction solid (f_l) by integrating this equation:

$$\frac{\partial f_l}{\partial T} = \frac{1}{\dot{T}_p (h_l - h_0)} \left[q' - c_p \cdot \dot{T}_p + z c_p \frac{dq'}{dt} + q' \cdot c_p \cdot \frac{dz}{dt} \right] \quad (96)$$

where it was assumed that $\dot{T} \approx \dot{T}_p$. Taking full advantage of computational thermodynamic packages like Thermo-Calc and a model of solute redistribution to predict the solidification path in multiphase alloys,^[63] Larouche and Javidani^[42] calculated the specific apparent heat capacity $\Gamma(T) = dh/dT$ of two solidifying 319-based alloys and then inserted

the result into Eq. 45 to obtain the heat flow q as a function of the temperature of the pan T_p . This approach was similar to the one proposed by Boettinger and Kattner^[64] to predict the DTA curve for a given system and cooling rate. In order to get a better fit between the experimental and calculated DSC curves, Larouche and Javidani considered a nonconstant thermal resistance on the basis that the thermal contact between the sample and the crucible changes significantly when the fraction solid reaches a certain level. Moreover, recalescence was taken into account by setting a driving force for the nucleation of solid phases. Figure 26 presents the experimental and theoretical curves obtained. The excellent agreement results largely from the accuracy of the thermodynamic database since the impact of the variation of the thermal resistance helped very few for the fit of the peaks associated to the primary phase and the binary eutectic.

The fit for the last peak was strongly improved thanks to the variation of z . As one can see in Fig. 27, the thermal resistance was assumed to increase below a temperature of 570°C, where the calculated mass fraction liquid was

Fig. 26 Heat flow as a function of the temperature of the pan for a 319 alloy containing 0.32% mass of Mg. Taken from^[42]

Fig. 27 Evolution of the thermal resistance $z(T)$ used to fit the experimental and calculated DSC curves. Taken from^[42]

Fig. 28 Evolution of the specific apparent heat capacity of a 319 alloy containing 0.32% mass of Mg as a function of the temperature

below 0.6. The good thermal contact provided by the liquid phase very likely started to decrease below that fraction liquid, producing thus an increase of z .

It is interesting now to compare the specific apparent heat capacity calculated by the solute redistribution model and the specific apparent heat capacity calculated by desmearing the DSC curve with Eq. 94 (see Fig. 28).

One important thing to notice in this figure is that the choice of $z(T)$ allowed obtaining a sharp vertical transition at the onset of reactions, which supports the value of z at these temperatures. The sharp peaks calculated by the solidification model are produced by the heat released by the solidification of the undercooled liquid, which was assumed to occur spontaneously in a given small temperature interval. The occurrence of these peaks is largely responsible for the discrepancy between the two curves, and it is likely that the solidification model has not predicted perfectly the heat released just after the onset of the reactions. In spite of this limitation, it is clear that the combination of a solidification model using thermodynamic calculations of phase enthalpies and DSC testing is a reliable method to assess the evolution of phase fractions during solidification.

ISOTHERMAL CALORIMETRY

Because of their capability to measure very weak heat flows, isothermal calorimeters are suitable to perform heat analysis of phase transformations occurring when artificial aging is done at a low temperature. To study isothermal phase transformations in aluminum alloys, the differential heat flux microcalorimeter, working based on the principle of the Tian–Calvet calorimeter, is the type of instrument suitable to this end. Figure 29 presents a schematic of such a differential heat flux microcalorimeter.

The cells are surrounded by a 3D arrangement of thermopiles, each one composed of multiple thermocouples in series generating an electromotive force proportional to the temperature difference between the inner and outer

junctions. The radial configuration of the thermopiles allows an integration of the heat close to 94%^[65] and may have a resolution as small as 0.1 μW . The main limitation of this type of instrument is the thermal lag caused by the large thermal inertia of the calorimeter. A thermal lag as long as 0.5 h can be expected, which prevents the obtaining of reproducible measurements during that time interval. But at temperatures below 200°C, the phase transformations in aluminum alloys are very slow, and isothermal calorimetry can be used to study precipitation kinetics under conditions similar to artificial aging. Starink and Zahra conducted isothermal calorimetry investigations on Al–Cu,^[66] Al–Si,^[67] and Al–Mg^[68] alloys. Figure 30 shows the heat flow obtained at 170°C, 180°C, and 190°C by isothermal calorimetry on Al–4.4 wt% Cu alloy.^[66]

Two precipitation processes were identified by the authors: Process A was related to GP zone formation while process B was related to θ' phase formation. It is interesting to notice that nucleation times are different depending on the process and vary likely with temperature. This is

Fig. 29 Schematic of a Tian–Calvet-type differential heat flux microcalorimeter. Adapted from^[41]

Fig. 30 Heat flow as a function of time obtained during isothermal calorimetry testing of the Al–4.4 wt% Cu alloy at three different temperatures^[66]

Fig. 31 Normalized heat flow as a function of time during isothermal aging of the Al–16 at% Mg alloy^[68]

the kind of information that cannot be retrieved from non-isothermal DSC testing since, in the latter, the incubation time of nucleation is shortcut by the increase in temperature. For the Al–16 at% Mg, the heat flow measurements show a similar trend related to the precipitation kinetics of β' (Fig. 31).

Some authors have reported isothermal calorimetric measurements performed with the help of a PC-DSC.^[69,70] The problem with the results presented is that all processes seem to start at time zero. There is no long incubation time like those observed in a Tian–Calvet calorimeter. The authors did not discuss why the incubation time was zero for all temperatures in their testing. Using the value of kinetic parameters found for peak C (see Table 2), one obtains a fraction transformed of 1% after 42 s at 280°C while it should take around 7.5 h at 180°C. The results obtained with a PC-DSC are therefore questionable regarding this issue.

CONCLUSION

Thermal analysis is a mature branch of science and considerable efforts have been made to exploit the high sensitivity of the different available techniques, which are

based on the simple, but so important, measurement of the temperature. The technical challenges to overcome for improving the instruments are unlimited since everybody would like to get signals free of noise and free of thermal lag. But with the existing instruments available, there is still room for improvement of the mathematical models used for the quantification of material variables and parameters. The incorporation of computational thermodynamics models in thermal analysis is certainly a good way to develop accurate mathematical methods which, in return, will be used to improve the databases. The kinetic models of phase transformation also require some attention, particularly regarding the nucleation and growth of precipitates at low temperature. These important transformations on the viewpoint of material properties are particularly difficult to investigate because of the scales involved (length, temperature, time). Advanced nucleation theories will be needed to get a better scenario of the mechanisms involved, supported by laser sharp observations, the latter maybe suggested by accurate thermal analysis.

Thermal Analysis of Aluminum Alloys

Consuelo García-Cordovilla and Enrique Louis

Abstract

Microstructural characterization of aluminum alloys is typically performed by combining microscopy techniques with measurement of physical properties such as conductivity and hardness. Relatively recently calorimetric techniques have been used to complement the more traditional methodologies. This article will discuss: basic principles, instrumentation and experimental procedures, reaction kinetics, and general rules for interpreting DTA and DSC data. Heat treatable, non-heat treatable alloy and aluminum-based composite characterization are discussed.

Keywords: Differential scanning calorimetry (DSC); Differential thermal analysis (DTA); Reaction rates; Recrystallization.

INTRODUCTION

Microstructure characterization of aluminum alloys is carried out by combining microscopic techniques, such as optical and electron microscopy, with the measurement of physical (macroscopic) properties, mainly conductivity and hardness. In the last twenty years, calorimetric techniques have been proved to be a useful (complementary) tool in microstructure characterization. Moreover, the gain in confidence triggered by many detailed studies carried out by different groups in different laboratories, and using a rather wide variety of equipment, has placed calorimetric techniques up to the level of the most widely used tools in metallurgical laboratories of the aluminum industry. In this chapter, we shall focus on nonisothermal measurements which include differential thermal analysis (DTA) and differential scanning calorimetry (DSC). No attention will be paid to thermo-gravimetric or thermo-mechanical techniques. Although in most cases isothermal calorimetry provides a higher accuracy, it has an elevated cost in terms of time and is not commonly used in industrial laboratories. Some reference will be made, however, to experiments carried out at constant temperature.

The chapter is organized as follows. In “Basic Principles”, we briefly discuss the basic principles. In “Instrumentation And Experimental Procedures”, the main characteristics of the most commonly used instruments are succinctly described. Calibration practices, choice of reference material, and sample preparation are also considered. Finally, the qualitative effects that varying the heating/cooling rate has on the curves are commented on. The main tools to investigate reaction kinetics by means of DSC are discussed in detail in “Reaction Kinetics”. Practices commonly followed to obtain kinetic parameters are discussed to some extent. The way DSC can be used in particle size determination is also briefly considered. “General Rules For Interpreting Dsc And Dta Curves” is devoted to

describing the key rules that may help in the interpretation of DSC or DTA curves. The main features of DSC curves for heat-treatable alloys are considered in “Heat-Treatable Aluminum Alloys”. No attempt is made, either in this section or anywhere in this chapter, to present a comprehensive review of the work carried out in this field. Our aim is rather to provide the reader the basic knowledge to use DSC as a metallurgical tool in the characterization of aluminum alloys. “Nonheat-Treatable Aluminum Alloys” is devoted to nonheat-treatable alloys, on which the amount of published work is substantially less. Aluminum based composites are dealt with in “Aluminum Based Composites”. Some questions that are mainly of technological interest, either because of its immediate applicability, or for being common in quality control (this is the case of solidification curves or the detection of small melting peaks associated with a noncomplete homogenization), are discussed in “Some Applications To Technological Problems”. Finally, some concluding comments are made in “Concluding Remarks”.

BASIC PRINCIPLES

Thermal analysis involves all techniques that are able to measure the physical properties of materials as a function of temperature. Whatever physicochemical reaction, or change of state, takes place, it has associated an absorption or liberation of energy. Thermal analysis techniques are designed to determine the enthalpy of these processes,^[1–6] measure the heat capacity, the thermal emissivity, and the purity of materials.^[7] In addition they can be used to yield phase diagram information and provide kinetic data.

In nonisothermal analysis, the temperature is usually raised linearly with time t as:

$$T = T_0 + ht \quad (1)$$

where T_0 is the temperature at which the run is initiated (commonly room temperature) and h the heating rate. In commercial DSC equipment the upper temperature is not substantially higher than the melting temperature of aluminum, while in DTA it can be as high as 1500°C.

The technique of differential thermal analysis (DTA) consists of measuring the difference in temperature between the sample under study and a reference material $\Delta T = T_s - T_r$, as both are heated or cooled at some fixed rate h , and recording this difference vs. time or temperature. The sample and reference materials are contained in a furnace whose rate of heating (or cooling) is controlled by a temperature programmer. Whatever transition in the sample, the sample originates the absorption or emission of energy that produces a deviation of temperature with respect to the reference. The magnitude ΔT at a given time is proportional to the enthalpy, the heat capacity, and the total resistance to heat flow.

A differential scanning calorimeter (DSC) measures the amount of energy absorbed or released by a sample (heat flow) as it is heated, cooled, or held at a constant (isothermal) temperature.^[1-6] In practice this is achieved by comparing the sample temperature with that of the reference. The amount of heater power necessary to keep both sample and reference at the same temperature when a reaction happens is a direct calorimetric measurement of the transition enthalpy. The precise measurement of sample temperature is also obtained with a DSC. Depending on the method of measurement, two modes can be distinguished: power compensation DSC and heat flux DSC.

The most widely accepted analysis of DTA is that of Borchardt and Daniels^[8,9] in which the reaction rate is written as:

$$\frac{d\alpha}{dt} = -\frac{1}{kA} \left(hc_p \frac{d\Delta T}{dt} + k\Delta T \right) \quad (2)$$

In this equation (valid for linear heating as in Eq. 1) α is the fraction of transformation completed at time t , c_p and k the heat capacity and heat transfer coefficient of the cell (both assumed to be temperature independent), and A the total area under the DTA curve. In cases, not so uncommon, of small samples and good thermal contact between the sample and the holder, the first term in the right hand side of Eq. 2 can be neglected and the reaction rate is proportional to ΔT . Then, the fraction reacted at time t is obtained from:

$$\alpha(t) = \frac{A(t)}{A} \quad (3)$$

where $A(t)$ is the area under the DTA curve from the time at which the reaction starts t_i , up to time t :

$$A(t) = \int_{t_i}^t dt \Delta T \quad (4)$$

Equation 3 also holds for DSC, provided that approximations similar to those used in deriving it are made. In this case, the area under the curve is given by:

$$A(t) = \int_{t_i}^t dt \Delta C_p \quad (5)$$

where ΔC_p is the heat evolved during the reaction. Actually the total area under the DSC curve is proportional to the molar heat of reaction ΔH .

INSTRUMENTATION AND EXPERIMENTAL PROCEDURES

Instruments

Commercial DTA and DSC equipment have been available since the late 1950s. Although the working concept has not dramatically improved during the last few years, the use of computers has changed analysis practices and improved reproducibility. DTA commercial apparatuses^[6,10] use pans placed on two identical holders symmetrically located in the center of a chamber that can be heated at a desired rate. One of the pans is the reference pan, while the other is the sample pan. A thermocouple is inserted in the middle of each holder. The peak areas are proportional to the heat of reaction and to the sample mass, and inversely proportional to the thermal conductivity of the sample. It is necessary to calibrate the instrument for each type of sample and range of temperatures, and to control carefully all the experimental parameters (sample/crucible position, type and flux of gas, etc.) to obtain reliable calorimetric data from a DTA curve. Modern systems have developed more accurate and precise ways of measuring heat flow. Base line stability, reproducibility, resolution, and sensitivity have been significantly improved.

In heat flux DSC systems, the sample and reference holders are twin calorimeters symmetrically positioned within the DSC enclosure. The differential heat flow signal of the empty DSC should be zero. In some modern systems, the cell has been designed including a raised sample and reference platforms machined from a single piece. High output area thermocouples are directly coupled to the platforms, and a Tzero sensor, located midway between the sample and the reference platforms, acts simultaneously as a control sensor to assure precise isothermal furnace operation. Better and more consistent base lines are claimed (TA technology). Other heat flow DSC have been developed using the Calvet principle, in which the difference of heat flux between the sample and the reference is measured by thermopiles that completely surround the sample and the reference (Setaram technology).

With power compensation DSC, the sample and the reference material are each confined on two independently controlled low-mass furnaces. The system is maintained

in a thermal null state at all times, which requires an amount of power that is directly proportional to the energy changes occurring in the sample. No heat flux equations are necessary with a power compensation DSC, since the system is directly measuring energy flow to or from the sample at all times (Perkin-Elmer technology).

Modulated DSC technology (MDSC) and dynamic DSC technology (DDSC) or StepScan DSC may in some cases increase the resolution and sensitivity allowing the separation of complex transitions into more easily interpreted components. In this case, a perturbation in the form of an oscillating wave of known frequency is applied to the linear temperature control program. The thermal response is analyzed using Fourier transformation with the component in-phase associated with the reversible changes and the out-of-phase component associated with the non-reversible changes.

Calibration

Before any quantitative measurements are made, the instruments must be calibrated to fix the temperature scale and specific heat accurately. Although the best procedure is to perform any required calibration according to the operational manual supplied by the equipment manufacturer, here we shall outline some general rules of rather wide validity. An almost neutral baseline is required to get the desired accuracy, and adequate sampling techniques must be used to obtain reliable results.

The Baseline

When DTA/DSC are used for specific heat measurements, the baseline deviation becomes important. A first adjustment of the baseline is made with empty holders to account for minor differences in sample and reference holders, thermocouples, etc. Getting an acceptable baseline requires in many cases an appreciable effort. Many adjustments should be made and a thorough maintenance of all equipment parts is required. Baseline adjustment could be made in the whole temperature range at once, or separately in narrower ranges to improve sensitivity. Modern equipment incorporates a variety of technological improvements that provide more reliable baselines.

Once sample and reference are introduced in their own holders, the baseline has to be checked again to neutralize differences amongst the two, mainly in specific heat. For instance in Refs. [11,12] two separate DSC runs were carried out. In the first run high purity annealed aluminum disks were placed in both the sample and reference holders, while in the second run the aluminum disk in the sample holder was replaced by the disk of the material under study. The actual DSC curve of the alloy was obtained by subtraction of the first from the second DSC curve. Many authors do subsequently subtract a linear baseline from the data, which represents the difference in heat capacity

between the alloy (with the alloying elements in solution and/or forming intermetallic particles or precipitates) and pure aluminum, which can be easily calculated from the Neumann-Kopp rule.^[13] This rule, however, is strictly valid for ideal solutions only; although some authors claim to have good fits using it, it is not clear to what extent the ideal solution approximation may affect the results. Other methods include: extrapolating a baseline between regions where no reactions take place, repeating the scan one or more times, comparison to other starting conditions (e.g., overaged), and calculation of the heat capacities using more sophisticated methods. These, or similar procedures, are currently followed by many researchers (see "Temperature Calibration" through "Specific Heat").

Temperature Calibration

Temperature calibration^[14] of the apparatus is required to determine the transition temperatures of the measured material. Calibration is accomplished by running high-purity standards and reference materials with known temperature and energy transitions. A series of standard reference materials, CRM (Certified Reference Materials), have been adopted by several organizations (ICTA, NBS/NIST, ISO, ASTM, etc.) for calibration. The melting transition of high purity metals (>99.999% In and Zn) are more often used for calibration when working with aluminum.

Enthalpy

Heat flow calibration^[15,16] of DSC, or quantitative DTA, is necessary to allow the determination of the heat or enthalpy of transition to be meaningful in an absolute sense. The heat flow associated with fusion (an endothermic process) and solidification (an exothermic process) is recorded and integrated over temperature or time.^[15] Absolute values for the enthalpy of fusion (or solidification) can thus be obtained. Calibration of the heat flow response of each DSC is made by recording the melting endothermic peak of a high-purity standard material (for which the heat of fusion is usually known within $\pm 1.5\%$) as a function of time. The peak is then integrated to yield an area that is proportional to the enthalpy of melting of the standard material. The calibration is extended to other temperature ranges by recording the specific heat capacity of additional standard materials over those ranges. The ratio of the measured specific heat capacity at the temperature range of interest to that for the range at which the calibration was made provides an instrument calibration coefficient at the new temperature range. Heat flow calibrations are sometimes determined in conjunction with temperature calibration. Some DSC and quantitative DTA equipment permit both heat flow and temperature calibration to be obtained from the same experimental procedure.

Specific Heat

DSC provides a rapid, simple method for determining specific heat capacities of materials.^[17] In the absence of any reaction, the specific heat gradually changes with temperature. DSC data is sometimes misinterpreted because the result obtained after a run may contain information about the instrument itself (specific heat of the sample holder and the reference) together with the proper data from the sample. Performing a baseline run, with no sample, using the same conditions could solve the problem. Synthetic sapphire disks (α -alumina) are recommended as reference to calibrate the specific heat capacity measurements. Specific heat capacity values for synthetic sapphire are given elsewhere.^[17]

To obtain a more accurate specific heat measurement the following actions are suggested: The DSC analyzed block temperature should be stable. High quality purge gas and constant flows should be used to have a consistent baseline. The instrument should be carefully calibrated. Proper temperature programs (low heating rates for large samples and higher rates for small ones) should be used.

Samples and Reference Material

For optimum peak sharpness and resolution, it is essential to have a good contact between the holder (sensor) and the sample (or bottom of the pan). This is especially critical when using large samples, since effects derived from thermal gradients could be unacceptably high. The method of encapsulating samples most widely adopted is the use of an aluminum pan with a domed lid that can be crimped. This could be also used with aluminum samples. In this way very thin disks, or even films, could be measured. However, in many cases samples can be located directly on the holder. For high temperature reactions (near the melting point), or if some melting reaction is expected to occur, graphite or other inert high thermal conductivity material pans must be used to avoid any undesirable reaction between the sample and the holder.

Sample and reference sizes should be similar. Sample size has to be chosen depending upon the process under study. It should be kept in mind that while small samples increase resolution, larger ones give better sensitivity (small changes are easier to see using large samples). Thermal gradients in the sample must be taken into account when using large samples. The reference material should preferentially have a specific heat close to the sample. The most common reference material when measuring aluminum alloys is annealed pure (or high purity) aluminum.^[11,18] Although this may be an adequate reference material for dilute alloys,^[18] it may not be for highly concentrated alloys or composites. For instance, in Ref. [19], the same material under investigation (an Al–Mg–Si/alumina composite) in the over-aged condition was used as reference. This procedure is an alternative to the use of the Neumann–Kopp rule mentioned above.

Care should be taken to avoid the introduction of deformation in preparing DSC samples when working with Al-based alloys. A common way to prepare DSC samples generally involves punching disks from a thin (or previously ground) material approximately 1 mm thick. Alternatively, cylindrical rods may be machined and sample disks cut out of these rods. Punching, grinding, machining, and cutting can introduce deformation into the material that may induce significant changes in the DSC curves, particularly when studying precipitation/dissolution reactions in some Al-based alloys. Actually, it has been shown that alloys such as Al–Cu and Al–Cu–Mg–Li–Zr have a great sensitivity to sample preparation (see “Heat-Treatable Aluminum Alloys” for a more thorough discussion). Punching and grinding samples of those alloys after solution heat treatment may shift some precipitation peaks to lower temperatures, or even eliminate them, as compared to samples punched and ground prior to the solution heat treatment.^[20–23] A possibility to reduce these unwanted effects is to prepare samples prior to the solution heat treatment. When the latter is not possible, spark cutting is a very efficient alternative.^[20]

Heating/Cooling Rates

The DSC and DTA signal is directly proportional to the heating rate. DSC apparatuses with low thermal inertia furnaces (small furnaces) attain high heating/cooling (linear) rates, and, as a consequence, allow high resolution and sensitivity to be achieved. Increasing the heating/cooling rate usually leads to: (a) shifting of peaks to higher temperatures, (b) sensitivity increases (reaction peaks are higher) allowing the detection of weak reactions, (c) reaction overlapping that, obviously, decreases resolution, and (d) less reliable base lines (base line drift may be appreciable). On the other hand, slow heating/cooling rates promote: (a) an increase in resolution and, consequently, reactions occurring at nearby temperatures can be resolved, (b) decrease of sensitivity, reducing the size of the peaks that can eventually be indistinguishable from the background noise, and, (c) improvement of the base line.

The peak shift occurring upon increasing heating or cooling rates could be originated by heat inertia coming from the equipment characteristics, sample size, crucible type, etc.; if so, it would require corrections to be introduced. Alternatively, it may be due to reaction kinetics (mainly in diffusion controlled reactions) being then used in kinetic analysis.

REACTION KINETICS

The Reaction Rate

The rate of a solid-state reaction can be written in the general form:

$$\frac{d\alpha}{dt} = g(\alpha)K(T) \quad (6)$$

where α is the fraction reacted at time t and T is the absolute temperature. The function $g(\alpha)$ is chosen depending on the actual reaction (see below), and the rate function $K(T)$ is usually assumed to be given by the Arrhenius law:^[9,24–26]

$$K(T) = K_0 \exp(-E_K / RT) \quad (7)$$

where E_K is the activation energy, K_0 the frequency factor, and R the gas constant. The fraction reacted is then given by:

$$f(\alpha) = \int \frac{d\alpha}{g(\alpha)} = \int K(T) dt = \theta(T) \quad (8)$$

and explicitly working out the latter integral leads to:

$$\theta(T) = \frac{K_0 E_K}{hR} p(x) \quad (9)$$

with the temperature integral $p(x)$ given by:

$$p(x) = \int_{x_0}^x \frac{e^{-x}}{x^2} dx \quad \text{and} \quad x = \frac{E_K}{RT} \quad (10)$$

where $x_0 = E_K/RT_0$, T_0 being the initial temperature. Following,^[26] we have introduced the state variable $\theta(T)$ that is fully determined by the path followed in the temperature–time diagram. Several approximations have been devised^[26,27] to facilitate the calculation of the temperature integral in Eq. 10.

Random nucleation and growth of nuclei control a wide variety of processes. In those cases, quite common in heterogeneous solid-state reactions, the reaction kinetics is satisfactorily described by means of the Johnson–Mehl–Avrami (JMA) equation:^[28]

$$g(\alpha) = n(1 - \alpha)[- \ln(1 - \alpha)]^{(n-1)/n} \quad (11)$$

or, alternatively:

$$f(\alpha) = [- \ln(1 - \alpha)]^{1/n} \quad (12)$$

where n is an exponent that accounts for nucleation and growth morphology. Although there is no sound theoretical justification for use of the JMA expression, the physical significance of various values of n has been discussed in some detail.^[29] Introducing this function in Eq. 8 produces the standard JMA expression for the fraction reacted is obtained:

$$\alpha(T) = 1 - \exp\{-[\theta(T)]^n\} \quad (13)$$

In the isothermal case the above equations lead to:

$$\alpha(t) = 1 - \exp\{-[K(T)t]^n\} \quad (14)$$

The JMA law does not always provide an adequate description of the kinetics. An alternative that holds in many processes is the three-dimensional diffusion rate relationship (see “Determining Particle Size from DSC”). A full discussion of this point can be found, for instance, in Refs. [27,29]. Many authors do still use expressions that are valid for homogeneous reactions in interpreting solid-state reactions in aluminum alloys. This procedure is doubtful, as stressed in Ref. [26]. It is pertinent to note that, while most rate expressions have only two kinetic parameters, namely, the activation energy and the frequency factor in the rate function $K(T)$, the JMA relationship has, in addition, the exponent n . In fact, the JMA expression is a family of expressions with n as a parameter. In most cases discussed hereafter we shall refer to kinetic analyses by means of the JMA expression with different n .

Up to now it was assumed that the different processes can be put aside. Actually, this is rather rare as in most cases reactions overlap. Recently a detailed analysis of a case in which two reactions partially overlap, appearing as a doublet in the DSC curve, has been published.^[30,31] These authors wrote the reaction rate for the split peak as:

$$\frac{d\alpha}{dt} = A_1 \frac{d\alpha_1}{dt} + A_2 \frac{d\alpha_2}{dt} \quad (15)$$

where the subscript denotes the two reactions. The related peak areas A_1 and A_2 were taken as parameters with the constraint $A = A_1 + A_2$, where A is the total peak area given by the DSC apparatus. Assuming a JMA expression, the DSC curve was fitted by using, besides the peak areas, the activation energy, frequency factor, and exponent n for each process as fitting parameters.

It is worth noting that even in cases of well-isolated reactions (leading to a single peak in the DSC curve at all heating rates) the transformation rate can be controlled by more than just one activation energy. For instance, an adequate description of nucleation and growth may require different rate functions (see Ref. [31] for a careful discussion of this point). In practice, however, either one process dominates, or a single kinetics is used as a semi-empirical (approximate) approach to the problem.

Before ending this subsection it is worth pointing out that the only way to obtain kinetic data compatible with isothermal experiments is to use the same reaction rate equation to describe both iso- and anisothermal kinetics.^[9,24–26,32–34] This procedure guarantees the transferability of kinetic parameters between the two types of calorimetric measurements.

Obtaining Kinetic Parameters: The Peak Temperature Method

As noted above, the three kinetic parameters characteristic of the JMA law are the activation energy E_K , the frequency factor K_0 , and the exponent n . The activation energy and the frequency factor can be obtained from the peak temperature method.^[9,25,26,35] The condition for maximum reaction rate, which occurs at the peak temperature T_p , leads to the following equation:

$$\ln \frac{h}{T_p^2} = -\frac{E_K}{RT_p} + \ln \frac{K_0 R}{E_K} \quad (16)$$

This expression is exact only for the JMA law with $n = 1$, and only approximate for arbitrary values of this exponent.^[9,25,26] Then a fitting of the experimental results for the variation of T_p with heating rate by means of Eq. 16 allows the determination of parameters E_K and K_0 . It is worth noting that the choice of a specific kinetics (i.e., the function $g(\alpha)$ in Eq. 6) only affects the second term in the right hand side of Eq. 16 and, thus, to the frequency factor. The exponent n can in its turn be derived from fitting the experimental data for the fraction reacted vs. temperature $\alpha(T)$. The latter can be obtained by integration of the reaction rate as described above.

In Table 1 kinetic parameters for a variety of processes in different aluminum alloys are reported. All were obtained by using the JMA expression. Even though processes are quite different in nature (dissolution and precipitation of phases and recrystallization) the activation energy varies in the rather narrow range 25–200 kJ/mol. Instead, the frequency factor varies by more than ten orders of magnitude. Different authors report similar values of the exponent n , around 1, for a wide variety of dissolution processes.^[11,36,37] However, n values significantly disagree for precipitation processes; namely, while exponents larger than 2 are reported in Refs. [31,37], other authors claim that experimental data are satisfactorily fitted with $n = 1$.^[11,12,38] It was argued in Ref. [38] that $n = 1$ is consistent with the low-temperature GPZ (Guinier Preston Zone) precipitation therein investigated. Analyses that use $n = 1$ for all precipitation and dissolution processes^[11] are doubtful.^[26] In those cases the claimed accuracy of the fittings may be a consequence of carrying out fittings at selected values of the fraction reacted, instead of fitting the full $\alpha(t)$ curve. Finally note that available experimental data for recrystallization in rather thin material (see Table 1) satisfactorily agree with theoretical analyses that predict $n = 2$ –3.^[28,29]

It has been argued that the exponent n may decrease as the reaction proceeds,^[39–41] likely due to a nonrandom distribution of nucleation sites. In Ref. [41], for instance,

Table 1 Kinetic parameters of the johnson–mehl–avrami equation fitted to DSC results for several alloys and processes. The activation energy E_K is give in kJ mol^{−1} and the frequency factor K_0 in s^{−1}. PM stands for powder metallurgy

experimental DSC data for the fraction reacted (precipitation of metastable β' and β'' in 6061-15vol%SiC_w) were fitted by assuming that $n(T)$ had a sigmoidal shape. Although the fittings, of course, improved, the changes were not dramatic. On the other hand, the average n almost coincided with the value obtained by fitting a constant exponent.

An alternative method to determine the activation energy was proposed in Ref. [42]. The method essentially consists of using directly Eq. 6 without assuming any particular function for $g(\alpha)$. A shortcoming of the method is that it does not provide a way to determine the frequency factor K_0 . Its major drawback, however, is more fundamental in nature: kinetic parameters do not mean anything without a full definition of the kinetics, including $g(\alpha)$. Changing the latter function changes the resulting values of the kinetic parameters (see, for instance, Ref. [42]).

Some authors have utilized absolute reaction rate theory^[43] to determine the free energy of activation ΔG_a , and used it in discussing, for instance, the relative stability of precipitates.^[19,44] Deriving the rate function in Eq. 7 from the DSC curve directly gives the activation energy, and allows the activation entropy ΔS_a from the pre-exponential factor to be obtained by means of absolute reaction rate theory.^[43] Then, the free energy of activation is given by:

$$\Delta G_a = E_K - T_p(R + \Delta S_a) \quad (17)$$

The activation enthalpy can also be obtained from the standard expression:

$$\Delta H_a = E_K - T_p(R + \Delta S_a) \quad (18)$$

Determining Particle Size from DSC

DSC can be utilized to determine average particle size by using the information derived from the dissolution peak. Kingery^[45] was first in suggesting that DSC could be used to obtain average particle sizes. He showed that the effect of particle size on the three-dimensional diffusion (3DD) controlled kinetic expression could be accounted for by including a factor $1/r^2$, where r is the particle radius. Then Eq. 8 becomes:

$$[1 - (1 - \alpha)^{1/3}]^2 = \left(\frac{D_0 E_D}{Rhr^2} \right) p(x) \quad (19)$$

It is worth noting that while K_0 is given in s⁻¹, the units of D_0 have to be m²/s, to ensure dimensional consistency. In fact D_0 is the frequency factor in the diffusion coefficient:

$$D(T) = D_0 \exp(-E_D / RT) \quad (20)$$

This point has been frequently overlooked in the literature, and dimensionally incorrect results have been reported. Note also that $p(x)$ is the integral given in Eq. 10 with $x = E_D/RT$.

While it was argued^[46] that the JMA function cannot be used in Eq. 19, a later study proved that it is approximately valid.^[47] Here we reproduce that argument. A detailed analysis of the kinetics of dissolution or growth of spheroidized, solute rich, stoichiometric precipitates in the surrounding matrix was described in Ref. [48]. In the case of macroscopic experiments such as DSC, the significant magnitude is the spatial average of solute concentration in the matrix at time t that we shall hereafter denote as $C(t)$. The expression reported in Ref. [48] can be rewritten as:^[47]

$$C(t) - C_M = (C_{eq} - C_M) \sum_{n=0}^{\infty} F_n^2 \left[1 - \exp\left(-\gamma_n^2 \frac{\beta^2 Dt}{r^2}\right) \right] \quad (21)$$

where C_{eq} is the equilibrium concentration of solute in the matrix at a given temperature, β is the cubic root of the volume fraction of precipitate phase, F_n are constants, and γ_n are the eigen values of the diffusion equation. The latter depend on β , the diffusion coefficient D , and a temperature dependent coefficient k that describes the transfer of matter at the particle-matrix interface (see Ref. [48] for details). Note also that in order to cope with the initial and asymptotic conditions at $t = 0$ and $t = \infty$, namely, $C(t) = C_M$ and $C(t) = C_{eq}$, the F_n^2 should be normalized. It is worth noting that series expansions similar to Eq. 21 obtained under more restrictive assumptions can be found in many papers and books.

The above equation can be rewritten considering that (a) the fraction reacted is $\alpha = [C(t) - C_M]/[C_{eq} - C_M]$, and (b) for long periods all terms but the first one, $n = 0$, are negligibly small. Then:

$$\alpha = 1 - \exp\left(-\gamma_0^2 \frac{\beta^2 Dt}{r^2}\right) \quad (22)$$

The rate equation derived from the latter is:

$$\frac{d\alpha}{dt} = \frac{\gamma_0 \beta^2}{r^2} D(1 - \alpha) \quad (23)$$

This is an equation of the JMA type with $n = 1$ and a rate function which, as shown in Ref. [45], is proportional to $1/r^2$. We note that although this result is not strictly valid for the first stages of the reaction, it may be extended to the whole process in a semi-empirical procedure to fit the experimental data.

The extension of this analysis to nonisothermal experiments requires some comments. Integrating the above equation involves a serious difficulty: γ_0 depends on D and k (both temperature-dependent) via a rather complicated expression. The only way to obtain a simple expression is

to assume that equilibrium prevails at the particle–matrix interface, as done in other approaches to the problem. In such a case $k \rightarrow \infty$, and γ_0 no longer depends on D nor on k . Under this assumption, the previous equation can be integrated as done before, leading to:

$$-\ln(1 - \alpha) = \left[\frac{\gamma_0 \beta^2 D_0}{r^2} \right] \frac{E_D}{Rh} p(x) \tag{24}$$

where the product $\gamma_0 \beta^2 D_0$ acts as an effective frequency factor. This analysis offers a theoretical background to the use of the JMA equation in deriving particle size from DSC measurements. The use of the JMA with $n \neq 1$ ^[46] can be justified from a semiempirical point of view.^[49] It is interesting to note that if the peak method discussed above is applied to the present case, only the second term in the right hand side of Eq. 15 will be modified. This implies that $E_K \cong E_D$ while the frequency factors may be appreciably different. This result justifies the comparison frequently made in the literature between E_K and activation energies for self-diffusion of elements or migration energy for atom–vacancy complexes.

Incorporating particle size adds a new parameter to the fitting process. The most commonly followed procedure is to fit the activation energy E_D and the ratio D_0/r^2 (or $\gamma_0 \beta^2 D_0/r^2$ in Eq. 24) to the full $\alpha(T)$ curve for a sample containing particles of a size previously determined by means of TEM.^[36,49] This allows deriving D_0 . Then kinetic equations can be used to predict particle size for other samples.

GENERAL RULES FOR INTERPRETING DSC AND DTA CURVES

Each alloy/temper has its own, characteristic, DSC or DTA curve, with a proper shape and position of the endothermic and exothermic reactions, that could be used for its identification (its fingerprint). When an endothermic reaction starts, the sample temperature is left behind the reference temperature (the programmed temperature) because of the reaction heat. This is the point where the curve starts to deviate from the base line. The peak temperature coincides with the temperature at which the reaction rate is maximal. Once the reaction has finished thermal diffusion forces the sample to rapidly return to the equilibrium temperature. DSC gives information on the type and size of the particles that are precipitating or dissolving (peak temperature), the amount of precipitation or dissolution (peak area), and the spread in particle size (peak width). The molar heat of reaction (or reaction enthalpy) and its sign (exo-or endothermic reaction) characterize the different processes. Table 2 shows typical values of the reaction enthalpy for the most common processes in aluminum alloys, which actually cover almost three orders of magnitude from the most (melting) to the less (recrystallization) calorific.

Table 2 Typical reaction enthalpies ΔH (in J/g) involved in various processes in aluminum alloys

Process	Peak type	Peak shape	Reaction enthalpy (J/g)
Melting	Endothermic	Sharp	Hundreds (400)
Phase dissolution	Endothermic	Broad	Tens (15)
Solidification	Exothermic	Sharp	Hundreds (400)
Phase precipitation	Exothermic	Broad	Tens (15)
Recrystallization	Exothermic	Broad	Tenths (0.8)

In order to interpret the peaks appearing in the curves several techniques are commonly used: conductivity and hardness measurements,^[18,50–52] electron and optical microscopy,^[19] and micro-analytical techniques such as EDAX. A typical example is shown in Fig. 1. The DSC curve of a cold rolled 1145 alloy shows two exothermic peaks, the first (weak) associated to precipitation and a second one accounting for recrystallization, and an endothermic peak related to phase dissolution. The hardness measured at room temperature on samples taken out of the DSC apparatus and quenched help in the interpretation of the DSC curve. The sharp decrease in hardness coincides with the strong exothermic peak related to recrystallization. The steady, less pronounced, decrease occurring at lower temperatures accounts for both recovery and precipitation reactions (checked by means of electron and optical microscopy; see Ref. [18]). Similar measurements (see also below), albeit costly, have aided in building up a solid basis for the use of calorimetric techniques as a powerful metallurgical tool. We note, however, that even the combination of a wide variety of experimental techniques does not always lead to an

Fig. 1 DSC curve for 1145 alloy 85% cold rolled without intermediate annealing (heating rate 40 K/min). The measurement of the Vickers hardness along the DSC run was carried out at room temperature on samples taken out of the DSC apparatus and quenched in water

unambiguous identification of all phases and, thus, of the processes occurring during the DSC run.

The effects of heating rate on solid-state reactions are illustrated in Fig. 2 which shows DSC curves for alloy 2219 in the T31 temper, taken at four heating rates.^[36] It is noted that while the first endothermic peak and the exothermic peak are strongly affected by the heating rate, the second (and last) endothermic peak is not. This is typical of two types of processes; namely, those affected by reaction kinetics (the first two peaks) and those dominated by the thermodynamics of the reaction (the last peak). Melting and solidification peaks are outstanding examples of the latter. In the case of Fig. 2, the almost null variation of the second endothermic peak with heating rate is probably a consequence of the rapid diffusion at the temperature range over which the last reaction occurs. Very high heating rates would likely affect the peak shape. Checking this point, however, would require a substantial increase of the heating rate, surely beyond the limits of the DSC apparatus.

As remarked above, in many cases several processes overlap, hindering the interpretation and analysis of the data. In the case shown in Fig. 2, although the first two peaks occur at systematically higher temperatures as the heating rate is increased, they preserve their identity. This is a typical behavior of binary Al–Cu alloys; a rather more uncommon characteristic is that a peak can be associated with a single reaction. Fig. 3 shows DSC curves for an Al–Zn–Mg alloy, which illustrate the opposite case, namely, that of several reactions occurring simultaneously.^[36] The experiment depicted in the figure consists of interrupting the run just at the end of the dissolution reaction, quenching the sample at room temperature, and initiating a second DSC scan. It is noted in the second runs that, while in the naturally aged material no signs of reaction are observed over the temperature range swept in the first run, in the artificially aged material the curve still shows a pronounced dissolution peak.

This indicates that, in the latter case, the first endothermic peak was in fact a composite peak resulting from the simultaneous occurrence of dissolution and formation reactions.

Finally, we refer to the fitting of the data for the fraction reacted vs. temperature obtained from the DSC curve. Although in some cases one may argue in favor of a particular function $g(\alpha)$ to be introduced in Eq. 6, in most cases it is a trial and error process. Alternatively, one may use the rather universal JMA function in a semi-empirical approach and with the aim of obtaining kinetic parameters that may allow, for instance, prediction of aging behavior. This is a practical and reasonable approach adopted by many authors. The results shown in Fig. 4 illustrate how standard fittings are carried out. The figure shows the experimental (DSC) data for the fraction recrystallized in a deformed 1145 alloy,^[18] and fittings by means of the JMA expression with several values of the exponent n . The best fit is obtained for $n = 2.5$, with the activation energy and frequency factor reported in Table 1. The fitting of double peaks by means of Eq. 15 is illustrated in Fig. 5. The results correspond to β' and β'' precipitation in 6061 alloy and 6061-15 vol%SiC_w.^[31] The kinetic parameters shown in Table 1 were obtained by using the JMA function, and through the following procedure (a) activation energies were derived from the peak temperature method, and (b) peak areas, frequency factors, and exponents for each process were obtained by direct fitting of the DSC data for the fraction reacted vs. temperature. The authors of Ref. [31] noted that the frequency factor derived from the peak method and that obtained in (b) were very similar, supporting the consistency of their procedures.

HEAT-TREATABLE ALUMINUM ALLOYS

DSC and DTA have been applied since the early seventies to investigate a variety of aspects of heat-treatable aluminum alloys.^[53] Recently,^[54] DSC curves for the most common alloys and composites have been stored in the databank THERYST.^[55] Here we shall illustrate the use of these techniques on selected examples. We shall also provide the characteristic DSC curves of the main alloy families in several tempers. Whenever possible we give the actual chemical composition of the alloy to which a particular DSC curve corresponds. The reader should be advised of the very important changes in the precipitation sequence of the different alloy families that variations in alloy composition could in some cases induce (for instance, new phases may appear).

Al–Cu and Al–Cu–Mg Alloys

The most widely accepted sequence for the decomposition of the super saturated solid solution α Al matrix is:^[56,57]

Fig. 3 Differential heat capacity of 7075 (a) aged for six months at room temperature. The first scan (solid line) was interrupted at 150°C, the sample was quenched to room temperature, and the second scan (dashed line) begun. The dotted line was obtained from an interrupted scan of a different sample of the same material. (b) Same for 7075-T651 (material aged for 24 h at 120°C). In this case, the first scan was interrupted at 215°C. Heating rate 10 K/min

where GPZ stands for Guinier–Preston zones. Nowadays, as the denomination of θ'' is preferred over GPZ-II, we shall hereafter use GPZ to denote GPZ-I and θ'' .^[57] In Al–Cu–Mg alloys phases θ'' , θ' , and θ are replaced by S'' , S' , and S .

DSC curves for the most representative metallurgical states have been studied intensively.^[11,36,52,58–64] Results for a 2011 alloy (Al–5.4wt%Cu) are shown in Figs. 6 and 7.^[52] The evolution of the conductivity σ and the Vickers hardness VH along the run (both measured at room temperature) is also shown. In the annealed condition a single endothermic peak is observed that accounts for the dissolution of the stable phase θ . This interpretation is compatible with the VH and σ results: VH starts to increase and σ to decrease at the peak onset temperature (in the annealed condition VH reaches its lowest value and σ its largest; see for instance Ref. [65]). Samples aged at 250°C show two endothermic

Fig. 5 Heat flow vs. temperature from a DSC run at 10 K/min for a powder metallurgy 6061-15vol%SiC_w composite (lower panel) and for the base alloy (upper panel) extruded at 498°C and 525°C, respectively, both in the as-quenched condition. Fits of the experimental data by means of the JMA expression are also shown. In fitting the data, it was assumed that two reactions were overlapping as in Eq. 15. The approximation for β' and β'' precipitation, taken as separate reactions, are shown by dotted lines

Source: With permission.^[31]

peaks overlapping an exothermic peak. While the latter is related to the formation of the θ phase, the endothermic peaks should account for θ' and θ dissolution. Roughly coinciding with the onset of the first endothermic peak VH and σ start to decrease, a behavior compatible with phase (θ') dissolution. In the range where the exothermic peak occurs, VH and σ remain almost constant, indicating that the effects of θ' dissolution balance those of θ formation. At higher temperature σ decreases monotonically while VH first decreases, and, beyond 450°C, increases, revealing that dissolution of all phases predominates. The main difference of the DSC curve for the alloy aged at 100°C (Fig. 7) as compared to the previous ones is an endothermic peak at around 170°C and an exothermic peak at 340°C, related to GPZ dissolution and θ' formation, respectively. VH starts to decrease at the onset of the endothermic peak and it attains the solid solution value before it increases again. This indicates that most GPZ dissolve before the beginning of θ' formation. This result is consistent with those of Ref. [36], which indicate that this peak is related to a single

process (phase dissolution). As shown in Refs. [36,52], the peak temperatures of those two reactions are strongly affected by ageing conditions (both temperature and soak time). It is worth noting that recent DSC studies^[58] indicate that Mn additions diminish, or even suppress, GPZ formation, increasing θ' phase precipitation. In the as-quenched condition (Fig. 7) a weak exothermic reaction below 100°C reveals the formation of GPZ,^[11,52] that are subsequently dissolved leading to the first endothermic peak. The results for σ support this interpretation: it first decreases (GPZ formation) and then increases when the zones dissolve. Above 300°C the DSC curve and the VH and σ results are quite similar to those of samples aged at 100°C.

Several authors^[11,36,52] have studied the kinetics of GPZ dissolution. A kinetic analysis that included particle size determination^[36] led to the conclusion that curve fitting with either a 3D diffusion equation or a JMA with $n = 1$ gave similarly good results. The author argued,^[36] however, that there was no physical justification for the use of a first-order relationship in solid-state reactions (see the

Fig. 6 (a) DSC curves for alloy 2011 annealed at 400°C for 6h and slowly cooled (left panel) and (c) aged at 250°C (right panel). discussion in “Determining Particle Size from DSC” of this chapter) and carried out the particle size analysis with the 3DD relationship (see Eq. 18). In doing so, the activation energy E_D was chosen to be equal to the activation energy for chemical interdiffusion in Al–Cu alloys, and the frequency factor D_0 was fitted to give the DSC curve for samples containing particles of average radius previously determined by TEM. Then, the so-defined kinetics was used to predict particle sizes for samples aged at different temperatures and soak times. The results were in satisfactory agreement with data obtained by means of TEM. Assuming a variable particle size as in Ref. [36] seems more consistent than alternative approaches that vary the activation energy in order to fit the changes in the DSC curves promoted by changing the ageing temperature. In Table 1 we show the kinetic parameters obtained by using the JMA relationship. Taking account of several important differences in alloy composition and ageing treatments, we may conclude that the range over which the activation energy varies is rather narrow. In particular the two values for the activation energy of GPZ formation are rather similar (56 and 68 kJ/mol) and, as pointed out in Ref. [11],

not far from the activation energy for vacancy migration (known to be essential in GPZ formation) in Al–Cu, that varies in the range 42–67 kJ/mol. What is less justified is an exponent $n = 1$ for all dissolution and precipitation processes of Table 1.^[11] As remarked above, while results for particle dissolution in a wide variety of alloys seem to be adequately described with $n = 1$, phase precipitation does not always fit into this scheme (see values of n reported in Table 1). Although it was remarked in Ref. [38] that $n = 1$ is consistent with low-temperature GPZ formation, no physical justification is offered in Ref. [11] for using $n = 1$ in all fittings. It is also worth noting the very large differences in the frequency factors reported by different authors for GPZ formation.^[11,38] This parameter is the most sensitive to small material differences and to fitting procedures.

It has been shown^[60] that deformation may appreciably affect precipitation in an Al–2.62wt%Cu–1.39wt%Mg alloy artificially aged at 190°C. In particular, it accelerates S' precipitation. This result is consistent with the sample preparation effects observed in alloy 2011 (Al–5.4wt%Cu) aged at 100°C.^[21] As shown by the latter authors, punching and machining significantly shift θ' formation to lower

Fig. 6 (Continued)

temperature. The effect was found to be much weaker in the more diluted 2036 alloy (Al–2.35wt%Cu–0.49 wt%Mg) aged at room temperature.^[22]

6.2 AL–ZN–MG and AL–ZN–MG–CU Alloys

The decomposition of the solid solution in ternary Al–Zn–Mg and quaternary Al–Zn–Mg–Cu alloys has been extensively studied^[56,57,66,67] and can be summarized as follows:

Several authors have suggested that two GPZ, I and II, can be identified.^[68–70] The equilibrium phase η is the binary intermetallic MgZn_2 , while η' is the corresponding meta-stable, hardening, phase. Depending on compositions (in particular on the ratio Zn:Mg) other phases, named T' and T , have been identified; in particular the T phase is the ternary intermetallic $\text{Al}_2\text{Zn}_3\text{Mg}_3$.^[57] There is still an unresolved controversy concerning the precipitate phases present in the different tempers of these alloys. For instance, while many authors claim that the T6 temper has a high abundance of GPZ (particularly in alloy 7050),^[44,71–73] others argue that the η' phase

predominates.^[73,74] We shall refer to this question in the following discussion.

The investigation of microstructural changes in these alloys by means of DSC over a period of thirty years^[36,37,44,67–104] is one of the most outstanding examples of the use of calorimetric techniques in physical metallurgy. DSC curves for samples of alloys with different contents of Zn–Mg–Cu in the as-quenched condition and in the T6 temper are shown in Fig. 8.^[84] The alloys have approximately the same Mg content (around 2wt%) plus either 5wt% or 7wt%Zn (A and B, respectively) or 5wt%Zn–2wt%Cu (C). In the as-quenched condition, a broad endothermic peak follows two exothermic peaks. The former should be ascribed to the dissolution of the stable phase η , and ends at a similar temperature for the two alloys without Cu, and at an appreciably higher temperature for the alloy with Cu,^[69,84] in line with the solid solubility of these alloying elements in aluminum.^[56] GPZ formation scarcely shows up in alloy A, although it occurs at a temperature similar to that for the alloy with the highest Zn content (B). In alloy C, GPZ formation is shifted around 50°C upwards. A similar trend is observed in the exothermic peak related to η' and η formation. The lowest peak temperature is found for alloy B, followed by alloy C, while it occurs at the highest temperature in alloy A. The

Fig. 7 (a) DSC curves for alloy 2011 after 24h ageing at 100°C (left panel) and (c) in the as-quenched condition (right panel). (b) and (d) Change in conductivity and Vickers hardness (VH) (both measured at room temperature) during a linear heating at the rate used to obtain the DSC curve (5 K/min)

Source: With permission.^[52]

fact that there is no endothermic peak between the two exothermic peaks indicates that GPZ transform directly into the η' phase (second exothermic peak). In the T6 temper, an endothermic peak shows up in first place, which accounts for dissolution of η' particles^[92] (note that there are authors who claim that GPZ predominates in the T6 temper). An endothermic peak, mainly associated with formation of the η phase, follows. In alloy C this peak appears as a doublet probably due to one (or several) of the following causes: (a) the concurrent formation of ternary phases,^[69] (b) the overlap of the dissolution of the larger (more stable) η' particles and the formation of the η phase, (c) the heterogeneous formation of the equilibrium η phase (it usually occurs first on grain boundaries, then on dislocations, and finally in the matrix), and (d) the variety of orientation relationships to the matrix and morphologies that the η phase may show. Note that these interpretations could all be valid but in different compositional ranges. DSC curves for naturally aged samples are similar to those of the T6 temper, the main difference being the peak temperature of the first endothermic reaction which is substantially lower, surely due to the lower

stability of GPZ as compared to η' particles. Overaged T7 tempers, on the other hand, show two endothermic peaks related to dissolution of η' and η particles.^[92]

Zirconium is added to these alloys with the aim of controlling grain size and recrystallization (recrystallized microstructures are more prone to stress corrosion cracking). In Ref. [69] the effects of Zr additions on formation and dissolution of phases in an 5.4wt%Zn–1.2wt%Mg alloy was investigated by DSC and electron diffraction. Figure 9 shows the DSC curves for two alloys (with and without Zr) in the naturally aged condition. It is noted that Zr additions slow down phase formation at room temperature (GPZ-II, according to the authors of Ref. [69]). Prolonged heat treatment at room temperature almost eliminates the differences between the two alloys. It is also noted that at short ageing times, η' phase formation (peak C in Fig. 9) is greatly enhanced in the alloy with Zr, possibly due to the lower amount of the precursor phase (GPZ-II) that forms in this alloy.^[69]

The effects of fatigue^[72] and warm working^[80] on the microstructure of these alloys have been investigated by means of DSC. The results of a study on a 7050-T6X

Fig. 7 (Continued)

alloy^[72] indicate that, while low cycle fatigue (strain below the elastic limit) had no measurable effect, high cycle fatigue dramatically reduced the GPZ dissolution peak (first endothermic peak in Fig. 8) whilst leaving almost unchanged the peak temperature. As noted in Ref. [72], the latter means that fatigue did not induce any increase in GPZ size. On the other hand, the results for the effects of fatigue on the heat of reaction are summarized in Fig. 10. The heat of reaction ΔH first decreases abruptly, but further plastic strain is less efficient, a behavior typical of particle cutting.^[72] The strong overall decrease in ΔH was interpreted^[72] as a fatigue-induced GPZ reversion. A similar study on 7050-T73651 found^[72] that fatigue promoted a slight transformation of the η' phase into the η phase. The DSC study of the effects of warm working on a 7075-T651 alloy^[80] concluded that the observed reversion of precipitates was mainly a thermal effect rather than a mechanical effect.

In the DSC study of the effects of deformation on natural ageing of a Al-6.1wt%Zn-2.4wt%Mg^[95] it was concluded that the dislocations introduced prior to ageing induce significant changes in the DSC curves (with respect to nondeformed samples). Specifically, while the GPZ dissolution peak is not much modified, the η' phase formation peak is greatly enhanced and shifted to lower

temperatures. In the only published study of the effects of the use of punching in obtaining DSC samples, carried out on a Al-4.9wt%Zn-1.9wt%Mg alloy,^[22] only minor effects were observed. However, the results of Ref. [95] are clearly a warning for those working on highly concentrated alloys.

Particle size determination by means of DSC has been carried out in Refs. [36,90]. In both cases, the three-dimensional diffusion Eq. 18 was used. In Ref. [90] particle size in a naturally or artificially aged Al-4.5at%Zn-1.75at%Mg alloy was carried out, concluding that particle size increased with ageing time, and that there was a good correlation between strength and the measured particle size. In Ref. [36], however, a study on a 7075 alloy concluded that there was no correlation between GPZ sizes measured by DSC and TEM. This negative result was ascribed to the composite nature of the GPZ dissolution peak discussed above (see Fig. 3).

The heat treatment known as retrogression and re-ageing (RRA) was originally developed to improve the combination of strength and resistance to stress-corrosion cracking of alloy 7075. The method consists of retrogressing the T6 temper for a very short time at temperatures above the dissolution temperature of the metastable phases (200–240°C in these alloys) and re-ageing at a temperature similar to

Fig. 8 DSC curves for three Al–Zn–Mg–Cu alloys with different contents (in wt%) of the alloying elements Zn/Mg/Cu, namely, 5.1/2.35/0.14 (A), 6.9/2.25/0.14 (B), and 5.05/2.17/2.1 (C). The results correspond to samples in the as-quenched condition (quenched in water at room temperature) and in the T6 temper

Source: With permission.^[84]

that used to obtain the T6 temper. DSC has been widely used to investigate the phase transformations promoted by RRA.^[73–75] DSC curves of retrogressed samples are qualitatively similar to those of the T6 temper, although quantitative differences indicate a higher volume fraction of η particles. The evolution of strength along retrogression at a constant temperature is particularly interesting. Strength initially decreases due to dissolution of particles present in the T6 temper (as noted above, most authors agree that these particles are of the η' phase). New particles precipitate concurrently with particle dissolution, giving rise to a minimum in strength. Finally, for very long soak times the strength decreases again due to particle coarsening. Aiming to throw light on this behavior, a kinetic analysis was carried out in Ref. [37] on two alloys with and without Cu. Dissolution kinetics was derived from the first (endothermic) peak in the DSC curve of the T6 temper (kinetic parameters are given in Table 1) while precipitation kinetics was derived from the first exothermic peak in the DSC curve for the naturally aged condition (see Fig. 8). The results for the alloy without Cu are shown in Fig. 11 (similar results were obtained for the Cu containing alloy). Adding up the results for the fraction reacted in the formation and dissolution processes

leads to the kinetics of retrogression. The minimum in the curve is clearly related to the minimum in the strength just mentioned. According to Ref. [37], the results for the time at which the minimum shows up in isothermal heat treatments carried out at several temperatures satisfactorily agree with the experimental data for the strength. Note that the late decrease in strength due to particle coarsening, mentioned in (c) above, is not accounted for by this analysis.^[37]

AL–MG–SI and AL–SI–MG Alloys

The decomposition of the solid solution in these alloys occurs as follows:

The main hardening phase β' and the equilibrium phase β have the same chemical composition Mg_2Si , differing only in the crystalline structure (hcp and fcc, respectively). As in the case of Al–Cu alloys, the β'' phase has been named by some authors GPZ-II. Again, we use here the most commonly accepted notation. Precipitation and dissolution

Fig. 9 DSC curves for an Al-5.4wt%Zn-1.2wt%Mg alloy without (solid line) and with 0.16wt%Zr (dashed line) after ageing at room temperature for 5 hours (a) and 28 days (b)

processes in these alloys are very complex and are greatly affected by the ratio Mg:Si and other additions such as Cu and Mn. In Cu containing alloys, the θ phase and its

precursor (see above), and the quaternary phase Q and its precursor Q' ,^[56,57] have also been identified.

Two alloys of the families Al-Mg-Si and Al-Si-Mg widely used in commercial applications are 6061 and A357. The DSC curves for these alloys in the as-quenched condition (see Fig. 12) illustrate the type of curves found in the two families.^[105-121] Although the curves are appreciably different, they show a similar sequence of peaks that are tentatively ascribed to the reactions specified in Table 3. The first stages of precipitation from the supersaturated solid solution in 6061 are far more complicated than the summary of Table 3 suggests.^[108] For instance it seems that prior to the formation of the GP zones there is clustering of solute atoms (preferentially silicon).^[107] In the TEM and DSC study of Ref. [107] peak A was ascribed to the formation of these clusters. These authors also observed that peak C was in fact a double peak associated with the formation of what they called GPZ-I and GPZ-II (β'' phase) zones. This picture is not, however, universally accepted: many authors ascribe peak A in Fig. 12 to GPZ formation^[106,108] and do not observe any splitting of peak C, as in Fig. 12. The assignment of peak E to the precipitation of free Si (Table 3) is based upon the work of Ref. [105]

Fig. 10 Effect of cumulative plastic strain $N \times \epsilon_p$, where N is the number of fatigue cycles and ϵ_p the plastic strain (which was taken to be equal to the half width of the hysteresis loop) on the molar heat of reaction ΔH_r for η' (see text) dissolution in 7050-T6X (first endothermic peak in Fig. 8)

Fig. 11 Formation and dissolution of the η' phase (see text) along an isothermal heat treatment at 180°C for an Al–5wt%Zn–2.4wt%Mg alloy. The kinetic parameters used in plotting these curves were obtained from DSC data and are reported in Table 2. The broken curve, obtained by adding the fractions reacted for those two processes, gives the kinetics of retrogression
Source: With permission.^[37]

on binary Al–Si alloys. We also note that peak E occurs below 650 K, a temperature above which the solid solubility of silicon in aluminum increases appreciably (at 650 K

the solid solubility of Si in aluminum is only 0.25wt%). Furthermore, the peak is much stronger in A357 than in the more diluted 6061, as expected had this interpretation been valid.

Kinetics of clustering formation in Al–Mg–Si alloys has been investigated in Ref. [12]. The DSC curve for the as-quenched material shows an exothermic doublet at low temperature, the first subpeak being related to the formation of Mg–Si (rich) clusters and the second to diffusion of Mg into those clusters. The experimental data were fitted by means of the JMA expression with $n = 1$. The results for the activation energy and frequency factor are reported in Table 1. In Ref. [12], it was noted that both increase with ageing time, a trend that can be clearly seen in the results shown in Table 1.

The effect of pre-strain (just after quenching) on precipitation in as-quenched samples of alloy 6111 (Al–Si–Mg–Mn–Cu) has been investigated in Ref. [117]. The results are illustrated in Fig. 13. As shown in the figure, pre-strain shifts peak C (formation of the β'' phase) to

Fig. 12 DSC curves for alloys 6061 (Al–1wt%Mg–0.6wt%Si–0.3wt%Cu) and A357 (Al–0.7wt%–0.6Mg) in the as-quenched condition

lower temperatures. This can be explained in terms of an increase in dislocation density, which causes nucleation of particle precipitation to occur faster. Electron microscopy confirms this interpretation. This result has some implications on DSC sample preparation. It was shown in Ref. [22] that punching may significantly affect the DSC curves for this alloy family, although up to an extent strongly dependent on alloy composition.

Al–Li Alloys

The most widely accepted precipitation sequence in binary Al–Li alloys is:^[56,67]

where δ (AlLi) is the equilibrium phase and δ' (Al_3Li) the metastable phase. Binary Al–Li alloys are strengthened predominantly by the finely dispersed precipitation of the metastable, coherent, spherical, δ' particles. A recurrent controversy,^[122,123] that will be addressed below, is whether prior to the formation of the metastable phase, other precursor metastable phases form (GPZ or the δ'' phase). At present, there is no experimental evidence of any metastable phase in the binary alloys that can be structurally differentiated from the δ' phase.^[67]

Among the many calorimetric investigations of Al–Li alloys,^[122–128] one of the most comprehensive is Ref. [122]. That is one of the works in which DSC curves are interpreted in terms of two types of GPZ and the δ'' phase, even though it was recognized^[122] that there was no information about other precipitates than δ and δ' . Figures 14 and 15 show some of the results presented in Ref. [122]. The curves for the alloys in the as-quenched condition are shown in Fig. 14. Reactions are observed only at Li contents above the solid solubility of this element in aluminum.^[56] Peaks Q

Source: With permission.^[122]

and D in the alloy with the highest Li content are ascribed to formation and dissolution of the δ phase. Reaction C accounts for δ' dissolution and has a peak temperature that increases with the Li content. This reaction has a shoulder B that was ascribed in Ref. [122] to the dissolution of precursors of the δ' phase formed in peaks O and P (it was also assumed that δ' phase formation took place in these two peaks). However, the most widely accepted interpretation for the double peak O–P relies upon the formation of δ' particles having a variable amount of structural imperfections and a composition away from the stoichiometric. A remarkable aspect of those curves is that the δ phase formation peak is only present in alloys with the highest Li content (2.7wt%). In fact for the alloy Al–2wt%Li, rather long heat treatments at temperatures above 300°C are required for that phase to precipitate (curves l and m in Fig. 15). In any case, it never forms during the DSC run, despite the rather low heating rate used to take all DSC curves in the two figures. These results indicate that kinetics of δ phase precipitation is very slow; the slower the more dilute is the alloy.

DSC curves for the Al–2.0wt%Li alloy artificially aged at various temperatures are shown in Fig. 15. Again the structure at low temperature (peaks A₁ and A₂) was ascribed in Ref. [122] to formation/dissolution of precursors (GPZ and/or δ'' phase) of the metastable phase. In a recent DSC study of an Al–2.5wt%Li alloy aged at room temperature for 6 months,^[123] it was shown that the first dissolution peak in the DSC curve did not change its shape when the heating rate was varied in the range 1–20 K/min. This was presented as a proof of the association of this peak to GPZ reversion, as at low heating rates the δ' phase would be expected to grow rather than dissolve.^[123] Once more we have to remark that, despite this appealing argument, the structural evidence works against this interpretation.^[67] Peaks evolve as the ageing temperature is increased probably due (according to the actual point of view) to changes in the characteristics of the δ' phase (particle size and structural imperfections). In particular peaks other than B and C only show up in the DSC curves for short treatments or at rather low temperatures. On the other hand, peak B gradually merges with peak C as the temperature/batch time is increased.

A recent study of the effects of sample preparation on DSC curves for as-quenched Al–2.33wt%Li–1.22wt%Cu–0.71wt%Mg–0.06wt%Zr (8090) alloy^[23] lead to the conclusion that punching or grinding after the solution heat treatment greatly reduces GPZ formation, enhancing δ' and S' formation (with respect to samples prepared before the solution heat treatment).

Finally, we note that DSC has also been used to determine particle size in an Al–3.2wt%Li–1wt%Hf^[49] aged at temperatures in the range 146–202°C and for 242–2400 min. It was reported that particles, which were identified as being of the δ' phase, had spherical shape and radii in the range 7–38 nm.

The Stability of Metallurgical States in Heat-Treatable Alloys

As discussed in this section, most calorimetric studies of heat-treatable alloys are addressed to the investigation of the sequence of reactions that occur upon heating. This is the way a particular metallurgical state is characterized. On the other hand, in the case of nonheat-treatable alloys, although some studies of topics such as the interaction between precipitation and recrystallization can be found in the literature (see below), most calorimetric studies deal with the measurement of the *energy stored* during deformation. This magnitude is used to quantify the stability of the deformed state with respect to the annealed condition. In this subsection, this question is briefly addressed for heat-treatable alloys.

DSC runs are commonly carried out up to a temperature close to the alloy melting point, well above the solvus of all phases. This means that once the run is over, the metal will be in its most unstable room temperature metallurgical state (solid solution). Then, one may characterize the relative stability of a given state or temper by measuring the total heat evolved along the DSC run. This, on the other hand, may simplify in some cases microstructure characterization.

Table 4 reports the total heat evolved in DSC runs of the 7017 in a variety of metallurgical states. All as-quenched samples gave a total evolved heat around zero, as one may infer from the above discussion. On the other hand, the fully annealed condition is the one that gives the highest stored heat, in accordance with its largest stability relative to solid solution. The heat evolved in the DSC run varies in a rather wide range and steadily decreases as the degree of ageing decreases. The hardness and conductivity are also shown in the table. The total released heat follows a trend similar to that of conductivity (apart from the minimum shown by the latter in the T4 temper due to GPZ formation) varying in a much wider range. Instead, hardness follows a less monotonic behavior. Combining these three measurements, the actual temper can in fact be rather accurately identified.

NONHEAT-TREATABLE ALUMINUM ALLOYS

The measurement of the energy stored in plastically deformed metals is a useful tool for the study of the mechanisms of plastic deformation and the processes of recovery

Table 4 Total heat evolved ΔH (in J g⁻¹) along a DSC run from room temperature up to 550°C, for an Al–Zn–Mg alloy (7017) in various tempers. The conductivity σ (in MS/m) and brinell hardness (BH) are also given. SS stands for solid solution and FA for fully annealed

	SS	T4–5 days	T4–8 days	T6	T651	FA
ΔH	0.0 ± 1.5	5	7	13	18	21
σ	18.5	18	18	20	21	23.5
BH	92	120	124	164	154	75

and recrystallization. The stored energy in work-hardening aluminum alloys has not received as much attention as the heat evolved in precipitation and dissolution processes in heat-treatable alloys. Classical work on the subject has always been carried out by means of isothermal techniques and on pure metals. The more recent use of DSC to investigate recrystallization in pure aluminum is discussed in Ref. [129]. Recrystallization and its interaction with precipitation/dissolution reactions has been investigated by means of DSC in deformed Al–Fe–Si,^[18,130–132] Al–Mg^[133,134] and Al–Mn^[135–137] alloys. The energy released in deformed pure Al/alumina composites^[138] has also been recently studied by means of DSC.

In one of the pioneering DSC studies of cold-worked alloys of the 1000 series,^[130] the first two exothermic reactions of Fig. 1 were ascribed solely to recovery and recrystallization, respectively. Later, more thorough investigations showed that precipitation may also be occurring in these alloys.^[18,131,132] Figure 16 shows DSC curves of samples subjected to intermediate annealing at various temperatures. The authors of Ref. [18] noted that the DSC curve for the sample annealed at 400°C does not show the first exothermic peak and that, precisely at that temperature, precipitation of Fe and Si was near its maximum (investigated by conductivity measurements). Then, they concluded that the first exothermic peak in Figs. 1 and 16 was mainly related to precipitation. This interpretation was further supported by similar studies on the alloy 8011 that has a significantly higher content of Fe + Si. Reaction kinetics was studied on samples subjected to an intermediate anneal at 400°C. Assuming a JMA law, the kinetic parameters were obtained by means of the peak temperature method (activation energy and frequency factor) and from fittings such as that of Fig. 4 (exponent n). The results are reported in Table 1. The value of $n = 2.5$ can be made compatible with Avrami analysis^[28] which predicts a value in the

Fig. 16 DSC curves for 85% cold rolled 1145 alloy: (a) samples without intermediate anneal, (b–d) samples subjected to a 2 h intermediate annealing at 200, 400, and 600°C, respectively, after 60% cold rolling reduction. Heating rate 40 K/min
Source: With permission.^[18]

range 2–3 for two-dimensional samples, by noting that the grain size in these materials is only three times smaller than the sample thickness used in Ref. [18]. The kinetic parameters obtained from the DSC curves were then used to calculate the reaction rate for isothermal experiments (standard industrial heat treatments are usually carried out at constant temperature). The agreement of the so obtained results with experimental data (see Fig. 17) support the usefulness of nonisothermal calorimetry in reaction kinetics studies.

Precipitation in cold rolled Al–Mg alloys has also been investigated by means of DSC. In Refs. [133,134], a low

Fig. 17 Isothermal reaction rate at $T = 317^{\circ}\text{C}$ (chain line), 307°C (broken line), and 300°C (continuous line) calculated by using the kinetic parameters obtained in non-isothermal experiments as those of Fig. 4. The time at which the maximum reaction rate occurs is indicated (experimental results in parentheses). The results correspond to a 85% cold rolled 1145 alloy subjected to an intermediate anneal at 400°C for 2 h (see Fig. 16)

Source: With permission.^[18]

temperature peak (at around 120°C) in the DSC curve of an Al-2.5wt%Mg alloy was ascribed to the dissolution of Mg clusters formed in dislocation walls. At higher temperatures, the curves show more structure that strongly depends on deformation (see Fig. 18). The endothermic peak for the low deformed alloy was interpreted^[134] as coming from the desegregation of the solute atoms from dislocations. Increasing the rolling strain gradually transforms the endothermic peak into a doublet formed by an exothermic peak followed by an endothermic peak. The exothermic peak was ascribed^[134] to recrystallization and its associated release of plastically stored energy when dislocations disappear. This gradually reduces the relative weight of the endothermic peak.

Recrystallization and its interaction with phase formation/dissolution in pure and commercial Al-Mn alloys have been investigated by means of calorimetry.^[135–137] DSC curves were found to be greatly sensitive to the degree of supersaturation (or purity) and deformation. The results reported in Ref. [135] for three samples of alloy 3003 with different degrees of supersaturation and strain hardening are shown in Fig. 19. The sample with low deformation and high supersaturation shows an exothermic peak that was related in Ref. [135] to Mn precipitation. A similar result was obtained in Ref. [136] for an alloy with a slightly higher Mn content, cold rolled and annealed. The weakly supersaturated/highly deformed sample shows, instead, an exothermic peak at around 335°C preceded by a weak shoulder, and a second exothermic peak around 470°C. These two peaks were ascribed^[135] to recrystallization (the weak shoulder to recovery) and precipitation, respectively. This result agrees with that of Ref. [136] for a pure Al-Mn alloy, although no precipitation peak was observed after the recrystallization reaction. Finally, the highly supersaturated and strongly deformed alloy shows a DSC curve

Fig. 18 DSC curves for alloy Al-2.48wt%Mg after different cold rolling strain, namely, $\epsilon = 0.1$ (continuous line), $\epsilon = 0.5$ (long dashed line), $\epsilon = 1$ (dotted line), and $\epsilon = 3$ (dashed line)

with a strongly structured exothermic peak followed by an endothermic peak associated with phase dissolution. In Ref. [135] the two shoulders in the main peak (at around 290°C and 335°C, respectively) were associated with the start of precipitation and recovery, respectively, while the main peak was ascribed to the maximum rate of recrystallization. Instead, in Ref. [136], by investigating the effects of several heat treatments, it was concluded that the main peak should be ascribed to precipitation and the two shoulders to recovery and recrystallization.

Finally, it is worth referring to a calorimetric investigation of deformed aluminum reinforced with alumina particles.^[138] The authors of that work concluded that the release of stored energy in the composite deformed in lubricated compression can be detected by means of commercial DSC equipment, for strains higher than 40%. In those cases, a single exothermic peak was observed.

ALUMINUM BASED COMPOSITES

DSC has also been applied to the investigation of precipitation/dissolution reactions in aluminum/ceramic composites.^[19,31,38,40,106,108,109,139–149] The main difficulty in comparing data obtained in different laboratories is that in many cases the studies were carried out on samples fabricated through drastically different methods (such as powder metallurgy or liquid metal routes). The characteristics of the reinforcement may also vary significantly. Despite these difficulties, several results are widely accepted. Experimental evidence indicates that the addition of silicon carbide or alumina to aluminum alloys does not qualitatively alter the precipitation sequence. It has also been reported, however, that the composite ages significantly faster than the unreinforced alloy. Precipitation and dissolution kinetics are affected up to an extent, which depends on the specific phase. Both nucleation and growth kinetics seem to be changed by the reinforcement. There is a general agreement concerning the origin of these changes. Since the thermal expansion coefficients of the matrix and the reinforcement are very different, a large plastic strain is originated upon quenching from the solutionizing temperature.^[106] Hence, the large increase in the dislocation density observed by transmission electron microscopy (see Refs. [106,108] and references therein), which significantly alters the kinetics of solid-state reactions in the matrix alloy. The way in which the reinforcement affects solid-state reactions in the matrix alloy has been shown to depend on the alloy chemical composition, and, to a lesser extent, on the fabrication process.

The main conclusions of the DSC study on a powder metallurgy 6061/SiC particulate reported in Ref. [106] are: (a) particle additions increase quench sensitivity, (b) the volume fraction of GPZ formed in the composite is significantly less than in the monolithic material (this behavior was ascribed to the reduction of quenched-in vacancies in the composite), and (c) the precipitation of intermediate phases (preferentially β'') is accelerated by SiC particles. The origin of these results seems to be the thermal expansion coefficient mismatch mentioned above. Results (b) and (c) are clearly illustrated by the DSC curves shown in Fig. 20 for 6061/SiC and 6061/alumina composites.^[109] It is noted that in the DSC curve of the monolithic alloy the peak related to β'' formation (peak D in Fig. 12 and Table 3) is much weaker than peak C (β' formation) while in the composites the opposite occurs. This suggests that, in the composites, GPZ transform more easily into β'' phase. It is also noted that peak G in Table 3 (β formation) is absent in the composites. Again, the thermal expansion mismatch is the cause of this absence. As noted in Ref. [19], the driving force for the transformation of the β'' and β' phases into the incoherent β phase is the high strain field induced by coherence. The fact that this driving force is much lower in the composite (as the energy cost of accommodating strain is substantially

Fig. 20 DSC curves for composites made of alloys 6061 and A357 (same as those in Fig. 12), and alumina and SiC particles, in the naturally aged condition. Curves for the monolithic alloys are also shown. Heating rate 20 K/min

Source: With permission.^[109]

less due to the higher density of dislocations) explains the absence of the G peak in the DSC curves. Conclusions similar to (b) and (c) are drawn from the results of an investigation on 6061/alumina particulate fabricated by compocasting.^[19] The study was carried out by means of DSC, TEM, and conductivity measurements. It was concluded^[19] that alumina particles accelerate nucleation (via the reduction of the incubation time for Si clustering) and growth of the precipitates (due to a higher diffusivity). Once more, both effects can likely be due to the increase in dislocation density promoted by the thermal expansion coefficient mismatch.

In a recent DSC investigation, no significant differences between the ageing behavior of composites fabricated by means of either squeeze casting or powder metallurgy were found.^[31,146] This result supports the general validity of the conclusions outlined above. A detailed analysis of the kinetics of β'' and β' precipitation was also reported. Some of the results are shown in Fig. 5, while the corresponding kinetic parameters are given in Table 1. It is clearly seen that precipitation kinetics is slower in the composite (larger activation energies and smaller frequency factors) probably due to the higher density of nucleation sites provided by the higher amounts of GPZ in the base material.^[31,109] The results of Ref. [149] further supports this view, as the activation energy for GPZ formation in 2618–15vol% alumina was found to be 8% higher than in

the base alloy. The authors of Ref. [31] were able to derive, from the activation energies of Table 1, the activation energy for diffusion, and thereon, the dislocation density, which resulted in being much higher in the composite, as expected.

An interesting observation reported in Ref. [109] is that the large differences found for A6061 with and without reinforcement (alumina and SiC particles) are sharply reduced in A357 (see Fig. 20). This result was ascribed to the large amount of free Si in A357 that produces effects similar to those of the ceramic particles (note that the thermal expansion coefficient of Si lies between those of alumina and SiC).

SOME APPLICATIONS TO TECHNOLOGICAL PROBLEMS

Solidification Curves

The knowledge of solidification curves, i.e., the solid fraction vs. solidification temperature, is important for the control and optimization of solidification processes and for developing solidification models. The most direct method to determine those curves consist of quenching the specimen at different stages during solidification and then determining the fraction of the solid present in the specimen by using quantitative image analysis. However, the difficulty in differentiating the microstructure (especially on commercial alloys containing complex phases), or in freezing the microstructure during quenching, makes this technique tedious and imprecise. The procedure most widely followed in industrial laboratories consists of determining the cooling curves by means of conventional thermal analysis (TA) and then converting them into solidification curves.

Solidification curves present a unique aspect depending on the alloy transformations occurring during the course of cooling. Those transformations are a function of the chemical composition and are also related to the alloy microstructure. For many years TA has been used to obtain information on how the solidification cycle takes place and how the microstructure is formed.^[150,151] The method has been mainly used to control the eutectic structure of Al–Si cast alloys (acicular, lamellar, globular, or fibrous depending on the amount of modified elements). Also, primary grain size in hypoeutectic Al–Si alloys, Si crystal size in hypereutectic Al–Si alloys, and shrinkage tendency of some eutectic alloys have been investigated. A novel technique^[152,153] that combines DTA and mathematical modeling has been proposed and used to determine the solidification curves of binary and ternary aluminum alloys (1050, 1070, 1100, 3003, 3004, 5052, 7075, A356, A390, and A430). The whole spectrum of the solidification curves was determined without requiring the knowledge of a number of thermophysical parameters.

An approach somewhat related to that of the preceding paragraphs has been followed in Refs. [154,155] to determine the extent of the reaction between silicon carbide and/or the oxide layer that usually covers this ceramic (silicon dioxide) and aluminum in composites of these two materials. In both reactions, one of the resulting products is free silicon that, once dissolved in the alloy forming part of the composite, decreases its liquidus temperature. This change can be easily detected by means of DTA. The method produced rather accurate results.

Flow behavior of the semisolid slurry is an important variable in thixoforming processes. The simulation of forming processes in the semisolid temperature range has been revealed as a promising tool in the thixoforming industry.^[156] Constitutive models for the distinct flow behavior of thixotropic aluminum alloys in the semisolid state are derived with respect to temperature and microstructure. Thermal analysis provides the necessary data (specific heat capacity and relative fraction of liquid and solid) to calibrate the models.

Alloy Development, Process Optimization, and Quality Control

In the preceding sections, we have illustrated the variety of problems that can be investigated by means of DSC and DTA. Several important issues related to alloy development can be readily tackled.^[53] The precipitation sequence can be investigated much faster and more thoroughly than by means of any other technique. Of course, in many cases the complementary information supplied by conductivity and hardness measurements, and optical and electron microscopy, may also be required. However, DSC is by far the best suited for that purpose. It may also help in identifying small variations induced by changes in composition, fabrication, or processing. Calorimetric techniques are the most powerful in the investigation of reaction kinetics that may help in designing homogenization and ageing heat treatments. It is possible to determine the homogenization level (type and amount of nondissolved constituent phases) by means of DSC.^[104,157,158] A nonequilibrium melting peak below solidus can be easily detected in the DSC curve. Low melting point phases can promote ingot cracking during hot rolling or subsequent high temperature treatments. Also, final properties, particularly toughness and resistance to fatigue and stress corrosion cracking of heat treatable alloys, can be lowered by the presence of hardening elements in nonsoluble phases or in large eutectic particles. DSC can easily obtain information of such major relevance in heat treatable alloys as the solvus temperature of the various phases. Solution heat treatment and quenching rate can be readily optimized and controlled by means of DSC. We can conclude that, nowadays, calorimetric techniques are an indispensable tool in alloy development.

Fig. 21 DSC curves for samples taken from defect-free (continuous line) and “blackened” (broken line) zones of anodized commercial extrusions of alloy 6063 in the T5 temper. Source: With permission.^[159]

The causes of a wide variety of defects that may appear in aluminum production can also be investigated by means of DSC. A rather common surface defect of Al–Mg–Si extrusions illustrates the use of DSC in fabrication and quality control. The defect is named “black spot” and seems to be related to massive (local) precipitation of the β' phase of Mg_2Si .^[159,160] Local rapid cooling originated by the graphite plates on the run-out table, followed by re-heating caused by the hotter surrounding zones, seem to be the origin of this precipitation. Figure 21 shows the DSC curves for samples of anodized commercial material taken from a defect-free zone and from a blackened area.^[159] While the DSC curve for the uncolored sample is typical of a T5 temper (see Fig. 21), that for the black spot is completely different. The first three reactions of the curve for the defect-free sample (two endothermic and one exothermic) now appear as a broad endothermic reaction with shoulders which indicate that either different phases, or a single phase with a large spread in particle size, are dissolving. The latter interpretation is in fact more likely as the range over which the reaction occurs suggests that it is mainly related to β' dissolution. The two DSC curves are conclusive evidence of the microstructural changes associated with the “black spot” defect, that have also been studied by conductivity and hardness measurements and optical and electron microscopy.^[160]

Stress Corrosion Resistance of Al–Zn–Mg Welds

As discussed above, RRA heat treatments allow improving the resistance to stress corrosion cracking (SSC) of weldable Al–Zn–Mg alloys without an appreciable decrease in mechanical properties. However, welding promotes important microstructural changes in a region known as the heat-affected zone, that adversely affect SSC resistance. A region adjacent to the weld bead, commonly called white zone (WZ) due to its response in nitric acid, seems to be responsible for this deterioration. The

main characteristics of the WZ microstructure are:^[161] (a) grains larger and more equiaxed, and (b) most precipitates located at the grain boundaries (the origin of its physical aspect). These changes are promoted by the rapid displacement of boundaries due to the sudden local heating. Figures 22 and 23 show DSC curves for the base (B) material and for samples subjected to a heat treatment that simulates the WZ microstructure (the zone is too small to take large enough samples; see Refs. [162,163]). It is noted that while the curves for the naturally aged samples are quite similar, those for the artificially aged indicate that the base material has larger amounts of the stable phase η . The DSC curve of WZ shows a much stronger exothermic peak related to η formation. The differences between base and WZ materials are substantially reduced, almost eliminated, for longer ageing. The sharp peak at about 488°C in the WZ curve is related to the Al– $\text{Al}_2\text{Mg}_3\text{Zn}_3$ eutectic formed through partial melting. Despite the similarity of the DSC curves for the two materials after a long enough ageing, the conductivity of B is still much larger than that of WZ (22.5 and 17.7 MS/m, respectively, after 48 h ageing). Full annealing further reduces the differences in

Fig. 22 DSC curves for 7017 in several conditions: (a) B(NA) and WZ(NA), where NA stands for naturally aged, B for base material; and WZ for white zone material; (b) artificially aged (AA) for 8 h at 150°C B(AA 8h) and WZ with two post-weld heat treatments WZ(AA 8h) and WZ(AA 48h) at the same temperature. Source: With permission.^[163]

 Source: With permission.^[163]

the DSC curves (see Fig. 23) keeping the large difference in conductivity. It was argued in Ref. [163] that the spatial distribution of particles was the origin of the difference in conductivity between samples otherwise similar from a microstructure point of view. In fact, low conductivity particles at grain boundaries decrease more effectively the overall connectivity of the medium than when distributed at random. This illustrates the need of carrying out complementary studies in order to unambiguously interpret changes in microstructure.

CONCLUDING REMARKS

Our hope is that the information presented in this chapter will convince the reader of the maturity attained by the use of thermal analysis in the characterization of the microstructure of aluminum alloys. Less than twenty years have elapsed since the times in which only DSC studies that were complemented by optical or electron microscopy observations deserved the attention of the community. Nowadays many material scientists, or, more precisely, metallurgists, trust calorimetric techniques and have the tools and knowledge to interpret the curves, in many cases without the need of carrying out complementary, and usually tediously costly, studies. Calorimetric techniques have entered into most areas of the metallurgy of aluminum alloys. Although heat treatable alloys have probably been the most brilliant area of application, its use in other areas is also reasonably well developed. If anything has to be highlighted we mention the enormous capability of DSC and DTA to provide data for the characterization of reaction kinetics. Calorimetric techniques, although in common with other techniques having many drawbacks (such as reaction overlapping, choice of reaction rate functions, etc.), have the great advantage of being the fastest. As discussed in this

chapter, a substantial effort is still being made to increase the sophistication of the methods used to derive kinetic information from DSC curves. The ability of exploring relatively large samples that calorimetric techniques have, as compared to electron or optical microscopy, has not yet been fully exploited, particularly in quality control. From the metallurgist point of view, it can be safely stated that the use of calorimetric techniques in the metallurgy of aluminum alloys has reached a steady state. Nowadays, once the grounds are solidly built up, DSC and DTA are being widely used and, as with other metallurgical tools, will experience improvements that will make their application more effective. Thus, we may expect that laboratories at manufacturing facilities will increasingly use DSC and DTA in daily material characterization, and not only in the less complex or less demanding evaluations.

ACKNOWLEDGMENTS

We wish to dedicate this chapter to the memory of Enrique Louis Rampa who pioneered the development of aluminum alloys metallurgy in Spain. Thanks are due to G. González-Doncel, A. Mortensen, Y. Ohmori, F. Viana, and S. Yannacopoulos for useful comments and sending us copies of their work, and to P. Baggethun and J.L. Murray for several useful remarks on the manuscript. We also acknowledge with thanks the editors and authors that have granted permission for reproducing the figures of this chapter. Partial financial support by the Spanish MCYT (grant MAT2001.0529) and the Universidad de Alicante is gratefully acknowledged. Consuelo García-Cordovilla is also thankful to the Aluminum Company of America (ALCOA) for permission to publish this work.

Abstract

Although aluminum (Al) and its alloys have an advantage of high specific strength, their applicability is limited due to relatively low hardness and low wear, corrosion, and heat resistance. The surface modification route provides an interesting platform to achieve the required engineering properties. In this direction, depositing different coatings, broadly classified as metallic, ceramic, cermet, composite, and functional material, on Al alloys using various thermal spray techniques is discussed with more emphasis on the electrical, thermal, wear, corrosion, and fatigue properties. The choice of techniques, namely plasma, high-velocity oxy-fuel, detonation, and cold spray is discussed based on the coating material type and application requirements. This article presents a brief summary of numerous studies reported under the aforementioned material categories, highlighting the influence of feedstock chemistry, spray parameters on various properties of coatings, resulting functional performance along with the potential applications in diverse industrial segments.

Keywords: Aerospace; Automobile; Cold spray; Detonation spray; HVOF; Metal matrix composites; Plasma spray; WC–Co.

INTRODUCTION

Industrial use of Al alloys has been constantly increasing due to their engineering advantages such as high specific strength, ease of casting, and ability to deform, and therefore attract a variety of applications in automotive, aerospace, marine, food processing, petrochemical, wire drawing, textile, and transportation industry segments. The main motive behind the use of Al alloys in automotive and aerospace industries in particular has been the significant weight reduction and corresponding fuel savings. However, low hardness and relatively poor wear and corrosion properties of Al alloys limit their applications. This limitation can be minimized by altering the surface properties of Al alloys by resorting to surface modifications. One of the most prominent ways of protecting the Al alloys is through coatings deposited using thermal spray techniques. In view of the above, this article provides a brief overview of thermal spray variants, including the fundamentals, process variables, and the resulting properties. Various coating materials such as metals, alloys, cermets, and composites deposited by different spray techniques such as air plasma spray (APS), high-velocity oxy-fuel (HVOF) spray, detonation spray coating (DSC),

and cold gas dynamic spray (CGDS) aimed to protect Al alloys are discussed in detail. In addition, application of these coatings in various industrial sectors has also been briefly illustrated.

AN OVERVIEW OF THERMAL SPRAY TECHNIQUES

Thermal spraying has gained most industrial acceptance and gradually emerged as a prominent method to deposit a large variety of coatings not only to protect newly manufactured components but also to repair/refurbish the worn parts. The process fundamentals that are common to any thermal spray technique are provided hereunder followed by brief description about most prominent thermal spray variants.

Process Fundamentals

Thermal spray is a generic term used for processes in which the coating deposition takes place by heating the particles (feedstock) to high temperature and subsequently accelerating them toward a substrate. Upon impacting the

Fig. 1 Sequence of events during thermal spray coating deposition

substrate surface, the accelerated molten or semi-molten particles undergo flattening (splats) to form the adherent layer. Subsequent impact of particles on the previously formed splats leads to the formation of thicker coating.^[1–3] Therefore, the thermal spray coating represents a typical layered structure with one splat built over another with a final thickness usually of the order of 50–500 μm . The sequential process steps as described above are illustrated in Fig. 1. The mechanism of the bonding between a sprayed coating and the substrate is mainly the mechanical interlocking that contributes to the adhesion. However, there is an evidence that in certain instances, a chemical interaction between substrate and coating results in metallurgical bonding as well. On the basis of the aforementioned sequence of events, equipments were designed to impart different means of heating and accelerating the particles. The characteristic features of different techniques such as APS, HVOF, DSC, and CGDS are briefly presented.

Air Plasma Spray

Among all thermal spray techniques, plasma spray technique is very popular and has been the workhorse for several decades for depositing a wide range of materials due to the high temperatures involved in the process. Plasma is a conductive gas that consists of positively charged ions, electrons, and neutral gas atoms. Plasma can be generated either by interaction of an electric arc with a gas or by high radio frequency excitation. DC arc plasma is most widely used for coating purposes and is shown schematically in Fig. 2. The plasma torch consists of water-cooled copper anode and water-cooled tungsten cathode. A direct current (DC), maintained between the anode and the cathode, ionizes the gas that flows around the concentric anode. This results in gas plasma with a core temperature between 8000 and 14000 K. When the powder is injected into the plasma, it gets heated and accelerated toward the substrate and forms the coating.^[4] The final temperature and heat transfer property of the plasma depend on the plasma power, anode–cathode design, type of gas injection (axial or radial), and also the type of gas. Nitrogen, argon, hydrogen, and helium are the commercially used

Fig. 2 Schematic representation of plasma spray gun

plasma gases. In general, argon is used most widely due to its low-ionization potential and thermal heat capacity. Nitrogen, on the other hand, is one of the hottest plasma gases. Helium and hydrogen are generally used as secondary gases to enhance the heating capabilities of the plasma. Further to note, argon and nitrogen are the heavy gases that provide higher particle momentum, while hydrogen and helium are used for an efficient heat transfer to the particles. The particle velocities in the plasma spray process also depend on their size and specific mass, which typically is below 300 m/s, except axial injection plasma torch wherein the particle velocity can reach 600–700 m/s.

Detonation Spray Coating

The DSC technique, also known with a trade mark as “D-GUN,” produces superior quality coatings for application in various industries.^[5–7] The most widely used spray gun design comprises one-end-closed steel tube with an internal diameter of 25 mm and an overall length of 1350 mm (Fig. 3). A typical DSC process consists of the following stages: A metered quantity of flammable gas mixture (oxygen and acetylene, as a most widely used fuel) is fed through the gun. Simultaneously, powder to be sprayed is injected through a powder feeder before the explosion is triggered by a spark plug. The detonation wave is formed instantaneously after ignition and obtains a velocity of around 2600–3500 m/s and a temperature of around 3500°C.^[8] This wave, followed by a rapid expansion

Fig. 3 Schematic of detonation spray process

of the reacted gas products, accelerates the powder particles so that they leave the open end of the barrel at a velocity of 700–1000 m/s and impinge on the surface being coated. Consequently, the coatings are dense and exhibit high bond strength. After each detonation, the barrel is purged with nitrogen gas and the process gets repeated several times per second (3–10 Hz). Thus, the gas detonation process being intermittent in nature allows the substrate temperature to be relatively lower (100–150°C) and therefore undesirable thermal deformation of the substrate can be avoided.

HVOF Spray

The invention and commercialization of HVOF process (JET KOTE) in the early 1980s successfully fulfilled the demands of the industry by providing dense cermet coatings with lower oxide inclusions. Ever since the introduction of the first HVOF system, growth of this technology has been phenomenal as propelled by the subsequent addition of numerous hypersonic guns (gaseous and liquid fuel based) made available in the commercial market. The schematic of HVOF gun is shown in Fig. 4. The HVOF process, although sharing an identical platform with the detonation spray technique in few aspects such as dedicated combustion chamber and use of oxy-fuel gas mixture, is a continuous process as opposed to the cyclic nature of the detonation spray technique. In the HVOF process, high-volume combustible gases are continuously fed into a combustion chamber to obtain a gas stream with

temperature below 3000°C and velocity in the range 1500–2000 m/s, which results in the formation of dense coatings (porosity < 1%). Hydrogen, propylene, propane, and acetylene are the most commonly used fuel gases. The powder, fed through the pressurized nozzle into the high-velocity combustion flame, gets heated up and attains high velocities ranging from 500 to 1000 m/s and impacts the substrate to form adherent and dense coatings.^[2] However, the relatively low flame temperatures available in the HVOF technique preclude the sprayability of refractory metals and ceramics, which represent a significant shortcoming compared to the detonation spray system. While the HVOF and DSC are the popular techniques to spray WC–Co cermet coatings, DSC technique is also popularly employed for spraying metals and oxides effectively.^[6]

Cold Gas Dynamic Spraying

CGDS, also known as cold spray (CS), is one of the thermal spray variants, where the thermal energy input is kept minimum while the kinetic energy component is relatively higher. The powder particles of 1–25 μm size range made out of a metal, an alloy, or composites are injected into the throat region of the converging–diverging de Laval nozzle. The particles subsequently get accelerated in rapidly expanding supersonic jet and eventually impact on the substrate to form a coating.^[9,10] The schematic of CS process is shown in Fig. 5. As the process involves high kinetic energy and low thermal energy inputs, the

Fig. 4 Schematic diagram of high-velocity oxy-fuel spray gun

Fig. 5 Schematic representation of cold spray deposition process

technique has drawn considerable global attention to deposit metallic, alloy, and polymeric coatings. The significantly lower thermal energy in the CGDS process suppresses many detrimental aspects of conventional thermal spraying such as high temperature oxidation, thermal degradation, phase transformation, and melting. Deposition of non-ductile materials such as ceramics using CGDS has not been successful unless used in combination with a ductile matrix. The most important aspect of the CGDS technique is that the particle adheres to the substrate only when the velocity of particle is above the critical velocity, otherwise the particle rebounds from the substrate surface leaving the deformation marks. Upon impact of particle at above critical velocity on the substrate, there will be a localized zone that experiences a flow stress break down and sudden increase in strain and temperature (adiabatic heating), with which the contact pressure aids in bonding of the particle to the substrate.^[9] The critical velocity depends on the material to be sprayed, size range, and typically falls in the range of 500–700 m/s for most metal–substrate combinations. The hardness and preheat temperature of the substrate, preheated particle temperature will also play a minor role in the critical particle velocity. Helium, air, and nitrogen are the most commonly used gas media employed in the CS process to accelerate the particles. Therefore, the exit velocity of the particles depends on the type of gas, wherein highest velocity can be achieved when helium gas is used.

It is noteworthy that each thermal spray technique as described above has its own characteristic feature of thermal and kinetic energy combination window as offered to the in-flight particles such that depositing a wide range of materials with vastly different property combination is readily attainable. To summarize the above description and to provide a common platform for cross-comparison, the principle characteristic features of various thermal variants are presented in Table 1. Similar to the aforementioned processes, flame spray,^[11] wire arc,^[12,13] kinetic spray,^[14] warm spray,^[15] and solution precursor plasma spray (SPPS)^[16] processes also have been used to deposit various protective coatings on Al alloys to a varying

degree. Flame and wire arc spray techniques are traditionally well known and extensively used to deposit various metallic and composite coatings on Al alloys. It may be noted that the kinetic spray is an extension to the CS technique and particles greater than 50 μm can also be deposited using kinetic spray. Warm spray is a slight modification of HVOF with low thermal input, and SPPS is a recently emerging technique where the coating of desired composition can be achieved by using suitable feedstock in the form of “solution,” and these techniques were not discussed in this article.

Key Process Variables

For a given thermal spray technique, careful selection of suitable feedstock properties (composition, morphology, and size range) is vital to achieve dense, thick, and adherent coatings. The temperature and velocity of the particles during deposition are the most important variables that significantly influence the coating properties. Also, the gap between the gun exit and the substrate called “stand-off distance” plays an important role in the thermal spray process. While the particle injection into the energetic flame is usually accomplished employing either an axial or radial injection system driven by the help of a carrier gas, the axial torches usually result in homogenous particle temperature and higher productivity. The average particle velocity depends on the carrier gas flow rate, exit diameter of the injection system, particle’s shape, size, and specific mass.^[3] For a given carrier gas flow rate, the momentum of particles depends on the cube of their diameters. Hence, feedstock with narrow size distribution provides uniform particle momentum and temperature during their impact on the substrate compared to wider particle size distribution. In most cases, angular and dense powder with reasonable narrow size distribution results in coatings with higher microstructural and mechanical integrity. Typically, the upper particle size limit for plasma spraying is around 50 μm for ceramic powders and 100 μm for metallic powders, while it is 50 μm for HVOF, DSC, and only 25 μm for CS.

Table 1 Principle characteristic features of important thermal spray variants

	Wire arc	Flame	Air plasma	HVOF	Detonation	Cold spray	SPPS
Coating material form	Wire/rod	Wire/powder	Powder	Powder	Powder	Powder	Solution
Heat source	Arc between two wires	Oxy-fuel combustion	Plasma flame	Oxy-fuel combustion	Oxy-fuel combustion with controlled detonation	Preheated gas	Plasma flame
Flame temperature (°C)	4000–6000	2000–3000	10000–15000	2500–3500	2500–3500	Gas heated to 750	10000–15000
Gas velocity (m/s)	<300	<300	400–500	1500–2000	3000	2500–3000	400–500
Particle temperature (°C)	Molten droplets	1500–2000	2500–3500	1500–2000	1500–2000	300–600	3000–4000
Particle velocity (°C)	50–150	50–100	100–300	500–1000	500–1000	600–1200	100–300
Most coated materials	Metals and alloys (electrical conductive)	Metals, alloys, metallic composites	Oxides, cermets, high temp. Ni and Cr alloys	Cermets	Metals, alloys, cermets, oxides	Metals, alloys, cermets	User defined composition from preprepared solution
Porosity	10–30	10–20	1–10	0.1–2	0.1–2	<0.5	1–10
Bond strength	High	High	Very high	Extremely high	Extremely high	Extremely high	High
Applications	Electrical conductivity, hardness, corrosion resistance	Electrical conductivity, hardness, corrosion resistance	Thermal barrier, wear resistance, oxidation resistance, corrosion resistance, dielectric	Wear resistance, hard and corrosion resistance	Wear resistance, oxidation resistance, corrosion resistance, dielectric	Wear resistance, corrosion resistance, electrical conductivity, thermal conductivity	Thermal barrier, Solid lubrication, photo catalysis, solar absorption

Auxiliary and Safety Equipment

Apart from the basic spray system, gun/torch, numerous other auxiliary subsystems such as manipulator (for gun and part to be coated), powder feeder, gas flow controls, sound proof chamber, de-dusting, and exhaust systems are necessary for carrying out the commercial operations. In the modern spray systems, robotic controls are being employed for effective manipulation of gun assembly, and component such that uniform standoff distance is maintained even in the case of fairly complex geometries. By employing specialized powder feeders, the specified powder flow is achieved throughout the deposition process. An effective de-gassing and de-dusting system needs to be employed to collect the leftover powder particles and combustion products in the spray booth. The general noise levels are above 100 dBA for most spray variants, whereas it is about 135–145 dBA for HVOF and DSC systems and therefore demands a soundproof chamber to reduce the overall noise levels outside the spray booth, which are regulated as per Occupational Safety and Health Administration, USA specified limits (85 dBA exposure per 8 h). Therefore, most spray processes are controlled and monitored remotely utilizing a panel located outside the spray booth. The typical costs of basic spray booth are in the range of 300,000 USD for plasma and 250,000 USD for HVOF systems.

In continuation to the aforementioned thermal spray variants and auxiliary system requirements, the subsequent sections are oriented based on the classification of material being sprayed to improve specific set of properties and the related industrial applications.

METALLIC AND ALLOY COATINGS

Deposition of metallic coatings on Al alloys tends to improve their electrical and thermal conductivities, hardness, and corrosion resistance. For example, deposition of Cu coatings on Al electrical lugs used to terminate aluminum cable conductors (as shown in Fig. 6a) improves the lug electrical conductivity close to that of Cu conductivity while the price is still closer to that of relatively cheaper

Al. Similarly, the deposition of silver coatings on various Al substrates is expected to enhance the electrical and thermal properties of Al alloys although this has not been industrially practiced yet.^[17] Further, the ability to deposit Al coatings on Al components enables the localized repair and refurbishment, leading to efficient material utilization and recycling.^[18–20] In addition, significant improvement (up to 30%) in fatigue life is obtained by performing shot peening before deposition of Al coating on an Al 8062 substrate.^[18] Similarly, the hardness and corrosion resistance of cold-sprayed 1100 Al coatings on a 1100 Al substrate were also found to be on par with the bulk 1100 Al substrate despite of small pores and splat boundaries present in the coating.^[19]

Due to extremely low thermal energy and significantly higher kinetic energy involved in the CS, the technique has been popularly used to deposit most metallic coatings without any danger of in-flight particle's oxidation as opposed to APS, HVOF, and DS coatings.^[21,22] It is noteworthy that the formation of thin oxide layer at coating splat boundaries in the coatings deposited by FS, APS, and HVOF techniques degrades the overall coating integrity (Fig. 7a). For instance, 60% electrical conductivity of bulk-annealed Cu can be obtained in cold-sprayed Cu coatings deposited using helium–nitrogen carrier gas mix than HVOF (40%) and Wire Arc Spray (WAS –20%) Cu coatings. The coatings deposited with helium (He) gas exhibit dense structure with 60% high hardness and correspondingly lower corrosion potential as compared to the substrate. In the case of coatings deposited with helium+20% nitrogen gas mixture, the hardness of coating is similar to that of the substrate noticed with relatively lower corrosion current density. Owing to the favorably higher specific heat ratio and specific gas constant of helium over nitrogen gas, particles attain higher velocities when He gas is employed is well known.^[23] Hence, the properties of coatings can be tailored simply by changing the particle velocity, therefore the final coating structure and residual stress distribution in the cold-sprayed coatings. Various bonding mechanisms, namely inter-splat and coating–substrate interface using FEM simulations, shear, and laser shock adhesion testing on Al alloys have been investigated quite extensively.^[24–26]

Fig. 6 (a) Al electrical terminal connectors (lug) coated with Copper for high electrical conductivity and (b) Al panels (bus bars: 2 m long and 50mm width) coated with Sn to join Al bars using friction stir welding

Fig. 7 Electrical conductivity of copper coating: (a) As-deposited by different spray techniques such as cold spray (CS), HVOF, and arc spray (AS) techniques and after annealing conditions and (b) cold-sprayed with air as carrier gas and annealed condition. The electrical conductivity value of bulk-annealed copper is shown as a benchmark reference

Optimization of CS process parameters and the influence of heat treatment on the properties of cold-sprayed copper coatings deposited on Al alloys were also well reported.^[27,28] Post-treatment of thermal-sprayed coatings by conventional heat treatment reduces stresses in the coatings and concurrently enhances the splat bonding, which results in improved electrical and mechanical properties. Annealing of cold-sprayed Cu coatings results in reduced porosity, increased inter splat bonding, and therefore enhances the conductivity.^[27] The cold-sprayed copper coatings deposited using air as carrier gas annealed at 300°C in vacuum for 1 h and annealed in air for 4 h impart 90%–95% electrical conductivity of bulk annealed copper, which is otherwise only 30% in as-sprayed condition as shown in Fig. 7b. It is to be kept in mind that the extra annealing step adds to the process cost and also not permissible to heat-treat all kinds of components. This extra step in the regular process can be eliminated by focusing an infrared light attached to the spray gun assembly such that the coating is quickly heat treated. Such a treatment was found to improve the Cu coating electrical conductivity up to 95% of bulk-annealed Cu, and these studies are currently in progress at authors' laboratory (ARCI). The deposition of Sn coating on Al bus

bars as shown in Fig. 6b using CS technique facilitates joining them using friction stir welding technique for electrical power transmission sector, which otherwise is not possible with bare Al bus bars. In view of the abovementioned qualities, although the CS technique primarily used to deposit metallic coatings; subsequently it has been extended to deposit alloy steels and metal matrix composite coatings as discussed in the later sections of this chapter.^[29]

It is very well known that the development of lightweight internal combustion engines with cast Al alloy blocks in place of gray cast iron blocks is significant in the automobile industry.^[30–33] However, the low hardness and poor wear resistance of Al alloys tend to reduce the overall engine performance due to wear and scuffing. The corrosion resistance of Al alloys is also concurrently reduced in the engine block environment due to the presence of sulfuric acid and other combustion products.^[34,35] Therefore, it is very much essential to deposit coatings on Al cylinder bore to enhance the engine life and efficiency. The deposition of alloy coatings such as Fe–C–Mn, Fe–C–Mn–Cr–Ni steels, and gray cast iron (GCI) on Al engine cylinder surface using plasma spray technique not only replaces the cast iron liners but also enhances the wear properties and reduces the wall length and overall weight of the engine.^[36] The coating procedures are well established industrially and already implemented to deposit more than 2.5 million passenger car cylinder bores. Steel-coated Al alloy tools in plastic molding did not exhibit any notable wear damage on the coated mold wall till 5000 plastic components were fabricated, while the uncoated alloy exhibits wear scars after producing 2000 plastic components, indicating the significant improvement in life of injection molding components.

Though the plasma spray is popularly used to deposit steel coatings on Al engine bores, HVOF is also employed for depositing steel coating on Al engine bore as schematically exemplified in Fig. 8.^[21,37] The bore surface is usually prepared with water jet machining process and subsequently coated utilizing HVOF spray gun. The multi-directional research investigations accomplished through optimization of deposition conditions, evolution of various properties under the simulated engine bore environment coupled with real-time testing of components over long service life periods have together helped to establish the industrial acceptance.^[37]

As mentioned in the case of cold-sprayed metallic coatings, several studies were also reported on how the coating process parameters, coating material, and substrate properties influence the microstructure and properties of HVOF, DS, and plasma-sprayed coatings.^[38,39] For example, the presence of oxy-hydroxide on the Al substrate resulted in the formation of bubbles beneath the splat of plasma-sprayed Ni–Cr coatings. The interaction of feedstock in molten droplet form with the hydrated substrate surface initiates numerous unwanted phenomena such as water vapor formation, splat fragmentation, and splat surface oxidation. Therefore, toward preventing such ill effects,

Fig. 8 Stepwise schematic of the thermal spray process inside a cylindrical bore: (a) Machining of cast cylinder wall; (b) water jet for surface cleaning and roughness creation; (c) deposition of thermal spray coatings on the wall; (d) honing of the cylinder wall to final size

preheating of the substrate appears to be essential to obtain dense coating structure without any gas entrapment.^[40,41] It is imperative that the presence of oxides, adsorbents, and condensates on the substrate surface adversely affects the adhesion between the splat and substrate surface. In order to achieve good bonding between the substrate and the coating, the surface of the substrate should preferably be cleaned thoroughly to remove oil and grease and grit blasted to remove all oxides prior to coating deposition.

METAL MATRIX COMPOSITE COATINGS

Aluminum-based metal matrix composites (AMMCs) exhibit higher hardness, strength, and wear resistance than the conventional Al alloys. However, compared to conventional alloys, AMMC are costly, and the manufacturing process is also fairly complex. Therefore, significant attention is being paid toward improving wear and corrosion of conventional Al alloys through AMMC coatings.^[42,43] It may be noted that the improved properties of AMMCs primarily depend upon the characteristics of matrix and reinforcement phases. Studies in this direction were extended to a large number of Al alloy systems including 5XXX, 6XXX, and 7XXX series and Al-Si alloy composites. The most commonly used

Fig. 9 Typical microstructural features of different composite coatings, namely (a) Al-SiC by plasma spray, (b) Al-50%Al₂O₃, and (c) Al-75%Al-Si by cold spray techniques

reinforcements for AMMCs are Al₂O₃, SiC, B₄C, Si₃N₄, ZrO₂, and TiN due to their excellent chemical stability and superior hardness.^[44–46] Typical microstructure of different composite coatings deposited by various thermal spray techniques on Al alloys is shown Fig. 9a–c. The bonding between reinforcement and matrix is a key parameter to achieve extended properties in AMMC coatings. Better bonding between matrix and reinforcement with notably higher reinforcement proportions in AMMC coating can be obtained by plasma spray deposition. However, the

oxidation of SiC during plasma spraying of Al/SiC coating leads to formation of cracks at the substrate–coating interface, and in turn results in poor adhesion. A careful selection of process parameters is very essential to minimize the oxidation of SiC and crack formation to get better bonding.^[42] The presence of both Al_2O_3 and CeO_2 in the Ni-based composite deposited on an Al alloy by plasma spray showed better wear properties as compared to Ni and Ni– Al_2O_3 composite coatings due to synergetic strengthening effect of both the oxides, therefore permitting coatings to be used for low- (below zero) as well as high-temperature applications.^[47]

Besides the oxide content at the inter-splat boundaries, the particular phenomenon of poor adhesion can be attributed to the mismatch of the coefficient of thermal expansion (CTE) between the substrate and coating materials over the operating temperature range.^[48] Hence, the combination of better wear and corrosion properties can be achieved in AMMC coatings by tailoring the thermal spray deposition conditions as well as matrix and reinforcement combinations. In the view of above, CS has become the relevant technique for depositing AMMC coatings on Al alloys^[49–52] (Fig. 9b,c).

Space-bound construction materials are usually subjected to severe environmental conditions including temperature gradient, strong UV radiation, high vacuum, and abrasive action of micrometeorites. One of the crucial requirements of a successful environmental coating for such applications is good substrate–coating adhesion for effective management of internal residual stresses and the external service-bound stresses. Accordingly, thick Al– Al_2O_3 metal matrix composites deposited by CS on Al 7550 structural alloy not only exhibits required adhesion but also demonstrates very low thermal conductivity of 0.2–2 W/m°C in the temperature range of +200°C to –150°C.^[50] It is apparent to note that thin contact areas (i.e., splat boundaries) acting as localized heat barriers are primarily responsible for the significantly reduced thermal conductivity. Very stable structure was observed when tested with atomic oxygen (AO) plasma, indicating that the coatings are stable in high AO concentration present in the low-earth-orbit environment.^[53] With other attracting properties such as low solar absorption, high infrared remittance, and oxidation stability of AMMC coatings, the space-bound structures with efficient thermal management of sensitive construction materials and electronics that are subjected to stronger solar radiation are well protected from environmental degradation.

As stated before, owing to significantly reduced thermal energy input to the particles in CGDS technique, the retention of original feedstock structure appears to be its key ability to attract numerous other applications. The nanocrystalline Cu–1% Al_2O_3 feedstock as sprayed using CGDS not only demonstrates that the nanocrystallinity is retained in the coatings but also provides 60% higher hardness value than the conventional Cu coatings. Besides

this, since the grain boundaries are pinned by the Al_2O_3 particles, both the nanocrystalline nature and its hardness are retained up to 950°C. Importantly, it is to be noted that the hardness of conventional Cu coating reduces to 60% of its room temperature (as sprayed) hardness at 950°C.^[54]

CERMET COATINGS

Traditionally, the use of chrome plating and anodizing makes the Al alloys suitable for diverse industrial applications such as landing gear components of air craft, cylinder liners and heads, and turbojet engine blade roots and edges, wherein wear and corrosion resistance are of prime interest.^[55] However, both the aforementioned techniques work on non-ecofriendly acid-based processes raising the environmental concerns. Thermally sprayed WC–Co cermet coatings are the promising candidate material as an environmentally safe alternative to Cr plating.^[56] Although plasma spray is used to deposit the WC–Co coatings, the tribological performance of plasma-sprayed WC–Co coatings is slightly inferior to HVOF and DSC-sprayed WC–Co coatings. The high temperatures involved in the plasma spray decomposes the WC cuboids present in the powder particles during deposition, leading to formation of an amorphous Co matrix enriched with W and C with concurrent decrease in hard WC phase, which deteriorates the tribological performance.^[57–59] In view of the above phenomenon, HVOF and DSC techniques emerged as widely used techniques to deposit the WC–Co coatings, wherein the retention of the WC phase with good inter-splat bonding can be achieved by employing optimum process parameters (Fig. 10). WC–Co coatings were deposited on different Al alloys to improve a handful of properties such as hardness, wear, and fatigue resistance.^[60,61] Further, a small addition of Cr and CrC–NiCr to the WC–Co feedstock powder is found to enhance the corrosion properties of Al alloys.^[55,61] In addition, the WC–Co coatings with nano-WC cuboids appear to improve the mechanical and tribological properties compared to conventional WC–Co coatings with micron size WC cuboids.^[62] It is noteworthy that the thicker WC–Co-based coatings deposited by thermal spraying could effectively resist the percolation of the electrolyte to reach the underlying substrate, and therefore provides adequate corrosion protection thereby making it suitable for various corrosion resistant applications. Therefore, various carbide-based composite coatings as deposited by plasma and HVOF techniques on Al alloys are widely used for injection molding tools. The deposition of carbide coatings on Al alloys did not show any deterioration in the fatigue properties of Al substrates.^[63] It is clear from the above discussion that the WC–Co cermet-coated Al alloys are potentially expected to expand the use of Al alloys for a large variety of applications. Attempts were also made to deposit WC–Co coatings with higher binder (Co) content on Al alloys using CS technique.^[64]

Fig. 10 HVOF sprayed (a) WC-10Co-4Cr coating on reinforced Al substrate and (b) its higher magnification SEM image showing coating-substrate interface

It has been reported that the coatings obtained by CS is competitive to standard high-velocity thermal spray processes. However, there is a greater need to reengineer the nozzle design and optimize the process parameters to achieve thicker and denser cermet coatings with reasonably higher deposition efficiency similar to that offered by competing thermal spray technologies.

OXIDE COATINGS

Ceramic coatings as popularly deposited using thermal spray techniques such as plasma spray and detonation techniques increase the resistance to wear, corrosion, oxidation, and fatigue degradation. The properties of ceramic coatings on Al alloys primarily depend on the conformity between coating and substrate as the difference in the CTE and thermal conductivity of ceramics and metals needs to be accounted properly.^[65] Fretting-fatigue resistance of detonation-sprayed Al_2O_3 coatings deposited on Al alloys exhibit thickness-dependent performance. Accordingly, a 40- μm thick coating demonstrated better fretting-fatigue properties due to high compressive residual stresses within the coating as compared to a 100 μm thick coating of identical composition. It is noteworthy that the uncoated Al alloys exhibit higher fretting-fatigue damage as compared to coated substrates, which is attributed to the difference in the hardness of uncoated (bare) and coated Al alloys (80 HV against 1020 HV).^[66]

In the wire drawing industry, ceramic pulleys and rollers are used to withstand the deformation and wear that occurs during wire passing. At the same time, solid ceramic pulleys are heavier and therefore motorized rotation is resorted, which in turn increases the power consumption. In addition, the surface of ceramic pulleys becomes rough after a few months of service and therefore necessitates periodic replacement. In order to reduce the load on motors and correspondingly power consumption, Al alloys coated with Al_2O_3 and $\text{Al}_2\text{O}_3+\text{TiO}_2$ compositions by plasma and

detonation spray techniques are used to achieve an identical service life as that of bulk ceramic pulleys (Fig. 11). It has also been reported that the plasma-sprayed Al_2O_3 coating on alternator (aluminum diode assembly) meets the required dielectric and corrosion properties, and the ZrO_2 -based thermal barrier coatings on the automotive piston crown imparts the necessary protection. Similarly, ZrO_2 coatings deposited on Al alloys by plasma spray with and without Ni-Al bond coat to impart the thermal shock resistance. The thermal shock resistance of the Al tube with Ni-Cr bond coat of 100 μm thickness and ZrO_2 coatings improved with an increase in the coating thickness of ZrO_2 .^[65]

NOVEL/FUNCTIONAL COATINGS

Functional or graded coatings are required to achieve a combination of properties compared to mono-material coatings.^[62] This can be achieved by tailoring a suitable compound/material at an appropriate place within the coating architecture. Toward this objective, composite coatings with different compositions such as Cu-Al, Cu-SiC, Cu- Al_2O_3 , Al-SiC, Al- Al_2O_3 , Al-Ti, Ti-SiC, and WC-Co-Cr+ Al_2O_3 , Cu- Al_2O_3 , Al_2O_3 + ZrO_2 are deposited using CS and computer-controlled detonation spray techniques on Al alloys.^[67] Conventionally, blended powders (typically mechanical mixing or ball milling) will be fed through the gun to produce composite coatings. To deposit multi-material coatings (Fig. 12a), for example, using CS, injection of powers at different locations like hard particles in the subsonic zone and easily sprayable powder in supersonic zone of the nozzle is adopted. Multilayer and gradient coatings as illustrated in Fig. 12 were also deposited by a twin powder feeder with independently adjustable spray parameters for each material in detonation spray to achieve multi-functional properties.^[68] Moreover, by varying the thermal and kinetic energy combination in a given deposition technique, the coating structure and

Fig. 11 Oxide coatings on Al wire guide pulleys and rollers: (a) Al_2O_3 on wire pulley by detonation spray, (b) Al_2O_3 on wire pulley by plasma spray, (c) Al_2O_3 on wire roller by plasma spray, and (d) and (e) $\text{Al}_2\text{O}_3 + \text{TiO}_2$ on wire rollers by detonation spray technique

the resulting properties can be varied utilizing the same feedstock powder.

Age-hardened Al–Cu alloys have been widely used in airplane fuselages because of their high strength up to 250°C . In these Al alloys, the high temperature properties can be achieved with nonequilibrium microstructures, i.e., finer dispersion of precipitates in the Al matrix.^[69] Accordingly, the Al amorphous/nanocrystalline materials demonstrated improved wear and corrosion resistance than the conventional Al alloys and therefore driving a

Fig. 12 (a) Composite Al–Ti coating by cold spray, (b) layered, and (c) gradient coatings by detonation spray techniques

new direction to utilize these materials as coatings to protect conventional Al alloys.^[70–72] Further, noteworthy to mention that it is very difficult to produce thick Al bulk metallic glasses due to low glass-forming properties of Al alloys. However, the most important challenge in realizing the above properties is the retention of the original structure in the coatings. Materials of this kind specially designed for structure sensitive applications are successfully deposited on Al alloys using CS technique up to a

Fig. 13 Cold-sprayed Al amorphous/nanocrystalline coating on Al 6061: (a) as sprayed and (b) heat treated at 350°C conditions

thickness of 300 µm as illustrated in Fig. 13. As exemplified before, since the CS technique involves low thermal energy input, it facilitates depositing the nanocrystalline copper coatings with improved wear resistance up to 50% compared to the conventional coatings.^[73] Fabrication of the nanocomposite structure of multi-walled carbon nanotube (MWCNT) reinforced hypereutectic Al–Si by plasma spray not only improves the modulus but also decreases the wear rate.^[74] Plasma spray technique is also utilized to produce amorphous coatings by complete melting of particles and rapid solidification upon impact with the substrate, while subsequent laser treatment of plasma-sprayed coating is provided to functionalize the nanostructures.^[75]

APPLICATIONS

In addition to the various applications as described in the previous sections, which are listed in Table 2, thermal spray methods are also used to fabricate free form via rapid prototyping and joining of materials. Carbon nanotube reinforced aluminum free-form tubes and Ti free-forms were successfully fabricated using plasma and CS techniques as shown in Fig. 14.^[76] Two Al plates successfully welded with Zn using CS technique demonstrate its viable choice for rapid prototyping and joining assemblies for thermally sensitive materials.^[77] These techniques are not only used for depositing coatings on new components but also used for repair and refurbishment of various parts in automotive, aerospace, and marine as an onsite repair solution instead of post-replacement of failed components.^[78,79] Corrosion is a serious concern in most marine structures as the atmospheric and localized corrosion results in reduction in component life, wherein the damaged component replacement is often a costly option too. Amorphous/nanocrystalline Al alloy coatings on 6061 alloy exhibited five times higher corrosion resistance in NaCl solution compared to bare 6061 alloy with significantly improved wear resistance under sliding and scratch modes.^[70,71] These properties are further enhanced by annealing of Al amorphous/nanocrystalline

Table 2 Various industrial applications and related feedstock details of thermal spray coatings deposited on Al alloys

coatings at 300°C in vacuum for 1 h.^[70,71,80] Portable CS systems are now commercially available, and the technique has already been demonstrated to repair the corroded surfaces of Mg naval gear box sealing. Recently, a navy valve actuator internal bore surface made of Al 6061 alloy was repaired using the same alloy coatings by the CS technique as illustrated in Fig. 15a,b.^[21] It is noteworthy that the coating passed all bench top service related tests and successfully deployed the part in the actual service.

CONCLUDING REMARKS

Thermal spray protection of Al alloys against numerous degradation mechanisms such as wear, corrosion, fatigue, and fretting-fatigue is an emerging field in which a reasonably large number of applications were already realized.

Fig. 14 (a) Plasma-sprayed Al-Si-10CNT coating of 5 mm thick and (b) Ti coating of 10 mm thick deposited by cold spray technique

Fig. 15 (a) Exfoliation and pitting corrosion damaged Al navy valve actuator internal bore (b) after repair and refurbishment with a coating deposited by cold spray technique

Considering the large-scale techno-commercial benefits, more and more applications using Al alloys are currently under consideration. Vast spectrum of processes with individual characteristic features falling under the umbrella of

thermal spray technologies as briefly discussed in this article have the proven potential to deposit a large variety of coatings with diverse combinations of properties. This particular aspect has been the backbone and driving force for realizing and implementing many industrial applications.

Various metallic coatings as deposited by CS technique on Al alloys although has demonstrated benefits in terms of electrical conductivity improvement, these coatings are now being applied for the repair and refurbishment of worn out parts. In particular, the portable CS coating systems that are commercially available in the market are expected to drive the onsite repair of heavy structures and remotely components. Plasma-sprayed alloy coatings on automotive Al cylinder bores and plastic injection molding tools are well established and industrially in practice. Thermal spray route offers flexible and cost-effective production of metal matrix composite coatings on Al alloys for improved chemical stability and enhanced tribological performance. Thermally sprayed WC-based cermet coatings with varied binder type and content are the emerging candidate materials as an environmentally safe alternative to Cr plating. With significantly increased coating hardness over an order of magnitude, the ceramic coatings as deposited by diverse thermal spray techniques on Al alloys provide substantial wear protection. Functionally graded, nanocomposite coating architectures appear to provide interesting combination of properties that are suitable for space applications.

ACKNOWLEDGMENTS

Thin Aluminum Sheets: Continuous Casting and Rolling

Ildiko Peter and Mario Rosso

DISAT, Politecnico di Torino, Corso Duca degli Abruzzi 24, Torino, Italy

Abstract

This article provides a short history and presents the state of the art of continuous casting and rolling of aluminum and its alloys, currently used for the production of Al alloy sheets for different applications. Some fundamental aspects related to this technology are integrated with experimental results obtained by the authors during the years spent studying the development of grain structure and the effect of homogenization treatment and rolling on the microstructural evolution of Al sheets.

Keywords: Al sheets; Continuous casting; Homogenization; Microstructure; Sheet rolling.

INTRODUCTION

Outline: Al-Based Alloys

Al-based alloys have a high strength/weight ratio, good formability, and an outstanding combination of castability and mechanical properties, making them suitable for many applications. The use of these alloys actively contributes to increasing fuel efficiency and to solving several environmental issues. Nevertheless, there are some limitations to the use of Al-based alloys, due to some weaknesses of their characteristics compared to other potential metals or alloys, such as Fe-based alloys, employed for the same purpose. The quality of casting is determined by several features, e.g., morphology of the constituents, presence of defects (e.g., porosity, segregation, or nonmetallic inclusions), which are usually generated during the solidification phase and/or through the homogenization treatment. The presence of such faults negatively affects the overall behavior of the alloy determining lower mechanical performance.^[1–8]

There are two important families of aluminum alloys: (i) wrought alloys, first cast as ingots and/or billets and then mechanically hot- and/or cold-worked into the chosen shape, and (ii) cast alloys, which are directly cast into their final geometry by employing different conventional or innovative techniques. The selection of the alloy is related to the assumed casting technology to be used and to the specific application of the final component.^[9–11] Usually, multifaceted components are produced by casting or forging processes. Due to their exclusive barrier properties, Al and its alloys are considered perfect packaging materials.^[12–14]

Objectives of the Article within a Multifaceted Topic

When Al is tapped from the electrolysis cell, a very large number of downstream activities are needed before obtaining the finished product. Refining, melting, alloying, casting, forming, joining, and product making are just some of the downstream processing activities that play an important role in manufacturing Al and its alloys and their further employment.

This article provides a short history and presents some of the aspects related to the state of the art of continuous casting (CC) and rolling of Al and its alloys, which are usually employed in the production of Al alloy sheets/foils. The article does not exhaustively cover any features concerning the downstream activities, but it illustrates some important features belonging to such an extensive topic. The experimental results introduced in the article relate to some of the studies performed by the authors on the development of the grain structure and the effect of the homogenization treatment and rolling of the produced Al sheets, which combine theoretical and real-world, i.e., industrial, approaches.

TYPES OF ALUMINUM ALLOYS USED FOR SHEETS PRODUCTION

Apart from the commercially pure aluminum 1xxx series (according to UNI EN 573-3, their denomination is EN AW-1200, EN AW-1050 A, EN AW-1070 A, and EN AW-1080 A), CC technology has been effectively used on an industrial scale to produce commercial sheet products

made of alloys with a low alloying element content, and more specifically, Al alloys belonging to the AA3000 (according to UNI EN 573-3, their denomination is EN AW-3004, EN AW-3003, EN AW-3005, EN AW-3103, and EN AW-3105), 5000 (according to UNI EN 573-3, their denomination is EN AW-5005, EN AW-5050, EN AW-5052, EN AW-5454, EN AW-5754, EN AW-5154 B, EN AW-5086, and EN AW-5083), and 6000 series (according to UNI EN 573-3, their denomination is EN AW-6060, EN AW-6012, EN AW-6061, EN AW-6101, and EN AW-6082). The alloys mentioned earlier are typically used for foil productions. The selection of the right alloy series is governed by the application required and working conditions.^[15–17]

Series 1xxx contains no alloying elements; the Al fraction is 99.3%–99.9%, and the rest is made up of insignificant impurities, mainly Fe and Si with some Cu, Mn, Mg, Zn, Ti, and other elements. Excellent corrosion resistance, high thermal and electrical conductivity, excellent workability, but low mechanical properties characterize these alloys. They are considered non-hardenable alloys with tensile strengths of about 40–60 MPa; significant increases in strength can be achieved by cold work (strain hardening). These alloys are used to produce electric wires, chemical equipment, foil, and decorative products.^[18]

Al alloy Series 3xxx, which are generally non-heat-treatable, contain a key alloying element Mn (up to about 1.5%). These alloys show about 20% higher strength than the 1xxx series; they are non-heat-treatable, but can be strengthened by cold work (strain hardening). The addition of Mg improves solid solution hardening even in annealed conditions. Generally, they are used to manufacture foil, cooking utensils, rigid containers, roof sheets, and beverage cans.^[18]

Al alloy Series 6xxx are heat treatable and contain Si and Mg in the proportions required for the formation of Mg₂Si. These alloys have good formability, weldability, machinability, and relatively good corrosion resistance, combined to a medium strength. Solution treatment followed by either artificial or natural aging enables the yield strength to be significantly increased, while their ductility decreases due to the segregation of Si at the grain boundaries. Alloys belonging to this family are generally employed in automotive, aeronautical, and architectural applications and as structural materials.^[18]

ALUMINUM SHEETS: DIFFERENT PROCEDURES FOR MANUFACTURING AL SHEETS

Continuous Casting versus Direct Chill Casting; Cold Rolling

CC has become increasingly employed in many industrial applications not only for Al alloys but also for other metals and alloys. Several CC methods have been employed

effectively for over 50 years to produce a large number of wrought Al products, including rod and feedstock for Al wire as well as for flat-rolled products. Simple production lines and consequently lower costs are the most important reasons to use the CC process as an alternative to the traditional direct chill (DC) casting and deformation processing for rolled products. As regards environmental concerns, CC is the preferred of the two mentioned techniques due to lower energy requirements (preheating of the ingot before hot rolling is avoided), which enhances productivity (15%–20% higher than for DC). Moreover, the material consumption is about 1.5%–2% lower than in the case of the conventional technique. For the mass production of collapsible tubes and rigid cans, the machines for the blanking of slugs or for extruding can be placed directly after the casting machines, leading to a continuous production line.^[19] Additionally, other activities after traditional semi-CC or discontinuous mold casting techniques are eliminated. CC is the preferred casting method in modern plants because it offers high productivity, but there are some limitations in its use since not all alloys can be cast by this method.^[20–22]

Industrially, two main types of CC methods are used for thin-sheet production, in particular twin-roll casting (TRC) and slab casting methods. In the first, the metallic sheet is solidified directly from the liquid metal (thickness of 5–6 mm), while in the second, a 13–21 mm thick slab is made and is directly hot-rolled to a thickness of 2–3 mm. Generally, CC technologies are used for high-volume production, i.e., foil and building products.

Figure 1a shows the standard DC procedure for Al alloy production, while Fig. 1b schematically illustrates the CC process. The DC method starts with a cast ingot with a machined top portion with no defects and impurities followed by homogenization and by breakdown rolling.

Over the years, it has been found that the most critical weaknesses relating to this technique regard the difficulties in casting alloys with high alloying element content. In these cases, the risk of cracks nucleation and development in the strip is higher, due to the wide freezing range of these alloys.^[23,24] The liquid or semisolid metal can leave the casting mold if not all the metal is solidified at the thinnest point of the casting machine. To avoid this inconvenience, lower casting rates can be chosen, but when too low, solidification in the direction of the casting nozzle takes place. Consequently, the casting rate of alloys is lower compared to that of the commercially pure Al.^[23,25] The CC of wire bars has important economic consequences as well, since it enables some production steps to be eliminated. As regards the alloy content, the same limitations have to be considered, and this is the reason why mainly commercial pure aluminum is cast.

Approximately 30% of rolled Al semi-fabricated coil stock is produced through the strip casting process; although the concept of solidifying metal between moving steel rolls was discovered back in the mid-1850s by

Fig. 1 Schematic diagrams of the (a) DC cast and (b) continuous cast methods for Al alloy manufacturing^[19]

Bessemer,^[26] J. Hunter developed the first successful Al roll caster in 1954.^[27] The most important metallurgical aspects, which manage the alloy compositions and processing lines to manufacture sheets and foils starting from roll-cast strip, are (i) fine, frequently nonhomogeneous, as-cast structures with a high level of supersaturation, (ii) limited opportunity for homogenization treatments, and (iii) lack of large amounts of hot deformation. Usually, the various TRC technologies are divided into processes according to the size of the finished product, as follows:

- For wide strip casting (width up to 2150 mm).
- For narrow strip casting (maximum width 800 mm).
- For strip that can be coiled immediately after casting (gauge max. 10 mm).
- For strip to be hot-rolled after leaving the casting machine (gauge between 20 and 40 mm).
- For thin-gauge casting (gauge under 3 mm).

TRC has been demonstrated as a valid procedure for the production of foil stock, of strip for painting and the production of strip from 3 to 10 mm thickness directly from the molten metal.^[28] Currently, TRC or strip casting is the preferred method for manufacturing thin-gauge Al sheets and foils. TRC combines two processes, CC and hot rolling. The molten liquid metal is directly transferred into the space prepared by two rotating rolls and sidewalls. Compared to conventional CC, the preliminary forming process using a mold is eliminated, so the production line from molten liquid metal to the final products is evidently shortened, reducing production costs, the amount of energy required, and the waste of alloy. However, macro-segregation is a challenge in TRC, significantly influencing the microstructure and the mechanical properties of the final product, namely decreasing the fatigue strength and causing localized porosities or cracks.^[29] Hence, control of such defects during the TRC process is very important. The rolling parameters to eliminate macro-segregation in aluminum alloys strips have been studied for decades,^[30–32] but the topic still remains unclear.

Al sheets are extensively used for packaging. Among other properties, the most important ones are their reasonable cost, their excellent flexibility and durability, and their good heat conductor capacity.^[33–36]

Generally, Al foils are produced by rolling sheet ingots cast from molten Al, followed by re-rolling on sheet and foil rolling mills to the chosen thickness, or by continuously casting and cold rolling, where the control of the constant thickness of the Al foil during the production process is very important.

The traditional process for rolling slabs manufacturing DC process is followed by the reheating of the rolling slabs to about 500°C, and consequently, hot rolling to a coilable thickness between 4 and 6 mm is performed. The CC process is simpler and more efficient than the DC process: the molten metal is poured into the gap between the two rolling steel belts (cooled by running water) leaving the mold as a continuous cast strip with a thickness of about 25 mm. After casting, the strip can be directly coiled or it can be immediately rolled into a coilable gauge without cooling down, reducing the time needed for production and consequently lowering the cost of the manufacturing process. During the rolling stages, some lubrication is needed, which is sprayed onto the foil surface before passing through the mill rolls. Kerosene-based lubricants are commonly used, while oils approved for food contact are employed for foil that is used for food packaging.^[37–39]

Some of the Consequences of Cold Rolling

The cold-rolling process generates higher hardness (less ductility); therefore, annealing is usually performed. The rolls of foil are heated up to the level of the desired softness, which may be up to 340°C for 12 h. During heating, the lubricating oils are burned off leaving a dry surface. Lubricant oils cannot be completely burnt off for hard temper rolls, which can make subsequent coating or printing more difficult. The rolls of Al foil are then slit on slitter rewinding machines into smaller rolls. Roll slitting and rewinding are an essential part of the finishing process.

Al foils thicker than 25 μm are impermeable to oxygen and water. Foils thinner than this become slightly permeable due to small pinholes caused by manufacturing.^[40–42]

Properties of the Product as a Function of the Manufacturing Line

The production line influences the microstructural characteristics and the mechanical properties of the materials produced. For this reason, the strip produced by DC, exposed to homogenization treatment before hot rolling, shows higher plastic deformation than that of CC alloys. CC cast slab demonstrates a higher solidification rate than the DC ingot. CC alloys reveal higher levels of solid solution, un-recrystallized grain structure, and a deformation texture after hot rolling. As a result, CC Al alloys have relatively inferior formability than the corresponding DC hot-band Al alloys (intermediate product after hot rolling).^[43–47] As in,^[48–50] the microstructure and texture of the Al alloy hot band are determined by the rolling temperature, strain, strain rate, and composition. According to,^[51–55] the mechanical properties, anisotropy, and formability are closely linked to the microstructure and texture of Al alloys during thermomechanical processing. In the convectional DC casting, macro-segregation also shows some difficulties. To overcome these defects, external physical fields are applied to the DC casting processes. In particular, low-frequency electromagnetic fields,^[56] alternating^[57] and direct electromagnetic fields,^[58,59] electric current pulse,^[60,61] and ultrasonic fields^[62] are some examples that are relatively effective to decrease or eliminate defects in DC casting. According to,^[63] apart from the refinement of primary Al structure by controlling the heat removal rate from the casting or using different additives, the possibility to refine the microstructure by using external physical entities, such as an electromagnetic field, and by increasing the frequency of the current supplied to the induction coil has been reported. This research showed that the rotating electromagnetic field produced by the current supplied to an induction coil with a higher frequency than that of the power network guarantees the refinement of the structure of pure Al without any addition of inoculants, such as Ti and B. Additionally, the study refers to the benefits of such methods instead of the use of inoculants, which reduce the purity level, electrical conductivity of pure Al and at the same time prevent the development of cracks in the rolling step, thus determining higher functional properties to the Al ingot.

The mechanisms related to the development of the structures and properties of TRC alloys have been extensively studied over the years. According to these studies, the authors in^[62,64] have recognized the basic concepts that explain work hardening, recovery, and recrystallization in strip-cast 3xxx alloys. A comparison of property development for roll-cast and DC ingots is reported in Fig. 2: the DC-cast material reveals the classical behavior with a

Fig. 2 Annealing curves for 3xxx alloy produced by DC and TRC process^[65]

different recrystallization temperature, while as the recovery temperature increases, the TRC alloy progressively recovers with only low strength loss.

In,^[66] the theories of recrystallization in two-phase alloys have been described. Stress-free nucleation of new grains in the foil thickness takes place in alloys produced by the DC process due to the presence of a sufficient amount of coarse particles, while the coarse grains on the surface of the alloys manufactured using the TRC technique are generated due to the particularly high density of the fine particles close to the foil surface(s). Some of the metallurgical difficulties related to the grain dimensions encountered mainly using 3xxx foil alloys have been resolved by using 8xxx alloys (Al-Fe-Si) with a higher amount of Fe and Si than 1xxx alloys. Al alloys belonging to the 8xxx series (8011 and 8111) were developed in 1970 and 1979, respectively, and they are customarily used in high-volume foil production. The properties of these alloys are not as good as DC-cast 3003 alloys, but thanks to the particle and grain size strengthening their characteristics are significantly higher than those of 1xxx alloys.

DEVELOPMENT OF DISPERSOIDS AND SOME MORPHOLOGICAL FEATURES DURING HOMOGENIZATION

Usually, to increase fracture toughness and to prevent grain growth during recrystallization, transition metals (e.g., Mn, Cr, Ti, Sc) are introduced into the alloy composition. These elements are combined with Fe during heating to the homogenization temperature, and a special phase, called dispersoid, development occurs. The importance of said phases is high, since the alloys with transition metal content include the most common commercial alloys.

Generally, the type of dispersoids differs according to the composition, i.e., presence of alloying elements, annealing temperature, and annealing time, and their evolution has an important impact on the recrystallization behavior of Al alloys. Over time, these features have been widely investigated.^[67–71] In particular, during homogenization, the dimension of the dispersoids increases as the temperature

and holding time increase, having a significant effect on the behavior of the final product. Many studies have focused on the mechanism of the homogenization, but research on the volume fraction evolution of dispersoids during heat treatment in 3xxx alloy has been only occasionally considered.^[72–74] The influence of Mn and Si content on the precipitation behavior of dispersoids in Al 3xxx alloys during low-temperature annealing has been studied, and it reveals that as the quantities of Si and Mn increase, the precipitation of dispersoids increases.^[72–74] By choosing an appropriate annealing condition, an important dispersion hardening result can be attained in such alloys. During the solidification of 3xxx alloys, most of the Mn is in the solid solution, which, during heat treatment, decomposes by the precipitation of dispersoids. To solve this problem, on DC castings and before hot rolling, homogenization is performed to moderate the concentration of Mn in the solid solution and to achieve the correct dimension, density, and distribution of the particles. In this way, a positive effect on the recrystallization, texture, grain size, and mechanical properties of wrought Al alloys can be obtained.

According to,^[75] in pure Al–Mn binary alloys, the decomposition of the supersaturated solid solution is very slow, and by adding alloying elements, the precipitation behavior can be controlled. Fe and Si significantly reduce the solubility of Mn in solid solution and accelerate the precipitation rate. Adding Cu can also improve the decomposition of the supersaturated solid solution, while Fe helps the precipitation of $Al_6(Mn,Fe)$ and Si acts on the precipitation of cubic α -phase, $Al_{12}Mn_3Si$; additionally, with the simultaneous presence of Fe and Si, the development of $Al_{12}(Mn,Fe)_3Si$ takes place. The phase transformation in a DC-cast 3003 alloy during heat treatment has been investigated in.^[76] The authors found that during heating up to 300°C for a long period or to 350°C for 16 h, the development of a coherent or a semi-coherent metastable phase, respectively, occurs, while in the case of higher homogenization temperature, α - $Al_{12}Mn_3Si$ dispersoids precipitate directly, with an unclear mechanism.

Compared to the ingot metallurgy process, CC leads to rapid cooling from the melt, and its product has different microstructures and mechanical properties to the traditionally produced material.^[77] The cold-rolling process and the subsequent annealing treatment can modify the microstructure, crystallite orientation, mechanical property, and formability of thin sheet, and at the same time, they can enhance the level of centerline segregation of second-phase particles.^[34,77,78]

CONTINUOUS CASTING OF AL ALLOYS SHEET: SOME EXPERIMENTAL RESULTS

In this section, some results approaching an application-oriented research in the field of CC carried out by the authors are briefly presented. Further details on the

Table 1 Chemical composition (wt%) of the AA8006 alloy

Elements	Si	Fe	Cu	Mn	Mg	Ti	Al
wt%	0.17	1.60	0.01	0.45	0.002	0.02	Balance

research can be found in.^[57,79] The alloy investigated belongs to the AlFeMnSi system, and it can be employed for different applications, e.g., packaging, in microelectronics industries, or for the manufacturing of some cooling apparatus, where, as far as possible, homogeneous microstructure and good ductile properties are needed. Table 1 shows the chemical composition of the alloy used. The aims of this research were to refine the microstructure and to reduce the microstructural difference between the inner part of the alloy and its surface, which are essential characteristics of this alloy to be successfully used in packaging industries. The development of the microstructure was observed at cast state and after annealing at different temperatures.

The AA8006 alloy has been produced by CC process: the liquid metal was solidified and rolled through the cylinders of CC tools (COMITAL S.r.l., Volpiano, Torino, Italy) providing some rolling mills with thicknesses of about 6 and 7.2 mm, respectively. A scheduled thickness of the coils was reached applying various intermediate stages. A refinement of the microstructure was obtained by homogenization treatment for 6 h in a temperature range of 460°C–530°C, applied to reduce or remove the presence of micro-segregations and to obtain a homogeneous structure with fine and well-distributed particles. The reduction to 0.6 mm was obtained through an intermediate thickness of 3 mm followed by an inter-annealing treatment at 300°C and fine rolling. The process was completed with an annealing treatment ($T = 300^\circ\text{C}$ – 320°C). Thin Al coils with about 380 μm thickness were obtained. A nonhomogeneous microstructure, both on the surface and at the central part of the sample, developed in as-cast samples (thickness of 6 mm), as shown in Fig. 3; additionally, there is a deformed grain structure where the grain elongation follows the rolling direction. A relatively extended inner part is covered by iron-rich micro-segregations, as illustrated in Fig. 4. The intermetallic particles, chemically made by Al, Si, Fe, and Mn, show a particular structure with the development of bands. On the surface, the bands follow a fine configuration, while in the core of the sample, larger grains have been detected (Fig. 5).

The Al alloys coils with 6 and 7.2 mm thicknesses, respectively, obtained using two different roll supporting forces, as indicated in Fig. 6, have been homogenized at different temperatures.

Although annealing in the as-cast state produces very coarse surface grains for both situations, a reduction of the thickness of the area close to the edge of the sample and a decrease of grain size have been observed when minor force was applied. This fact can be associated to the dynamic recrystallization of the surface during casting;

Fig. 3 Optical microscopy image showing the microstructure of the samples analyzed

Fig. 4 Micro-segregation in the as-cast sample (core) with a Fe content: about 5 (wt%)

when the applied force is higher, the alloy appears more deformed and this phenomenon might involve material at a higher depth. Figure 7 shows a higher magnification of the microstructure of the samples annealed: these microstructures demonstrate more in detail that close to the edge (Fig. 7a), the fine intermetallic particles are homogeneously

dispersed in the Al alloy matrix, while in the central region (Fig. 7b), the elongated shape of the secondary particles and the areas corresponding to the eutectic phase are more extended compared to the former situation.

Taking into account the aspects illustrated earlier and also considering industrial suitability, the alloy obtained by CC with a roll supporting force associated to 250 t and homogenized for 6 h at different temperatures has been submitted to cold rolling until a thickness of 0.6 mm has been obtained. An intermediate annealing treatment (300°C–320°C) and a final rolling and annealing at 300°C–320°C complete the production process. The material prepared in this way has been analyzed, and the development of the grain structure has been monitored. The effect of the temperature change on the microstructural evolution is evident as illustrated in Fig. 8, where the structural characteristics at the core and at the surface of the AA8006 samples are appreciably different, highlighting the gradual coarsening of the cast structure toward the core as temperature increases. The finest morphology has been reached at 500°C (Fig. 8a). As the temperature further rises up to 530°C, the grain size grows as a sign of unreasonably high annealing temperature. This can be considered as an indication of an excessively high annealing temperature. At 500°C, the total volume fraction of

Fig. 6 Evolution of the grain evolution of the sheets annealed at different temperatures 460°C (a, e), 470°C (b, f), 480°C (c, g), and 490°C (d, h) force 400 t (top) and 250 t (bottom)

Fig. 7 SEM image showing the evolution of the grain structures of the Al sheets annealed at 500°C: (a) near to the edge of the sample and (b) in the middle part of the sample

the intermetallic particles has decreased and a relatively homogeneous microstructure has been obtained. Figure 9 shows the rate of the intermetallic particles that cover a defined surface area: a higher number of small particles have been observed in the core of the sample (about

Fig. 8 Evolution of the grain structures of the sheets annealed at 500°C (a), 510°C (b), 520°C (c), and 530°C (d)

7.66% of the total area is covered) compared to the border part of the sample (about 4.66% of the area appears covered). The microstructure related to such areas is included in Fig. 9.

Homogenization at 500°C obtains the highest ductility (Fig. 10), which is an important characteristic at technological level; as the annealing temperature increases over 500°C, the ductility decreases.

CONCLUSIONS

The aim of this article was twofold. The first section was dedicated to presenting a short history and to illustrating some of the aspects related to the state of the art of CC and rolling of Al and its alloys for the production of Al alloy sheets/foils. The article has illustrated some significant features that are appropriate to such a widespread topic. Second, the experimental results obtained by the authors over time and illustrated here were intended to partially support the theoretical approach by providing a real case study.

In this article, the metallurgical benefits and faults of CC technology were highlighted. It also focuses on how CC and generally production technologies have to be managed in order to achieve high-quality products for the fast-growing industrial market.

ACKNOWLEDGMENTS

The authors wish to thank Ing. A. Zago for some experimental analysis and COMITAL S.r.l., Volpiano, Torino, Italy for providing the samples and for their collaboration during the study.

Tube Bending Forming Technologies: Advances and Trends

Heng Li, He Yang, and Jun Ma

*School of Materials Science and Engineering, Northwestern Polytechnical University,
127 West Youyi Road, Xi'an, Shaanxi, 710072, China*

Abstract

Bent tube parts have been widely used, as one kind of key components with enormous quantities and diversities, to satisfy the increasing demands for lightweight and high-performance products in broad industries such as aerospace, marine, automobile, energy, and health care. Tube bending is one of the key technologies used for manufacturing these lightweight products. The recent advances in tube bending are critically reviewed from four fundamental issues in tube bending, viz. characterization of tubular materials, prediction of multiple defects, bending formability, and innovative optimization design. Advantages and limitations of some recently developed innovative bending approaches are reviewed. Finally, considering the urgent requirements of more lightweight and high-performance bent tubes with hard-to-deform materials with complex structures, the development trends and corresponding challenges are thereafter presented for realizing the precision and high-efficiency tube bending.

Keywords: Accuracy; Bending limits; Flattening; Springback; Tube bending; Wall thinning; Wrinkling.

INTRODUCTION

Since they satisfy the current needs for products with lightweight and high performance in the aspect of both material and structure, metallic bent tubular parts, as one kind of key lightweight component for “bleeding” transforming and structure loading bearing with enormous quantities and diversities, have attracted increasing applications in broad industries such as aerospace, marine, automobile, energy, and health care. Tube bending, an important branch of the tubular plastic forming field, has been a vital technology for manufacturing bent tubular products with certain bending radius and bending angle.^[1–3]

Many tube-bending methods have been developed in response to the diverse demands of tube geometrical specification, cross-sectional shapes, material properties, forming limits, forming tolerance, and application scenarios. These tube-bending technologies can be classified into various branches by different criteria. According to the forming temperatures, there are cold bending at room temperature, and warm and hot bending with elevated temperatures. From the viewpoint of loading conditions, bending methods can be divided into pure bending, press bending, stretch bending, push bending, roll bending, rotary draw bending (RDB), and laser bending, etc. From a material point of view, there are steel tube bending, aluminum alloy tube bending, copper alloy tube bending, magnesium alloy tube bending, and titanium alloy tube bending, etc. Based on tubular cross-sectional shapes, bending types can be

classified into round tube bending, rectangular tube bending, and other irregular section tube bending. Through the history of tube fabrication, they are welded tube or rolled tube bending, drawn tube bending, and extruded tube bending. From the viewpoint of bending difficulty, bending can be divided into easy bending with large bending radius and tough bending with small bending radius.

No matter what type of bending process is used, complex nonuniform tension and compression deformation states are induced simultaneously at the extrados and intrados of bent tube, which are the root causes of multiple defects such as wrinkling, over-thinning (cracking), cross-section flattening (distorting), and springback. These defects directly determine the forming limits and quality of the bent tubes. By using analytical, experimental, and numerical methods with regard to different bending processes, great efforts have been made to investigate the characterization of tubular materials, mechanisms of these physical phenomena, prediction of the multiple defects, excavation of bending limits, improvement of bending accuracy as well as optimization design of the tooling and processing parameters to promote the development of tube-bending science and technology. Thus, it is of great significance to get hold of the state of the art in tube bending for further advancing the bending technologies.

Up to now, there are several reports addressing the developments in tube bending.^[1–4] However, most of them focus partially on the abovementioned issues of tube bending, or the cited references were results of previous years. It is noted that tube bending is a rapidly developing field.

In recent years, along with further requirements for higher bending quality and forming limits, tougher bending needs to be characterized with hard-to-deform tubular materials and difficult-to-form geometrical structures, which brings out new challenges for achieving precise and efficient bending deformation. This article attempts to provide a critical review of the most recent advances in tube bending in the aspect of four fundamental issues, i.e., characterization of tubular materials, prediction of multiple defects, bending formability, and innovative optimization design. Then, some currently developed innovative bending approaches are reviewed regarding their advantages and limitations. Finally, considering the current demands of bending forming with more precision and higher efficiency, the development trends and corresponding challenges are discussed. The author wishes to apologize in advance for any inadvertent omission of relevant publications.

CHARACTERIZATION OF TUBULAR MATERIALS FOR TUBE BENDING

Different from sheet materials, tubular materials have a history of more complex thermal-mechanical processing, such as rolling, drawing, extrusion, and annealing. The processing history may induce complex evolution of microstructures of tubular materials, including grain size/shape and crystallographic orientations. These microstructural features undoubtedly make the tube exhibit unique plastic response upon bending. The efficiency and precision of tube bending depend on the knowledge about

mechanical properties of the tubular materials. Especially, finite element method (FEM) has been the most promising tool to develop advanced forming technologies.^[4] Accurate finite element (FE) modeling and simulation heavily rely on input mechanical parameters such as constitutive models and tribological models. Thus, how to obtain and characterize the mechanical properties of tubular materials is the foremost issue that urgently needs to be solved. Relatively, the advances in characterization of tube materials lay behind those in the case of sheet materials. In this section, the most recently proposed characterization methods for tubular materials are briefly summarized.

Tension-Dominated Testing

Generally, knowledge about most of the tube properties is obtained from the conventional uniaxial tension tests used for sheet metals. As shown in Fig. 1, for tubes with large or small diameter, uniaxial tension tests of both arc-curved and full-size tubular specimens can be adopted. The curved clamp die is designed to ensure a stable deformation along uniaxial tension of the arc specimens. Both longitudinal and vertical strains can be simultaneously measured by longitudinal and vertical extensometers. Thus, the stress-strain curves as well as variations of the Lankford coefficient R can be obtained to calibrate the material models. Recently, instead of the contact mechanical extensometer, the digital speckle correlation method-based tension is used to characterize the diffuse necking limit hardening and the variation of the Lankford coefficient along larger strain as shown in Fig. 2.^[5] Besides the rolling (axial) direction, the

Fig. 1 Specimen design of high-strength stainless steel tube (HSST) for uniaxial tensile test: (a) clamp die for curved specimen and (b) tubular specimen

Fig. 2 True stress–strain curves and the Lankford coefficient R along tension deformation

ring hoop tension test (RHTT),^[6,7] is proposed to establish the plastic flow of tube along hoop direction, the flow rule and the evolution of R -value along the hoop direction are proved to be different from those along the axial (rolling) direction of tube.^[8] The drawbacks of the RHTT are that the friction effect cannot be avoided, and the properties cannot be calculated directly.

Besides the abovementioned methods, several complex approaches are proposed to probe more information about tensile-dominated properties of tubes under complicated loading paths. These different loading paths introduce spatial stress and stress states, which is similar to the deformation modes in tube bending. The tension tests combined with torsion or internal pressure have been used to establish the yield locus and hardening behavior of

thin-walled tubes under biaxial tension stress states.^[9–12] However, the abovementioned methods require perfectly designed equipment, which is relatively complex to be conducted. More simply, as shown in Fig. 3, the tension tests with notched arc and tubular specimens are adopted for exhibiting the biaxial tensile stress states in outside of bent tubes.^[13] On this basis, a hybrid inverse method for determining the flow stress in outside of bend tubes is proposed based on physical simulation, orthogonal numerical simulation, regression analysis, and genetic algorithm.^[14] Thus, a more accurate modeling of the tube-bending processes can be achieved. Recently, ring plane-strain tension test (RPST) is used to obtain the plastic response under different combinations of tension and shear loading paths, which can be controlled by

Fig. 3 Uniaxial tensile testing of the notched arc specimen: (a) FE model and (b) stresses state of the notched arc specimen with different hole diameters

designing different inclination degrees.^[8] With the aid of finite element analysis (FEA) of the RPST specimens, the plastic work contour is plotted in the axial-hoop plane-stress space at constant levels of shear stress.

Compression-Dominated Testing

It has been recognized recently that the compressive stress state-based material parameters should be calibrated to accurately analyze the tension-compression nonuniform deformation for tube bending. As shown in Fig. 4, several experimental methods have been designed to capture the deformation behaviors of tube under compressive loadings by compressing the samples with different shapes, including small brick samples and ring samples.^[14] Azhikannickal et al.^[15] adopted uniaxial compression of small brick sample and ring sample in determination of compressive mechanical properties of the oriented polypropylene tube. Zeng et al.^[16] studied the deformation behaviors of commercially pure titanium thick-walled tube during uniaxial hot compression of brick sample. However, for the uniaxial compression of brick samples and ring samples, there are several limitations: (1) both methods are only suitable for thick-walled tubes since the buckling easily occurs for thin-walled tubes, (2) the small brick sample is much difficult to be cut from the as-received tubes with small thickness or diameter, and (3) the friction effects on barreling cannot be avoided to significantly lower the prediction accuracy. In contrast, the lateral compression test of ring samples has the following advantages for identification of tube material parameters: (1) the friction has little influence on the force–displacement data,^[17] and (2) a large deformation degree can be obtained, so that enough experimental data can be provided for the FE simulation and inverse identification. Recently, Liu et al.^[14] identified the Swift hardening law of 6061-T4 and 1Cr18Ni9Ti thin-walled tubes by using a hybrid inverse identification method that is proposed based on tube lateral compression test with a combination of FE simulation, regression analysis, and genetic algorithm.

Fig. 4 Compression samples for identification of tubular/sheet material parameters

In addition to the abovementioned tension/compression-dominated testing methods, several advanced approaches have been developed to characterize the complex anisotropic/asymmetric deformation behaviors and Bauschinger effect of tubular materials by aid of experiments, crystal plasticity modelling and FEM. Based on a Knoop indentation-based characterization method, uniaxial tension/compression experiments as well as crystal plasticity modelling, Li et al.^[18,19] proposed a hybrid methodology to investigate the anisotropic and asymmetrical plasticity and physical mechanisms of tubular materials. Taking the hexagonal-close-pack (HCP) structured titanium alloy tube as the case, the full-field tension/compression properties can be accurately characterized, and then several advanced constitutive models were used in RDB for improved prediction accuracy.^[19] To explore the Bauschinger effect of tubular materials, Ma et al.^[20] designed a small-gauge sample for cyclic tension-compression test by aid of digital image correlation (DIC)-based strain measurement.

PREDICTION OF MULTIPLE DEFECTS IN TUBE BENDING

Subjected to nonuniform tension-compression stress states, there are inevitable deformation phenomena that include wall thinning at the extrados and wall thickening at the intrados along with cross-section flattening during tube bending. To some critical extent, the compressive instability of wrinkling may occur in the inner wall of bent tube, the tensile instability of over-thinning and cracking may happen in the outer side of bending tube, or the cross-section distortion and springback may also happen. The accurate prediction of these multiple defects is crucial for exploring the occurring mechanisms and efficiently controlling the forming quality. In this section, the most recent advances in prediction of wrinkling, ductile fracture, and springback are summarized.

Prediction of Wrinkling Instabilities

Accurate prediction of wrinkling in thin-walled parts forming processes is still a challenge for industries and academies because the initiation of wrinkles is affected by a combination of many factors such as stress states, mechanical properties of the material, geometry of the workpiece, and especially contact conditions. It is especially true for wrinkling prediction of tube bending which is constrained by multiple tools.^[2]

The prediction methods for the onset of wrinkling and its propagation can be generally divided into two categories: analytical approach and numerical simulation. The analytical approach refers to the static equilibrium method,^[21–24] the energy method, or the initial geometric imperfection method.^[25,26] There are three types of

numerical procedures that can be used to solve bifurcation problems: eigenvalue buckling analysis, static-implicit FEM, and dynamic-explicit FEM.

It is known that when the compressive load is uniformly or linearly distributed, the analytical approaches such as the static equilibrium method and the energy method can calculate the critical conditions of instability and estimate the explicit expression of deflection function. The eigenvalue buckling analysis cannot solve plastic deformation behavior, but it can estimate the intrinsic buckling modes of the structure. The implicit FEM is not suitable to the wrinkling prediction under complex boundary conditions (CBC) because the complicated contact conditions always result in convergence problems. Due to no iteration requirements of nonlinear systems and no convergence control, the explicit FEM is more efficient for complicated forming processes with CBC. However, it cannot detect the bifurcation point and buckling modes of the structure. In early years, the analytical methods are used to solve the wrinkling problems of pure bending.^[27–30] Later, the numerical methods are adopted to simulate the occurrence and growth of wrinkles in tube-bending process.^[31] However, solely using analytical

solution, implicit or explicit FEM, this problem cannot be well solved. A detailed comparison between different methods can be found in Table 1.

A hybrid method that combines the analytical and numerical approaches is promising for accurately predicting the wrinkling instability during tube bending.^[32] To predict wrinkling that occurs in a thin-walled tube RDB process, Li et al.^[33] proposed an analytical energy-based model combined with explicit algorithm of FE, in which a segment shell model, as shown in Fig. 5, was established to capture the critical wrinkling region of bent tube. The explicit FE model was used to provide instantaneous stress and strain fields for the minimum energy model. However, the abovementioned hybrid model is essentially an uncoupled one of the analytical and explicit FE models. The assumptions made in energy model, such as inerratic compressive stress filed, cause the prediction model to show some discrepancy compared with the actual forming. Limam et al.^[34] assigned initial geometric imperfections with the wavelength of the wrinkling bifurcation mode in FE shell model, and the evolution of wrinkling and its eventual localization are simulated successfully.

Table 1 Assessment of research methods in terms of their advantages and limitations

Methods	Items	Advantages	Limitations
Analytical method	Static equilibrium method	A global view.	Cannot solve problem with complicated contact nonlinearities. Large simplifications and assumption are made in material model, geometry, and boundary conditions.
	Energy method Modified energy method	Only considers the beginning and the end of deformation A global view.	
Implicit FEM	The bifurcation analysis of a perfect structure The non-bifurcation analysis with initial imperfection	Determinant of the stiffness matrix at each iteration of the increment. Accurate buckling predictions.	Cannot solve problem with complicated contact nonlinearities. Hampered by convergence problem. Selection of magnitude and distribution of imperfections.
Eigenvalue analysis	Eigenvalue buckling analysis	Linear perturbation. Extract the eigenvalue and eigenvectors.	Only applied to elastic problem.
Explicit FEM	Quasi-static	Avoids decomposing the stiffness matrix of a system. Absence of convergence problems. Solves problem with complicated contact nonlinearities.	Cannot solve the buckling modes. Omit the bifurcation (branching) point. Sensitive to mesh density, simulation speed, element type and time, and mass scaling factor.

Fig. 5 Segment shell model for wrinkling prediction in NC tube-bending process

Recently, by introducing geometrical imperfection into the idealized mesh, a coupled model, i.e., a numerical simulation method combined with the analytical approach, is proposed to accurately predict wrinkling instability in tube bending.^[35] Considering the distribution of compressive stress in the tube-bending process, as shown in Fig. 6, two simplified models, i.e., tube under pure bending and tube under axial compression, are employed to obtain the bifurcation modes of a tube in RDB. By using the eigenvalue buckling analysis and the Timoshenko energy method, two kinds of imperfections (axisymmetric and non-axisymmetric) are generated based on the above simplified compressive instability models, respectively. And then, a series of geometrical imperfections are defined on the basis of the deflection function and the eigenvalue buckling modes. After that, these micro imperfections are scaled and embedded to the tube to perturb the nodal

coordinates of the 3D elastic-plastic explicit FE model. By considering the appropriate imperfection, the predictor is more sensitive to the compression instability compared with the results based on perfect geometry. Thus, the proposed method is able to accurately predict the onset moment, actual shape, and size of wrinkles in RDB.

Prediction of Ductile Fracture

Under in-plane biaxial tensile stress states at the extrados of bending tube, the over-thinning-induced ductile fracture is one of the major defects in RDB. As there is a possibility of over-thinning, necking, and further crack in formation processes of thin-walled aluminum alloy tube, high-strength steel tube, and titanium alloy tube, the ductile fracture becomes a major problem that affects the bending limits and precision due to limited elongation of

Fig. 6 Analytical model of tube under compressive stress: (a) eigenvalue buckling analysis of a tube under pure bending and (b) a thin cylindrical shell under axial compression

such materials compared with the good-ductility materials such as stainless steel. However, similar to wrinkling, prediction of damage evolution and ductile fracture is also still a challenging issue due to its complex micro-/mesoscale mechanisms.^[36]

Compared with other models or indicators such as elongation ratio, plastic instability theory, critical wall thinning, and forming limit diagram (FLD), the ductile fracture criterion (DFC) can consider nonlinear stress and strain loading histories in plastic deformation. Several attempts have been made to use the DFCs for predicting the damage evolution in tube bending. Gholipour et al.^[37] used the Gurson-based damage model to predict the deformation behaviors of tube bending and subsequent hydroforming, while they could not predict the burst pressure using the Mises model. By coupling two DFCs, i.e., continuum damage mechanics (CDM)-based model and Gurson–Tvergaard–Needleman porous model, into FE simulation, Li et al.^[38] predicted the critical wall-thinning of 5052O Al-alloy tube bending. Through the uniaxial tensile test of the curved specimen, the damage parameters of both the two fracture criteria Al-alloy tube are iteratively determined. Thus, as shown in Fig. 7,^[36,38] the virtual damage initiation and evolution (when and where the ductile fracture occurs) in bending of Al-alloy tube are investigated, and the application study of the above DFCs in the thin-walled tube bending is performed. Recently, to accurately predict the uneven deformation-induced fracture of HSST bending, by replacing the Mises effective stress with the extended Hill anisotropic one, the coupling framework of DFCs with anisotropic plasticity is established. As shown in Fig. 8,^[5] considering the interplay between inhomogeneous deformation and damage evolution, the coupling model with the improved anisotropic plasticity provides the most accurate prediction of overall performance in all cases.

BENDING FORMABILITY OF TUBULAR MATERIALS

Common Bending Behaviors

By using experiments, analytical methods, and numerical simulation, the bending behaviors of tubes under different forming conditions are extensively investigated with regard to wall thickness changes and cross-section flattening. These studies provide transferable knowledge about innovative design of the bending process and tooling for improving bending quality and forming limits.

The bending formability of a thin-walled tube in changing sizes, D and t , is clarified via both the analytical and FE simulations.^[39,40] It was found that anti-wrinkling capability of the tube decreases with a larger D and a smaller t , and the effect of t is greater than that of D even under rigid supports. The wall thinning increases with a larger D and a smaller t , and this tendency becomes much more obvious under rigid supports. Based on the analytical model, it can be found that the cross-section deformation increases with a larger D and a smaller t , while this tendency becomes opposite due to the nonlinear role of mandrel die. The tube diameter is the most important parameter with respect to the degree of tube flattening.^[41]

Regarding the 1Cr18Ni9Ti stainless steel and 5052O aluminum alloy tubes with size factors D/t of 38 and 50, respectively, the effects of various forming parameters on wall thinning, cross-section flattening, and wrinkling risk were addressed, including the number of mandrel balls, mandrel extension length, bending angle, lubrication between tube and tools, pushing assistant velocity of pressure die, bending radius, and material properties.^[42–44] It was found that the hoop strain of the aluminum alloy tube under small bending radii cannot be neglected, and the over-thinning and flattening of the aluminum alloy tube were prone to occur compared with the stainless steel tube. The multiform and asymmetric local distribution features

of wrinkling were revealed in RDB, and it was found that the friction and clearance between tube and tools as well as the mandrel parameters are the key factors influencing the wrinkling onset.

Forming Limits of Tube Bending

Knowledge about the bending limit, i.e., the maximum deformation a tube can experience without bending failures, is a crucial aspect in the exploration of the forming potential and the optimal design for precision tube bending.^[45] However, the bending-induced nonuniform tension-compression deformation may result in multiple inelastic instabilities such as wrinkling, over-thinning (cracking), and cross-section distortion. Wrinkling not only reduces the strength, stiffness, and fatigue life of tube, but it also determines forming limit and bending quality and even leads to tooling wear and damage as well as interruption of process. The degree of wall thinning directly affects the pressure resistance of bent tube, while section flattening influences flow resistance within the transmission medium and thus reduces the reliability of tubular components. The diverse occurring mechanisms of these defects cause coupling or even conflicting effects of various forming parameters on tube-bending limits. A method for reducing one type of instabilities may probably cause another one to be much more severe.^[46,47] The coexistence of multiple defects and their interactions makes determination and improvement of tube-bending limit a challenge.

The bending limits of tubular materials were extensively investigated under different bending operations. The bending limits of both aluminum square and circle tubes in RDB were studied.^[48,49] The suppression effects of the rigid arcwise mandrel on wrinkling and section distortion were analyzed, and also the influence of forming parameters (clamping force, pressure die force, pushing assistant force, and bending speed) on the wall thickness change and section flattening was addressed. Zeng and Li^[50] studied the influences of internal pressure and friction on the pushing bending, and experimentally achieved difficult push bending of an Al-alloy tube with R_d equaling to D by using reasonable internal pressure and lubricant conditions. Goodarzi et al.^[51] experimentally proved that shear bending can produce Al-alloy bent tubes with a small R_d via combining shear and bending modes. By using the minimum energy principle and the deformation theory, Wang and Cao^[29] analytically calculated the wrinkling limit in tube bending, viz. minimum R_d without wrinkling, which is presented as a function of geometric parameters and material properties. Based on several experiments, the wall thickness distribution was analyzed, and the minimum relative bending radius limited by wall thinning was obtained.^[52] Li et al.^[53] proposed the “stepped mandrel retraction” method to avoid wrinkling in Al-alloy tube bending with small bending radii. By introducing a new wrinkling wave function, Yang and Lin^[54] analytically

obtained the effects of material properties on wrinkling limit. Lee et al.^[55] studied the bending limit of a square Al-alloy tube in rubber pad bending via experiments and FE simulation. Regarding a nondimensional shape degradation factor, Lee et al.^[56] numerically obtained a hoop-buckle limit of oval tube bending. With respect to thinning, Khodayari^[57] experimentally and analytically established the bending limit curve (BLC) of tube in RDB for various steel tubes and verified that the BLC provided more accurate prediction of thinning limit than the standard forming limit diagram (FLD). Yang et al.^[58] found that the larger friction at tube-pressure die and tube-clamp die improves bending quality, while the larger friction at tube-wiper die and tube-mandrel die reduces bending limit. For mandrel-free RDB (without internal supports) of small-diameter tubes, the relationship between tube geometrical variables was correlated with cross-ovalization by Mentella and Strano.^[59] Okude et al.^[60] showed that the usage of a wiper die and axial tension can improve the wrinkling limit of a square section tube in RDB. By applying the internal pressure as the “fluid mandrel,” hydro-bending of bi-layered tubes with a diameter-to-thickness ratio of 63 and a relative bending radius of 2.2 was successfully performed.^[61]

These studies provide beneficial understanding of bending limits of various types of tubes. The bending limit of a tube is still mainly established by the single defect based on empirical and analytical methods. However, for tough bending with difficult-to-deform tubular materials with extreme geometrical specifications, a tube may undergo larger/unequal strain conditions and thus encounter higher risks of multiple defects co-occurring.^[62] This sharpens the difficulty in determining and improving bending limits of tubes. Taking the most universal bending of RDB into consideration, a comprehensive map of tube-bending limits considering a wide range of tube sizes and material types is proposed.^[43,45,47,63] For each instability, the intrinsic factors (tube geometrical parameters, D and t , and mechanical properties, m) dependent bending limits are clarified, and evident interactive or even conflicting effects are observed. Under mandrel bending, the significant effects of intrinsic factors on wrinkling limit are reduced, and the neglected effects of D/t on thinning limit are magnified; the significant influences of D/t on flattening limit even become contrary, and the effects on wrinkling and thinning limit are opposite to that on the flattening limit. Taking D/t as the basic design parameter, a conceptual multiple defect-constrained bending limit diagram (BLD) is constructed as shown in Fig. 9, and a knowledge-based stepwise method for determining and improving tube-bending limits is proposed, considering coupling effects of multiple forming parameters, e.g., intrinsic factors, tooling/processing parameters, and uncertainties. The method is experimentally verified by several practical bending scenarios for different kinds of tubular materials with extreme sizes. Figure 10 shows the obtained bending products of a large-diameter thin-walled

Fig. 9 Conceptual multiple defect-constrained BLD vs. basic design parameter D/t

Fig. 10 Wrinkling-constrained bending limit of LDTW Al-alloy tube 150×1.5 mm

(LDTW) 6061-O Al-alloy tube with the specification of $150 \times 1.5 \times 1.75D$ mm. For this thin-walled larger-diameter Al-alloy tube, the bending limit is restrained mainly by wrinkling, and the bending limit is $(1.75D, 180^\circ)$.

Forming Accuracy of Tube Bending

It is known that the accuracy of tube bending is directly dependent on the efficient controlling of springback after unloading. The springback affects both the geometrical and shape precision, which directly determines the connection and sealing performance of tubes with other parts as well as the internal structure compact. By using the previously mentioned analytical methods and numerical methods combined with the experiments, the nonlinear springback rules in tube bending are addressed for realizing precise and efficient control of tube bending accuracy. Generally, there are two ways for controlling the springback of tube bending, viz. reducing the springback and compensating for the springback.

Lou and Stelson^[69] developed the bend–rebind control to obtain the springback data and compensate for it online, and a process control method was developed to optimize the overall control strategy. By establishing a reliable FE model of the whole process of thin-walled tube RDB, retracting mandrel and springback, Gu^[64] studied the effects of geometrical, material, and process parameters on the springback of thin-walled tube in RDB. It is discovered that the springback of aluminum alloy tube decreases with the increase of retracting mandrel times. It can be used to decrease the springback to apply axial tensile or pressure force on the back end of the tube during bending tube and to apply axial tensile force on the back end of the tube after retracting mandrel. Li et al.^[65] studied the effects of forming parameters on the springback behaviors in 6061-T4 Al-alloy tube bending. It is found that the springback becomes larger with increase in bending velocity, tube-die clearance, relative bending radius, tube-pressure die friction, and relative push assistant speed. On the contrary, the springback decreases with increase in mandrel extension length, number of mandrel balls, and tube-mandrel friction.

Recently, some special springback behaviors during bending of difficult-to-form tubular materials have been paid attention. By the experiments of RDB, Daxin and Liu^[66] found that the time-dependent springback of 1Cr18Ni9Ti stainless steel tubes takes up a significant portion of the total springback. Jiang et al.^[67] numerically studied the coupling effects of material properties such as Young's modulus, yield stress, strain hardening exponent, and normal anisotropic coefficient on the springback angle regarding annealed Ti-3Al-2.5V tube bending. For high-strength Ti-alloy tube (HSTT, stress-relieved Ti-3Al-2.5V), Li et al.^[68] discovered that the springback of the HSTT

Fig. 11 Mechanical models of the springback of tube bending: (a) bending portion and (b) straight portion

should be characterized by significant angular springback, radius growth, and sectional springback. As shown in Fig. 11, it is revealed that angular springback is attributed to the elastic release of both the curved bending region and the two straight transitional ends of tube, while radius growth is only related to bending portion and independent of bending angles. As shown in Fig. 12, at early bending stages, angular springback increases nonlinearly with larger bending angles, and then it increases linearly when bending angle exceeds a critical one. While radius growth decreases exponentially with increase in bending angles at early stages, it remains unchanged when bending angle exceeds another critical value. The springback behaves more nonlinearly under smaller bending radii. The relationship between radius and angular springbacks is quantitatively identified and clarified. The variation of material properties affects both the springback phenomena much more significantly than the change of processing parameters. Based on the

knowledge of remarkable elastic recovery, a two-level springback compensating methodology is proposed to consider both angular and radius springbacks for achieving precision bending deformation of the HSTT.

Prediction of Springback

The elastic release, viz. springback, is another inevitable phenomenon in tube bending when the multiple bending tools are removed due to internal residual stress and elastic deformation, which results in decreased bending angle, increased bending radius and cross-section variation. The springback directly affects the forming accuracy of tube bending. Similar to the abovementioned two plastic instabilities, because of the complication of mechanisms and coupling effects of multiple factors, the prediction of springback is still a challenge in tube bending.^[2]

Fig. 12 Angular and radius springbacks of HSTT under different bending radii and angles

The experiment-based springback prediction is always a reliable way to realize the accurate prediction of springback in tube bending, though the obtained springback data were only suitable for the tube bending with the same forming conditions.^[39] Lou and Stelson^[69] experimentally found that springback angle had a linear relationship with bending angle when the bending angle was larger, and bend–rebend control was used to obtain the springback data and compensate for it online.

Analytical method is another useful way to obtain the springback data of tube bending. Though many factors are difficult to be considered such as nonlinear material properties, contact conditions, and uneven 3D stress/strain distributions, the analytical model could directly provide insight into the physical mechanisms of the elastic recovery phenomenon. Considering the classic beam bending theory, the analytical formulae were derived for predicting springback behavior and residual stress distributions in tube-bending with the assumption of elastic/perfectly plastic behaviors, plane strain condition, and symmetrical cross section.^[70,71] Tang^[72] employed the deformation theory of plasticity to calculate stress distributions and bending moment for springback calculation. Based on the stress formulae,^[72] the cross-section distortion and the wall thickness change of tubes under axial force and internal pressure were developed.^[73] Megharbel et al.^[74] introduced an elastic-plastic analytical model for predicting the moment, springback, and residual stress distribution for forming the tube to a specific radius of curvature. Recently, Daxin and Chen^[75] and Daxin et al.^[76] derived the formulae to calculate the springback angles of tubes subjected to combined bending and additional tension according to the characteristics of tube under RDB. Li et al.^[77] used the deformation theory to develop an analytical prediction model for both angular and radius springbacks of tube bending. Though the multi-tool constraints and corresponding tensile/compressive stress induced by the pressure die and clamp die cannot be considered, the above analytical formulae can provide direct understanding of springback. In the abovementioned analytical methods, the calculation of neutral layer shifting (NLS) in tube-bending is the fundamental issue. Via analyzing the equilibrium conditions of moment and force during tube-bending, an axial force equilibrium (AFE)-based hybrid analytical-numerical framework for NLS calculation is established and numerically implemented, in which the anisotropy/asymmetry behaviors, and the geometry parameters can be comprehensively considered.^[78]

To improve the prediction accuracy of springback, combined with the experimental and analytical methods, the FE numerical simulation is used as a primary tool. Via a numerical-analytical method, Zhan et al.^[79] predicted the springback angle of thin-walled tube bending, while the stress/strain states of bent tube were obtained from the rigid-plastic FE simulation. Via the explicit/implicit-based

FE simulation of overall process such as bending, mandrel retracting, and unloading,^[80] it was found that the total springback angle considering mandrel retracting was much smaller than that not considering mandrel retracting with a maximum difference between them being 107.34%. Based on the isotropic-hardening model, mixed-hardening model, and Yoshida–Uemori two-surface model, the accuracy of springback prediction, such as section sag after springback, springback radius, and springback angles, was studied for RDB of thin-walled rectangular H96 tube to achieve a high precision of springback prediction.^[81] Xue et al.^[82] developed an FE numerical model to accurately predict the twist springback evaluation of asymmetric thin-walled bent tube, in which the surface-based coupling HINGE constraint and YLD2000–2d anisotropic constitutive models as well as identified interfacial friction coefficients were employed.

INNOVATIVE OPTIMIZATION DESIGN OF PROCESS/TOOLING

Based on the above fundamental understanding and knowledge of tube-bending deformation, many inspiring innovative optimization designs of process and tooling have been implemented for achieving more precise and more efficient bending forming of tubular materials urgently needed in broad industries.

Optimization Design of Tube Bending

Due to the complexity of tube bending with multiple defects and factors, from the mathematical viewpoint, the process/tooling optimization is a multi-object problem with multiple constraints. In most practice, the empirical data or operator-based “trial and error” is still the major approach to obtain feasible bending parameters. This method may be applicable for the relative easy bending processes with small diameter, thick wall, large bending radius as well as loose tolerance of forming quality. For precise and efficient process with small bending radius and difficult-to-deform tubular materials, the above method is not feasible anymore. However, the empirical data can provide rules for initial value determination in optimization process.

By using the object-oriented programming techniques and the goal-driven search mechanism, Jin et al.^[83] developed a knowledge-based system (KBS) to aid the design of tube bending including bending methods selection, tool/die design, and process parameter setup. Though the knowledge is the empirical data, the system showed effectiveness in tube-bending production with a significantly reduced number of potential defects and failures. Via experimental data and empirical formulae as well as fuzzy logic, Strano^[84] proposed a computer-based tooling and process design system, i.e., Tube ProDes for RDB. First, numerical calculations were performed to compensate for

springback, and then by evaluating the severity of the bend (i.e., the risk of the occurrence of defects) and assessing the sensitivity of the process with variations of the materials properties, the tooling setup was designed by fuzzy logic according to the material properties, the geometrical data of the bend, and the variables previously calculated as input. While the processing parameters were not considered, neither of the selection results was totally dependent on a great quality of experimental data or empirical formulae about steel tube. Thus, the design reliability is low with undesirable effectiveness and applicability. Based on generic CAD models driven by heuristic and algorithmic knowledge, Johansson^[85] developed an automated tooling design approach and manufacturability analyses for RDB to shorten the lead time and improve the product performance. The knowledge is collected and stored in central systems, thus allowing full control over the design of production. Whether the design is feasible can only be confirmed after the tooling try. Recently, Li et al.^[86] proposed an integrated methodology for robust and loop tooling design for tube-bending by combining several technologies such as knowledge-based engineering, parametric CAD modeling, and parametric FE modeling. For these systems, the optimal data are urgently needed.

Kim et al.^[87] conducted FE simulation to optimize the boost condition and axial feeding for stable tube bending. Mentella^[88] estimated the correlation between the booster and the pressure die velocity curves by considering main geometrical parameters and the strain distribution in RDB. By using an FE-based “trial and error” method, Ankur^[89] optimized process parameters to avoid defects in tube bending. By using the backtracking method, Liu et al.^[90] obtained optimal post-stretching elongation in stretch bending of aluminum hollow profile, and the forming index is comprehensively evaluated based on normalizing and weighting four forming defects. By coupling Taguchi’s orthogonal array with FE simulation, Nguyen et al.^[91] tried to improve the formability of tube bending for a copper material.

It is recognized that a single method cannot be used to sufficiently solve complex optimization problems, and “good-enough” results should be achieved by combining hybrid methods such as numerical optimization methods, artificial intelligence (AI) technology, FE simulation, and design of experiment (DOE).^[92–95] Considering maximum stress and strain distributions, Beauchesne^[96] optimized the friction coefficients and pressure die forward motion coefficient in RDB based on 3D-FE simulation, DOE, and Kriging method. Based on the grey relational analysis method combined with the orthogonal experimental design and FE simulation, taking wall thinning and flattening as objectives, 3D-FE and response surface method (RSM) are combined to optimize RDB with design variable D/t and R_b (R_b -bending radius).^[97] Guan et al.^[98] performed the process optimization of laser bending process by integrating the FE simulation with the genetic algorithm. Xiao et al.^[99] established a grey relational analysis model to obtain the optimal clearances and friction

coefficients between tube and various dies for the RDB of double-ridged rectangular H96 brass tube. Taking into account the distribution of initial tube wall thickness and the variation of thickness due to bending steps, Bihamta et al.^[100] conducted a global optimization algorithm for tube hydroforming.

For tough bending of LDTW Al-alloy tube, multiple defects and multiple factors should be simultaneously considered, and this inherent complexity makes the optimization highly nonlinear and finding global solution not realistic.^[101] Considering the coupling effects of various forming parameters on multiple defects, the authors in Refs [102–104] developed a knowledge-based substep methodology to solve the deterministic optimization of LDTW Al-alloy tube bending with multi-objective and multi-variable under multiple factor constraints. Considering narrow forming window under small bending radii ($R_b < 2D$, R_b -bending radius, D -initial tube diameter), an FE-based stepwise iterative search method is proposed to optimize key forming parameters of LDTW Al-alloy tube under small R_b , and the search direction is based on bending knowledge, while for large R_b bending with wide optional ranges of forming parameters, a hybrid optimization approach is used by combining virtual DOE, FE simulation, approximate response surface model, sequential quadratic programming algorithm, or genetic algorithm. Using orthogonal experimental method, 3D-FE simulation, experimental data, and analytical formulae, knowledge of key forming parameters, coupling effects on multiple defects, effect significance, and design rules, as well as initial values and design ranges, are obtained. The deterministic optimization of mandrel parameters and processing parameters is achieved, for the specifications of LDTW Al-alloy tube bending with small R_b $100 \times 1.5 \times 150$ mm, and with large R_b $50 \times 1 \times 100$ mm, and $100 \times 1.5 \times 200$ mm. Figure 13 shows the optimization results for $100 \times 1.5 \times 200$ mm.

Innovative Design of Tools and Processes

With the increasing requirements of tubular bent products with lighter weight and higher performance, the existing bending tools and processes may present their limitations. Based on the fundamental studies on bending deformation, the innovative techniques as well as creative tooling design were invented for realizing more precision and more efficient forming of new developed tubular materials with complex structures.

Great efforts have been made to improve the bending limits and forming potentials of some hard-to-deform tubular materials based on existing universal bending technologies. Based on the in-depth understanding of the essential of NLS, Li et al.^[78] proposed several possible innovative approaches to improve the bending formability by positively coordinate the nonuniform bending deformation and thus reconstruct the NLS, such as temperature-field-based innovative processes and multi-tool design-based innovative processes. Baudin et al.^[105] proposed the push bending to

Fig. 13 Equivalent plastic strain contour plots of the initial and the optimal results ($100 \times 1.5 \times 200$ mm): (a) before optimization and (b) after optimization

form an elbow section from a straight tube using internal pressure and a rigid die. A comparison between using internal hydraulic pressure via a liquid and using a urethane rod to supply the internal pressure was undertaken. Then, the forming capability of pushing bending has been upgraded from the cold bending of stainless steel tubes to the hot push bending of the large-diameter stainless steel tube and Ti-alloy tube.^[106] By combining expanding deformation with bending deformation, the Archimedes spiral based ox-horn pushing bending is proposed to manufacture the thin-walled ring tube with even wall thickness. However, it is difficult to obtain the spatial ensemble bent tubes with straight portion in large batch since all tubular should be pushed through the bending die; meanwhile, the wrinkling instability is so prone to occur due to the axial compressive stress induced by the pushing force with inappropriate dimensions of dies. Zhang et al.^[107] further used $\Phi 1.2$ mm ball filler as the filling medium, and the bending of copper tubes with 0.5 mm wall thickness was achieved. The shear tube bending is another method proposed to realize considerable small bending radii, in which shear deformation is induced to bend the tubes.^[51] By applying the internal pressure, a shear hydro-bending was proposed by Han et al.^[108] to solve the difficulties in forming aluminum alloy rectangular tubes with a small bending radius. Based on the traditional press bending, internal pressure is applied to bending tube to prevent wrinkling and cross-section deformation, thus improving bending limit with small bending radii.^[109] It is noted that, whether push bending, shear bending, or press bending is used, only a single elbow can be formed. By integrating the numerical controlling (NC) techniques with bending, the RDB method has been the most universal and most primary technology for realizing the accurate and efficient forming of bent tubes with multiple elbows. Tang et al.^[110] numerically studied the role of booster system in the improvement of forming quality to reduce both wall thinning and sectional fattening in RDB. To improve the multi-defect-constrained

bending formability of tube in RDB, Li et al.^[111] designed several push assistant loading (PAL) conditions and found that the PAL conditions under synchronous mode play more significant effect on bending behaviors than sole pressure die mode. Lăzărescu^[112] studied the RDB of aluminum alloy tubes with internal fluid pressure by FE simulation and experiments. Recently, in response to the currently increasing requirements of hard-to-form lightweight materials with complex spatial tubular structure such as large diameter, thin thickness, and small bending radius, the heat assistant RDB may present promising potential for precision bending deformation of the above tubular materials.^[45,113] Wu et al.^[114] explored the effects of temperature, bending velocity, and grain size on the bendability of Mg-alloy AM30 tubes. The thermomechanical coupled FE model for heat RDB was developed, through which the rational working temperature range, heating scheme, die design, and processing parameters were optimized comprehensively.^[115] Figure 14 shows the designed heat assistant RDB tools.

Fig. 14 Experiment equipment W27YPC-159 for heat assistant RDB

Besides the above studies on improving forming limits, mass investigations have also been conducted for efficiently achieving small batch bent tubular products with complex structures such as different radii or even variable curvatures. Gantner et al.^[116] proposed a novel tube-bending technique, call free bending, which has advantageous characteristics such as fast bending speeds and an almost free definable bending geometry with transition-less bend-in-bends and spline bends without re-clamping. Another highly flexible forming operation, i.e., three-roll push bending, has been developed to manufacture the 3D free-form bending tubes with variable radii.^[117–119] For producing flexible, continuous, and adaptive 3D tube profiles with symmetrical and asymmetrical cross-sections, Chatti et al.^[120] developed a new roll-based torque superposed spatial bending. By kinematic adjustment of bending contour and superposing a torque, the variation of bending radius and bending angle can be implemented. Recently, an innovative tube-bending process with a combined diameter-reducing process, namely combined tube spinning and bending, was developed to achieve 3D bending of tubular materials.^[121,122] Liang et al.^[123] proposed a flexible 3D stretch-bending technology for aluminum profile to manufacture 3D structural parts. Another noted flexible bending, viz. laser bending, was newly used for bending of thin-walled nickel micro-tubes.^[124] This approach has advantages of contactless flexible forming, short production circle, and minor springback. Since the overall bending deformation is accomplished by multiple scanning accumulations, the difficult-to-form materials can be bent. However, though with higher flexibility, the above processes are suitable for manufacturing the bent tubes with relatively large bending radius and small diameter. In recent years, Goto et al.^[125] developed a flexible tube bending, in which the tubes are bent by shifting the relative position of the mobile die when they are fed into the fixed and mobile dies. The bending radius is controlled by the relative distance and orientation between the mobile die and the tube. The bending angle is controlled by the length of the fed tube. Based on RDB, to meet the requirement of modern manufacturing with characters of much varieties and small batch, some attempts have also been made. Wen^[126] proposed a new concept of RDB die called MDB-Die (multiple-diameter bending die), in which tubes with different outer diameters within a definite range can be bent using the same die by only adjusting the pads inside the die set. Salem et al.^[127] proposed a new mandrel type called “chain link mandrel” for RDB with lower cost and simplicity compared to mostly used ball link mandrels.

TRENDS AND CHALLENGES FOR TUBE BENDING

The rapid developments of many industries such as aerospace and automotive call for more accurate and efficient bending forming theories and technologies of tubular

Fig. 15 Demonstration of bent tube application as “bleeding” transforming function in aircraft engine

products with lighter weight and higher performance as shown in Fig. 15. After the above critical review of the advances in tube bending, the trends and corresponding challenges are summarized in this section.

More and more advanced new or unusual tubular materials have been tried to be adopted to further improve the performance of bent tube products. However, these materials are generally hard to deform and nonhomogeneous. Compared with the commonly used stainless steel and aluminum alloy tubes, these newly used materials, such as magnesium alloy tube, titanium alloy tube, ultra-high-strength tube, high-strength aluminum alloy tube, high-temperature alloy, double-walled metallic tube (laminated tube), and composite tube, often present high deformation resistance and poor plasticity at room temperatures. Besides the usages of these advanced materials, more complex 3D spatial tubular products are frequently needed to further satisfy the function and the assemble efficiency. These bent parts are characterized with difficult-to-form structures such as large diameter ($D > 40\text{ mm}$), thin wall thickness ($t < 1.5\text{ mm}$), small bending radii (relative bending radii $D/t < 2\text{ mm}$), variable bending radii, or irregular cross sections. Thus, new bending processing methods or improvement in tooling/equipment design should be developed to satisfy the precise and efficient bending of the abovementioned new hard-to-deform materials with difficult-to-form structures. Thus, the corresponding challenges are thrown out as follows:

- It is known that the tubular materials directly determine tooling setup, forming parameters, forming limit, and bending quality. The efficiency and precision of tube bending depend on the knowledge about mechanical properties of the tubular materials, and also the reliable FE simulation relies critically on accurate modeling of the properties of tubular materials. Also, the tubular materials are generally fabricated with complex processing and present remarkable nonlinear and anisotropic responses. However, the hollow structures of tube with curvature make it difficult to quantitatively

characterize the elastic-plastic response along different directions. Though some advances have been achieved, there is still a lack of suitable physical tests and modeling theory for characterizing tubular materials. The crystal plasticity FE-based virtual experiments should be a promising approach to achieve the above goals.

- Though the different defects in tube bending have been extensively studied and knowledge of the instabilities have been obtained, the accurate prediction and efficient control of the defects/failures are still intractable tasks for tube bending of the hard-to-deform materials with complex structures, especially for large-diameter tube bending with a small bending radius or for high-strength tube bending. The forming limit under multiple failures/defects should be deeply addressed since there may be various instabilities occurring in tough tube-bending deformation. The new innovative processes such as heat assisted RDB bending should be developed by combining the existing bending techniques to achieve more precise and flexible forming deformation.
- The optimization of the overall bending process is still under questions for achieving precision bending deformation with high quality, satisfied properties, and high efficiency. In practice, the tooling design is still mainly dependent on the empirical experiences of the technicians. The current optimization of the tool and process mainly focuses on certain tubular materials with special specifications. The optimization methodology considering the coupling effects of multiple parameters and various defects/failures should be studied. Both the certainty and uncertainty factors such as contact conditions and variation of tubular material properties should be considered simultaneously, and also both the dimensional accuracy and property variations should be taken into account. The efficient mathematical models with the multi-objective and multi-constraint should be developed. The database on tube bending should be established, and the intelligent bending should then be investigated.

CONCLUSION

1. The recent advances in tube bending are briefly reviewed from four fundamental issues, i.e., characterization of tubular materials, prediction of multiple defects, bending formability, and innovative optimization design. Tube bending has been one of the key forming technologies used for producing lightweight and high-performance parts in many industries. There are so many types of bending techniques with special advantages and drawbacks regarding forming limits and bending efficiency. The RDB has become the primary technology for realizing both accurate and efficient tube bending. By combining the existing bending methods or

introducing additional force fields, several innovative processes have also been established to further improve forming limits or bending flexibility. It is noted that, no matter what kind of bending method used, the efficiency and precision of production are vitally related to the insight into the occurring mechanisms of the various defects in tube bending and then accurate prediction and effective controlling.

2. The trends and corresponding challenges are tried to be put forward. With the increasing needs for better performance and lighter weight, the more complex 3D spatial tubular bent components of advanced materials are urgently required. The geometrical structures of these components are characterized with thin-walled thickness, large diameter, small/variable bending radius, and irregular cross-sections. The tubular materials are generally hard to deform with high strength and limited ductility. Considering the facts of tough tolerance in applications and inherent complication of tube bending, several challenges should be overcome, viz. calibration and modeling of tubular materials, accurate prediction and control of multiple defects, and robust optimization design of tooling/process for achieving precision bending with high quality, satisfied properties, and high efficiency.

Twist Compression Welding of Aluminum

T. Yokota, T. Hashimoto, M. Otsuka, M. Nobutoki, and T. Ueki

Shibaura Institute of Technology, Tokyo, Japan

Abstract

Diffusion welding of metallic materials requires contact of clean surfaces by removing surface films. However, there is microscopic unevenness on the surfaces and they are covered with oxide layers, absorbed gas layers, contaminating substance layers, etc. Welding is prevented by this unevenness and by these surface films and it is the stability of the surface films, in particular, which affects welding. Aluminium is regarded as a particularly difficult material for diffusion welding since it has a highly stable strong oxide film. Hence, to weld aluminium, it is necessary to remove this stable film so that welding can be performed. This article describes will describe the result of the investigation into the effect of twist angle, welding pressure and temperature, film thickness and surface roughness on the joint strength of the material.

Keywords: Faying surface; Fracture; Microstructure; Surface treatment; Twist-compression.

PREFACE

In theory diffusion welding of metallic materials requires clean surfaces to be brought into contact by removing surface films from the faying surfaces. However, in reality, there is microscopic unevenness on the faying surfaces and they are covered with oxide layers, absorbed gas layers, contaminating substance layers, etc. Welding is prevented by this unevenness and these surface films and it is the stability of the surface films, in particular, which affects welding. Aluminium is regarded as a particularly difficult material for diffusion welding since it has a highly stable strong oxide film.^[1] Hence, to weld aluminium, it is necessary to remove this stable film so that welding can be performed between clean surfaces. The methods reported so far for this purpose include the application of large scale deformation,^[2,3] the use of insert metal,^[4,5] the addition of ultrasonic vibration^[6] and the introduction of the argon ion impact method.^[7]

However, to apply large scale deformation is not acceptable from the viewpoint of precision welding. The use of insert metal is not always suitable because it induces the production of different structures from those of the base metal. Moreover, if the welding temperature is high, the deterioration in properties of the base metal caused by the increase in grain size cannot be avoided. For these reasons, it has been hoped to design a welding method without these disadvantages in which welding time can be shortened.

Incidentally, most conventional solid phase welding methods have employed only stress normal to the faying surfaces. In contrast, in this study, a new method was designed in which shear stress (twist) is added to the interface under normal stress.

This method - the twist compression welding method - has the following advantages compared with conventional methods.

1. The close contact of the faying surfaces and the destruction of oxide film can be achieved simultaneously.
2. Deformation is less.
3. Welding can be performed in shorter time and also in the atmosphere.

When this method was actually applied to industrial purity aluminium A1050, it produced nearly as good a result as expected. This report will describe the result of the investigation into the effect of twist angle, welding pressure and temperature, film thickness and surface roughness on the joint strength of the material.

MATERIALS USED IN THIS EXPERIMENT AND TEST METHODS

The material used in this experiment is extruded purity aluminium A1050 whose chemical composition is shown in the Table 1.

Figure 1 shows the principle of the welding equipment. In this, the end surfaces of the specimens (10 mm in diameter, 60 mm in length) which had been ultrasonically-cleaned in acetone were butted together and subjected to high frequency induction-heating. They were brought to the given temperature in the atmosphere under pressure applied by a small jack before welding was performed by twisting the top specimen at a rotational speed of 6 rpm to create friction

at the welding interface. The average rate of increase of temperature was set at 1 Ks^{-1} . The temperature at the weld was detected by a 0.3 mm thickness chromel-alumel thermocouple installed 1 mm away from the faying surface on the side surface of the bottom specimen. Welding was conducted three times with the same conditions and the average values calculated were used as the measured values.

Three kinds of treatment were applied to the faying surfaces: (1) machining with a lathe, (2) emery polishing (#220, #800, #1500) after machining, and (3) anodic oxidation treatment (treatment conditions: 20–40 V for 300–900 seconds in 295 K boracic acid) after machining. The conditions for anodic oxidation and the thickness of oxide films were selected in accordance with Nagata.^[11] Specimens were machined from the welded joints so that the interface could be positioned at the centre of the gauge length (20 mm in length, 8 mm in diameter) (Fig. 2). Their performance was then evaluated using an Instron type testing machine. Strain rate was $5 \times 10^{-5}\text{ s}^{-1}$. Furthermore, the bond interface and surrounding area were buff-polished and etched in 3% HF solution so as to allow structural observation by an optical microscope. In addition, by making thin films by the twin jet method, an examination of their structure was made by a transmission electron microscope (TEM). The composition of the electropolishing fluid was 2 parts of perchloric acid and 8 parts of methyl alcohol. The electropolishing conditions were a

Fig. 2 Tensile test specimen machined from the welded joint

temperature of 266 K and voltage of 20 V. The acceleration voltage for the TEM was set at 150 kV.

TEST RESULTS AND EXAMINATION

The effect of twist angle and welding pressure

Figure 3 shows the relationship between twist angle and tensile strength under varied welding pressure at the welding temperature of 573 K. For comparison, the figure also shows the tensile strength of the base metal to which the same thermal history as that for the joints was applied (that is, it was heated at 573 K for the length of time shown by the top horizontal axis). With welding pressure at 9.2 MPa, the average value of joint efficiency for a twist angle of 2π rad (one rotation) was as low as 49%, and the data showed considerable scatter. As the twist angle increased, however, the joint strength showed a tendency for a gradual increase, reaching 94 MPa (joint efficiency of 82%) at 12π rad. When the welding pressure was raised to 16.5 MPa, joint strength was not sufficient until the twist angle reached 3π rad, but, at 6π rad, a strength as high as 105 MPa (joint efficiency of 87%) was obtainable, and the data were less scattered. As the twist angle increased further, about the same level of joint strength could be obtained until the strength reached nearly the saturation value. At 12π rad,

Fig. 3 Effect of twist angle and pressure on the room temperature tensile strength of the welded joint at 573 K

joint efficiency became 92.5% owing to a decrease in the strength of the base metal, but the base metal did not fracture. The welding deformation rate (value obtained from dividing compression displacement after welding by the length of the specimen before welding) at this point of time was very low, i.e. 0.1%. However, when the welding pressure was raised more than this, tensile strength showed a tendency to decrease instead. For example, tensile strength became 86 MPa (80% in joint efficiency) at 21.4 MPa in pressure and 6π rad in twist angle, whilst it remained at 86 MPa (68% in joint efficiency) at 30.6 MPa and 2π rad. With this increase in welding pressure, welding deformation increased to 0.5% - 1.5%, and simultaneously deformation caused by twist became apparent. Thus, a further increase in twist angle did not give a better result, and only induced an increase of twist deformation.

As described above, tensile strength improves as welding pressure is increased, but there is a most appropriate value for the welding pressure. When it exceeds this value, joints become weaker instead, though the reason is not clear. It was thus clarified that the application of shear is effective in improving weldability and that there is a most appropriate range for shear displacement and welding pressure.

With 573 K and 16.5 MPa, the most appropriate welding pressure, about the same level of joint strength could be obtained at both twist angles of 6π rad and 12π rad. Hence, the performance of joints in terms of ductility was evaluated. The relationship between the reduction of area and twist angle is shown in Fig. 4. Whilst the reduction of area is about 50% at 6π rad in twist angle, it is 80% at 12π rad. Therefore, when a joint is evaluated, it is considered necessary to take account of ductility too.

The effect of welding temperature

Figure 5 shows the result of a welding test when welding temperature was raised from 573 K by 100 and 200 K. As shown in the figure, when welding temperature was

Fig. 4 Effect of twist angle on the reduction of area

Fig. 5 Effect of twist angle and pressure on the room temperature tensile strength of the welded joint at 673 K and 773 K

raised, a decrease in the strength of the base metal was apparent, and so welding pressure was made less than that for 573 K. At 673 K and 3.1 MPa, the highest tensile strength, 55 MPa (75% in joint efficiency) was exhibited with 4π rad, and the joint strength displayed a tendency to decrease slightly as twist angle was increased. The same tendency was observed with the pressure of 6.1 MPa. At 3π rad in twist angle, the highest tensile strength was achieved, i.e. 43 MPa, but joint efficiency remained fairly low, i.e. 57%. When twist angle was increased further, buckling deformation occurred. As with 573 K, it is shown that an excessive increase in welding pressure induces tensile strength to decrease instead. It also shows that the twist angles which correspond to the maximum value of strength decrease as temperature rises. When temperature was raised by another 100 K, i.e. 773 K, a joint strength of 43 MPa was obtainable at 1π rad in twist angle, but ductility was poor (about 1%). In addition, considerable torsion occurred near the weld, and deformation was high, i.e. 2.3%. Moreover, when the twist angle was more than 1π rad, buckling deformation was produced as with 673 K and 6.1 MPa. When welding temperature is too high, as in this case, the base metal, which is softened, is subject to torsion deformation, and the twist friction effect on the welding interface ceases, preventing the achievement of sufficient weld strength. From these factors, it is considered that welding temperature ought to be kept as low as possible so that the softening of the base metal will not cause its mechanical properties to deteriorate. Welding at a low temperature is also desirable because it allows effective application of high friction torque.

The effect of surface treatment

As reported above, in the welding of aluminium, the thicker the oxide film, the more difficult diffusion welding becomes because metallurgical contact at the interface is prevented.^[7] On the other hand, in room temperature

pressure welding, which produces greater welding deformation, welding is said to be easier since the oxide film is more easily destroyed.^[8] The surface roughness has also been reported to affect weldability.^[9,10] Therefore, with this welding method, too, an investigation was made into the effect of the surface finish and the thickness of oxide film on the joint. A comparison was made using the welding conditions with which joint strength and ductility were the highest, i.e. 573 K, 16.5 MPa and 12π rad.

Figures 6 and 7 show the results of the tests with regard to the effect of surface finish and oxide film respectively. Surface roughness in Fig. 6 was controlled by varying the grain size of the emery paper for the final finishing from #1500 to #800 and then to #220. The figure also shows the values for average roughness ($R_a/\mu\text{m}$) at the centre line of the weld surface which were obtained by a probe type surface roughness analyser.

Fig. 6 Effect of emery polishing on the tensile strength and ductility

Fig. 7 Effect of anodized oxide film thickness on the tensile strength and ductility

When the surface was just machined with a lathe, the joint strength was about 100 MPa with a joint efficiency of over 90%, and the reduction of area was about 80%. With the surfaces polished with emery papers of #220, #800 and #1500, the joints showed about the same strength and ductility as those with machine-finished surface, although the reduction of area with #1500 is slightly inferior. On the other hand, as shown in Fig. 7, when the thickness of anodised oxide film was increased to 20 nm, 40 nm and 100 nm, strength as well as ductility was maintained at about the same level as those with a machine finish.

From these results, it can be concluded that weld strength and ductility are not affected by the surface roughness between #220 and #1500 and an anodised oxide film thickness of under 100 nm. The possible reason for this is that, in this welding method, the faying surfaces are rubbed against each other strongly under pressure. This sliding at the interface forces the film to be broken even if the state of the surface varies. Thus, this welding method has a characteristic in that stable welding results can be achieved without being influenced by the state of the surface.

SEM observation of the tensile fracture surfaces of welded joints

The result of SEM observation of the tensile fracture surfaces of welded joints is shown in Fig. 8. All the specimens had fractures at the bond interface, and on the fracture surface concentric patterns were observable which were caused by the torsion deformation of the specimens. In the case of the welding conditions with lower joint strength, i.e. 573 K, 16.5 MPa and 2π rad (Fig. 8 (1)), black regions which have not been bonded co-exist with white dimple regions. The dimples show that the welded portions of both metals were indeed united, whilst, in the regions which are not bonded, as shown in B, since the bond interface did not have sufficiently close contact, there were areas whose surfaces were damaged by the contact between the polish traces and the convex portions of the faying surfaces. When the rotation angle was changed to 6π rad, as shown in Fig. 8 (2), the oxide film was destroyed and dimples could be observed on the whole surface. As described above, an excessive increase in welding temperature caused welding strength to be reduced instead (Fig. 5). When an observation was made of the fracture surface of the specimen which was welded with the conditions of 673 K, 3.1 MPa and 4π rad (Fig. 8 (3)), in spite of the progress of overall contact, it exhibited damaged surfaces in some parts as shown in B, showing that the dimpling is not deep and hence bonding is not sufficient. This tendency becomes more distinguishable when the welding temperature is increased to 773 K. As shown in Fig. 8 (4), though shallow dimples are apparent in one part (Region B), the fracture surface is generally flat and the traces of sliding at the interface are revealed by concentric circles (Region A). What is considered to

Fig. 8 Scanning electron micrographs showing tensile fracture surface of the welded joint

have happened here is as follows. At this temperature, the yield stress of A1050 is extremely low, and therefore, out of the total twist angle applied externally, only a small amount was converted to shear at the bond interface and the rest was mostly converted to torsion deformation of the base metal.

Observation of the structure of welded joints

Figure 9 shows a representative optical microstructure of a bond zone in a specimen which showed high joint efficiency. The bond zone does not exist as a clear planar surface, but as a narrow lamellar region (bond layer) and the flow of material caused by torsion deformation is apparent on the outside. As far as the optical microscope could observe, oxide film was not found in the interior of this bond layer. Therefore, a TEM observation of the bond interface was conducted. Figure 10 (1) shows transmission electron micrographs of a bond zone. Welding conditions were 573 K, 16.5 MPa and 6π rad. Though the observation

was conducted over an extensive area, there was no indication of the existence of oxide film which showed the original position of the bond interface. Instead, the bond zone comprised of fairly regular sub-grains in which a large number of dislocations were apparent. However, though slightly obscure, black spots were observable decorating the dislocations. They were considered to be the fragments of oxide film broken up during the shear at the interface.

Fig. 9 Microstructure at and near the bond interface

Fig. 10 Transmission electron micrographs showing dislocation substructure in (1) bond zone, (2) base metal and (3) region about 5 mm from the bond interface

For comparison, transmission electron micrographs of the base metal and the position 5 mm from the bond zone are shown in Fig. 10 (2) and (3) respectively. Both micrographs show hardly any dislocations in the sub-grains, in contrast to the interface. There are no fragments which look like oxide in the sub-boundary, either.

CONCLUSIONS

To improve the solid phase weld strength of metals, a method in which compression as well as shear by twist were added to the interface (the twist compression welding method) was designed and applied to A1050 aluminium which was difficult to weld by usual diffusion welding methods. The results were as follows.

1. When this welding method is employed, aluminium can be welded in the atmosphere quickly at a fairly low temperature, and the reduction of area is less.
2. Joints obtained at 573 K welding temperature, 16.5 MPa welding pressure and 12π rad twist angle were found to have a tensile strength of 105 MPa (92.5% joint efficiency) and 80% reduction of area.
3. This method is less likely to be affected by the state of the surface such as surface roughness and the thickness of surface oxide film, unlike conventional simple diffusion welding methods.
4. As a result of the TEM observation of the bond interface, oxide film was considered to have been broken into fine pieces and scattered.

Abstract

This article describes the concept of uphill quenching process applied in the heat treatment of aluminum alloys. Uphill quenching is interesting since residual stress reductions of up to 80% has been reported. In addition, substantial improvements in dimensional stability have been achieved for several types of aluminum parts. Often, uphill quenching is applied after quenching and before aging during the heat treatment of aluminum alloys. The uphill quenching process consists of the immersion of the part in a cryogenic environment, and after homogenization of the temperature, the part is transferred to the hot steam chamber to obtain a temperature gradient that will maintain the mechanical properties gained with this process. The results obtained are lower residual stress and better dimensional stability. The aim of this article is to provide a review of this process and to compare it with conventional heat treatment.

Keywords: Aluminum alloy; Cooling rate; Heat treatment; Liquid nitrogen; Quenching; Residual stress; Uphill.

INTRODUCTION

Residual stress is a major concern for the heat treatment and manufacturing of aluminum alloys for the aerospace industry. Often an unacceptably large fraction of aluminum alloy components must be reworked or discarded due to failures associated with unacceptably high residual stress including distortion and cracking.

For heat treatable wrought aluminum alloys such as the 2XXX, 6XXX, and 7XXX series and the 3XX cast alloys,^[1] the quenching process is the stage where the greatest residual stresses are developed.^[2] During aluminum alloy heat treatment, the creation of internal stresses is a function of cooling rate.^[3] The faster the cooling, the greater the residual stresses, which are formed due to increased thermal gradients.^[4] Increased surface cooling rates lead to contraction and the generation of surface compressive stresses on the part. Conversely, slower cooling within the part leads to tensile stresses. The residual stresses generated are due to internal strains within the material resulting in the unbalanced compressive and tensile stresses created during heat treatment (mainly during quenching) or machining. These stresses are created in the

part either through mechanical strains or by temperature gradients formed during heat treatment and cause unequal plastic deformation.^[2]

A common problem, particularly during water quenching, is the instability of the vapor film surrounding the part prior to rupture and nucleate boiling (Leidenfrost temperature). In these cases, there may be pockets of trapped vapor leading to nonuniform rupture and a further increase in thermal gradients.^[5] These increased residual stresses may lead to dimensional instability of the part during subsequent machining operations.^[6] In addition, these stresses remain in the material even with the imposition of external strain.^[7] The goal is to transform this condition from an elastic state to a plastic state.^[8]

One of the methods of reducing residual stresses is by mechanical working, by stretching, or by compressing the material^[3] that produces plastic strains.^[9] If the parts possess a complex shape, residual stresses cannot be relieved by this method. Alternatively, residual stress reduction may be accomplished by heating to decrease the yield stress by transforming the material to a plastic state.^[3] However, aluminum alloys may undergo precipitation if the temperature is greater than the homogenization heat treatment

temperature resulting in the loss of strength. During the aging process, the temperatures that are typically in the range of 205–535°F (96–279°C)^[10] are insufficient to result in significant reduction of residual stresses.^[11–13] Furthermore, long aging times (up to 50 h) are also ineffective for residual stress reduction.^[14]

One process that has been shown to be highly effective for reducing residual stresses is by using a thermomechanical process designated as “uphill quenching,” which is alternatively referred to as “cold stabilization” or as a “thermal shock process.”^[8] Uphill quenching involves cycling of aluminum alloy parts below and above room temperature. Thus, it is possible to counteract quenching stresses by subsequently cooling a part in liquid nitrogen (LN₂). LN₂ is a colorless clear liquid with a density of 0.807 g/mL and a dielectric constant of 1.43. Under atmospheric pressure, nitrogen is a liquid at 63–77.2 K (i.e., –210°C to –195.8°C or –346°F to –320.44°F). Below this temperature, LN₂ is a solid and above this temperature, it is a gas.^[15] After cooling the part to LN₂ temperature, it is then immediately heated by blasting with high-velocity steam in a steam box (thermal shock).^[8]

Note: Traditionally, steam is defined as follows: low-pressure steam below 50 psi_g (3.5 bar_g), medium-pressure steam that is above 50 psi_g (3.5 bar_g) but below 250 psi_g (17.5 bar_g), high-pressure steam that which is greater than 250 psi_g (17.5 bar_g), and ultrahigh-pressure steam that is greater than 600 psi_g (40 bar_g).^[16] For uphill quenching, the use of high-pressure steam has been reported. From steam temperature tables, the steam temperature at 50 psi_g is reported to be 297.7°F (147.6°C).^[17] Steam may also be defined as high-velocity steam. The velocity of steam is actually the speed of water droplets at the steam line discharge point.

The remainder of this article is a general review of the uphill quenching process.

UPHILL QUENCHING

The uphill quenching method, also referred to as “deep freezing” or “tricycle stress relieving,”^[18] was developed by Alcoa metallurgists.^[19] The objective of using uphill quenching, a thermomechanical treatment process, is to relieve or eliminate residual stress in aluminum alloys due to quenching.^[20] This is a thermal–mechanical process because stress relief is followed by mechanical plastic deformation.^[13] The presence of residual stresses in aluminum alloy forgings, for example, leads to an increase in non-approved parts which increase production costs and besides damages during production.^[21]

As a result of detailed research on the uphill quenching process, the Alcoa researchers concluded that optimal results were obtained by cooling the component after quenching in LN₂ followed by immediate steam heating yielded optimal results by generating large thermal gradients to develop residual stresses to counterbalance stresses

generated from quenching.^[13] Steam heating of the component following cryogenic cooling is used to generate a maximum temperature gradient to cancel the stresses due to quenching.

Uphill quenching does not influence the mechanical properties,^[13] since the steam heating process temperatures are relatively low. The objectives of the uphill quenching process include the following:

- Development of an optimal thermal gradient by cryogenic cooling in LN₂ followed immediately by high-pressure steam heating.
- The steam heating temperature is below that necessary for degradation of mechanical properties.
- The thermal gradient produced by uphill quenching is sufficient to produce plastic deformation of the material.^[13]

THE UPHILL QUENCHING PROCESS

After solution heat treatment, the aluminum part or component is quenched using a suitable quenchant such as water or aqueous polymer.^[22–24] The strategy of quenchant selection is to obtain the maximum strength while minimizing residual stresses and distortion.^[18] The traditional process of aluminum alloy heat treatment is shown schematically in Fig. 1.

Figure 1 indicates that relatively rapid cooling during the quenching process produces large temperature differences and residual stresses.^[3] Sufficiently fast cooling is required to maximize mechanical properties; however, minimum distortion requires lower thermal gradients provided by slower cooling. Therefore, the challenge is to optimize the cooling rate that will permit the formation of design minimum properties^[25] while yielding minimum distortion. The objective of uphill quenching is to develop compressive residual stresses from a material with tensile stresses formed during quenching.^[26] As a result, uphill quenching is a stress relieving process.

Uphill quenching consists of the following steps:

1. Immediately after quenching, the component is cooled in a cryogenic medium to –196°C (–321°F) or stored in an icebox at –17.8°C (0°F) to minimize the risk of precipitation. This part of the process provides temperature homogenization and stabilizes the structure.
2. After temperature homogenization, the component is transferred to a steam chamber with low-pressure, high-velocity steam. The residence time for the component in the steam chamber is dependent on the section thickness but should not be excessive.^[20] Typical steam heating times that have been reported are 10–30 s for AA6061-T6.^[3]
3. The temperature can be measured inside and outside of the steam fixture and in the part to monitor the

Fig. 1 Conventional heat treatment process of an aluminum alloy

variation of temperature and obtain the temperature gradient.

4. The part is removed from the steam chamber and residual stresses are measured, typically by X-ray diffraction.
5. After residual stress analysis, the component is then aged at the desired temperature.^[20] Aging is a precipitation-hardening process that is conducted to maximize mechanical strength and hardness.

The uphill quenching process is shown schematically in Fig. 2.

When the component was transferred to boiling water instead of steam, the formation of an interfacial ice layer was observed that had an undesirable effect of decreasing the heating rate in this step of the process, thus limiting the degree of final stress relief.^[27] This is why low-pressure, high-velocity steam heating during this step is preferred since optimal residual stress relief is dependent on the thermal gradient created during the uphill quenching process.^[4]

COMPARISON OF UPHILL QUENCHING AND CRYOGENIC QUENCHING PROCESSES

A common error has been to consider uphill quenching to be equivalent to cryogenic quenching (cooling), usually in LN_2 . (Note that while LN_2 is usually used, other cryogenic media including^[28] argon, hydrogen, helium, and oxygen could conceivably be used). However, uphill quenching and cryogenic quenching are fundamentally different processes. In the previous section, an overview of the two-step uphill quenching process: (1) cryogenic cooling after conventional quenching followed by (2) high-velocity steam heating. After the uphill quenching process was completed, the component was then aged to achieve precipitation hardening.

Cryogenic quenching, also referred to as “Cryoquenching”^[29] of aluminum alloys, is a single-step process immediately following solution treatment and is usually performed in LN_2 to reduce residual stress.^[30] Uphill quenching is an old process first reported in the 1930s^[31] and developed into a commercial process in the 1950s,^[13]

Fig. 2 Aluminum alloy heat treatment incorporating uphill quenching

Fig. 3 Aluminum alloy heat treatment using cryogenic quenching (cryoquenching)

cryogenic quenching of aluminum alloys was developed in the 1960s.^[29]

After cryoquenching, the component is then aged. There is no intermediate steam treatment. Figure 3 schematically illustrates a cryoquenching process. Figure 4 illustrates cryoquenching of a solutionized aluminum component.

Interestingly, while cooling of hot aluminum in LN_2 might be expected to be very fast, this is not the case because of the relatively stable, uniform, vapor blanket surrounding the hot aluminum.^[30] Cryogenic quenching has been reported to produce lower distortion relative to conventional quenching in water or aqueous polymer solutions.^[32] Because of the lower distortion achieved with cryogenic cooling compared to conventional quenching, it has been used in the production of optical mirrors for use in space.^[33]

Cryogenic cooling has reportedly been used with good results for the quenching of thin sheets, up to 5 mm, of AA6061 and AA2024 while providing excellent

mechanical properties with very low distortion and residual stress and distortion relative to water quenching which is attributable to the more stable vapor film surrounding the component during cooling.^[30,34] Thicknesses greater than 5 mm resulted in corresponding losses in mechanical properties. Furthermore, microstructural analysis of cryogenically quenched material shows a uniform microstructure with no dissolved secondary phases. In one study using Navy C-ring test specimens of Duralumin D16AM, a Russian aerospace aluminum alloy, the distortion and deformation produced by cold water, boiling water, LN_2 , and air were compared. The results shown in Table 1 show that the distortion was lower for LN_2 than either the cold water or boiling water quench.^[34]

In reference,^[35] an intermediate “cryogenic treatment” (CT) between the quenching and aging process (uphill quenching) was reported. The roundness of AA6061 components was shown to be significantly improved in relation to conventional quenching. Furthermore, after 18–21 h at CT temperatures, substantial increase in hardness and improved surface roughness and finish after machining was reportedly due to more refined precipitates.^[35] The conclusions of this study included^[35] the following:

1. CT at -185°C for 18–21 h between quenching and aging in the T6 temper produced a hardness approximately three times greater than when CT was not performed.
2. Variations in electrical conductivity indicate differences in the secondary precipitation behavior induced by the CT that is time dependent.
3. CT improves surface roughness after machining.

Another term for a heat treatment, uphill quenching, and aging is cryogenic heat treatment (CHT).^[27] The residual stress of a water-quenched AA6061 cylinder after

the following: (1) Water quenching with aging to a T6 condition; (2) water quenching followed by uphill quenching without aging, and (3) water quenching, uphill quenching and aging to a T6 condition (CHT). In this study, the uphill quenching process involved boiling water and not steam. The compressive residual stresses were reduced 40% following uphill quenching and 65% after uphill quenching and aging as shown in Table 2. Table 3 shows the increase in hardness obtained by uphill quenching + aging relative to conventional water quenching.

EXAMPLES OF THE UPHILL QUENCHING PROCESS

One of the questions related to uphill quenching is the maximum thickness of the aluminum alloy to obtain a significant degree of residual stress reduction. Thin parts

up to ¼ in (6.35 mm) generally exhibit a lower temperature gradient or temperature difference between center and surface during cooling and therefore do not usually exhibit considerable residual stress.^[20] For thicker parts, when the part is quenched, a larger temperature gradient is obtained that results in greater residual stress. Figure 5 shows the relationship of the temperature gradient and residual stress relief. Table 4 summarizes the effect of section thickness on AA7049 subjected to uphill quenching as a function of section thickness 3.

Figures 6 and 7 illustrate the compression and tension stress level for 1/2 in. (12.7 mm) and 2 in. (50.8 mm) thick AA7075 obtained by uphill quenching and conventional aluminum alloy heat treatment using cold and hot water quenching.

One report has shown that the use of uphill quenching followed by aging resulted in a 25%–40% residual stress reduction.^[37] Other reports have shown that uphill

quenching can produce residual stress reductions up to 80%, whether the material is natural or artificially aged.^[3] Figure 8 shows that long aging times at high temperature reduces the strength when the part is at room temperature. However, the yield strength is not greatly affected.

Therefore, to achieve the desired residual stress reduction, the material must be heated to a plastic state to achieve optimal residual stress reduction.^[3] However, increasing the aging temperature increases the risk of precipitate formation and corresponding decreases in strength. Therefore, it

Fig. 7 Compression (C) and tension (T) stress level for each piece of a 2 in. (50.8 mm) thick AA7075 part with uphill quenching and conventional aluminum alloy heat treatment compared to cold and hot water quenching^[13]

Fig. 8 Influence of aluminum alloy aging time on the decrease of AA7XXX yielding stress^[14]

is preferred to conduct uphill quenching within 30 min after quenching, while the yield stress is still low, to provide the optimal residual stress reduction.^[31] Minimal time delay from the conventional quenching to the uphill quenching process is recommended as shown by the data summarized in Table 5.^[3] In addition to maximum reduction in residual stresses, optimal distortion and dimensional stability is obtained.

It has been shown that machining of an AA6061 tube after stress relief by uphill quenching, it is possible to attain an increase of dimensional precision with lower distortion

Table 5 Effect of delay between conventional quenching and uphill treatment on residual stress reduction

than obtainable by conventional water quenching followed by aging that produced much greater distortion after machining.^[26]

A variation of the uphill quenching process involves complex 70mm thick AA7050 aircraft bulkhead die forgings that were cooled in LN₂ to -321°F (-196°C) after solutionizing but instead of immediately heating in high-velocity steam, the cooled part was transferred to a proprietary and undefined quenchant designated as QCW-01 to 302°F (150°C) for 15 min and then cooled to room temperature.^[4] The result was a 71% reduction of residual stress and nearly 30% decrease in machining time results in a substantial reduction in manufacturing costs.

A comparison of hot-water and high-velocity steam as the reheating medium after cryogenic cooling was reported previously. This study showed that quenching aluminum tubes in high-velocity steam resulted in substantially greater residual stress reduction than quenching cryogenically cooled tubes in boiling water.^[26] Comparatively, this result related to residual stress relieve was achieved both before and after aging as shown in Fig. 9 numbered as (3).

UPHILL QUENCHING PROCESS EQUIPMENT

When performing uphill quenching, the use of either a dewar or tank of LN₂ is required. If the parts cannot be uphill quenched immediately after solutionizing, refrigeration equipment capable of maintaining temperatures of parts to at least -17.8°C (0°F) before uphill quenching becomes necessary. Because LN₂ is being used, it is essential that appropriate safety equipment: safety glasses, protective gloves, apron, and shoes are necessary. At no time, should hands, even with gloves, be immersed into the LN₂ media!

In addition, a high-velocity steam chamber (or steam box) for reheating of the parts after cryogenic cooling is also necessary. The cryogenically cooled part is placed

in a fixture in the steam chamber.^[3] The fixture has holes that are sized so that flow of the steam from the incoming steam line will be uniform around the parts being heated. Some characteristics of the steam supply that is necessary for uphill quenching are summarized in Table 6.^[19]

Tubing and connections as well as the steam chamber must be certified for the process temperatures and pressures involved. Furthermore, when heating with steam is performed, heat is lost and condensation of water results, and heating efficiency will be reduced if the condensate is not removed. As discussed in reference,^[13] effective condensate removal is necessary to prevent deposition on the part being heated. One method of accomplishing condensate removal is with the use of a “trap.” Various steam trap designs and operating mechanisms that are beyond the scope of this article except to state that a steam heating chamber must be equipped with a trap for condensate removal.

Figure 10 depicts a laboratory steam chamber used for uphill quenching of test specimen. The system is comprised of a steam boiler with a sufficient pressure to generate a high-velocity steam at the necessary process temperature. Steam temperature as a function of pressure can be readily determined from steam tables such as that shown in Appendix A. Figure 11 illustrates the overall uphill quenching system that includes dewar of LN₂ (not shown in the photo), steam boiler, steam chamber, and data acquisition system.

ADVANTAGES OF THE UPHILL PROCESS

Various methods used for mitigation of residual stresses in aluminum alloys, including major advantages and disadvantages, are summarized in Table 7.^[38] In addition to those advantages enumerated in Table 7, other advantages have been reported. Residual stress reduction, greater than 80% is achieved by uphill quenching with high-velocity steam. These are substantially better than residual stress reductions achieved by a conventional quenching process using either cold (10°C–32°C) or hot (60°C) water or aqueous polymer solutions. If the component is conventionally quenched into an aqueous polymer quenchant followed by uphill quenching (reheating from a cryogenic temperature) using high-velocity steam, further improvements in

residual stress reduction relative to only aqueous polymer quenching without uphill quenching is observed.

It has been reported that the use of liquid helium [–452°F (–268.93°C)] may produce a relatively small increase in strength compared to LN₂ [–196°C (–321°F)].^[19,39,40] Aluminum alloy strength improves significantly with decreasing cryogenic temperature, –100°F to –423°F (–73.4°C to –252.78°C). However, there is little improvement in strength when still lower cryogenic temperatures are used.

Ref. [36] describes the use of perfluoromethyldecalin at its boiling point (instead of high-velocity steam). The structure and physical properties of perfluoromethyldecaline are summarized in Table 8. Residual stress reductions of up to 90% were obtained using boiling

Table 7 Summary of methods for controlling residual stress

Residual stress mitigation method	Advantages	Disadvantages	Reference
Hot water quenching	Significant residual stress reduction	Reduces strength potential of aging significantly	[41]
Overaging	Reduces residual stress slightly but is relatively a simple operation ^d	Reduces strength significantly and does not reduce residual stress significantly	[41]
Heat treatment of rough machined part same as billet	Very high strength. Reduced residual stress.	Significant residual stress remains	[41]
Straightening	Part deformation to desired shape	Creates residual stress; part can deform later. Produces premature fatigue failure or breakage during use.	[41]
High PAG quenchant concentration ^a	Prevents residual stress formation	May reduce strength, but in a controllable fashion by reducing quenchant concentration ^{a,f}	[42]
Uphill quenching	Maximum strength with minimal residual stress	Requires significant process development effort and use of specialized fixtures. Uphill quenching is not commonly used in the industry.	[3]
Selection of a different material or alloy	Some alloys/materials do not develop significant residual stress	May not work well with other design constraints.	[42]
Purchase aluminum in the T651 ^b or T7351 ^c condition	Stretching can reduce residual stress by ~80%; compression can reduce residual stress by ~50% ^c	Generally cannot be done with a finished part due to part complexity. Cannot be done with large parts.	[41]

^aPoly(alkylene glycol)—PAG quenchants are defined in Ref. [22].

^bSolution heat treated, stress relieved by stretching, and artificially aged. Equivalent to T6 and applies to plate and rolled bar except AA2219.

^cSolution treated and specially artificially aged. Applies to AA7075 sheet and plate which have been specially artificially aged for improved stress corrosion.

^dOveraging by annealing for extremely long times causing coarsening of second phases used for strengthening of age- or precipitation-hardened alloys.

^eReference [38].

perfluoromethyldecalin instead of steam as shown in Table 9. From Table 9, it is evident that residual stress reductions increase as the uphill quenching thermal temperature gradient increases.^[31,37]

DISADVANTAGES OF THE UPHILL PROCESS

It is reported that in spite of its success in providing stress relief, uphill quenching suffers from a number of major disadvantages and two of the most significant are that it is a relatively difficult and costly process.^[43] One of the major sources of cost is the cryogenic media and the hardware necessary for its use, particularly the high-velocity steam system whether LN₂ (−320°F) or dry ice (−100°F) is used. The use of lower cost hot water or boiling water instead of high-velocity steam did not provide enough reduction in residual stress to justify the use of the process.^[13,18,31] In addition, the design of the inlet steam nozzles are necessarily complex, which is necessary to assure uniform heat transfer during the heating process, which is a significant contributor to the overall expense of the steam heating process.^[4,36,44] Finally, for optimal results, uphill quenching is typically quite time consuming to perform.

Uphill quenching performs best for parts with larger section sizes. For section sizes less than ¼ in. (6.35 mm),

uphill quenching did not produce a sufficient reduction in residual stress to justify its cost.^[20] A minimum of 1–1.5 in. (25–38 mm) is recommended. However, the greater the section sizes, the larger the steam chamber and boilers necessary to produce the larger quantities of steam that leads to even greater capital and manufacturing costs.^[44]

Minimal delay in transferring parts from the quench to the uphill quenching system is necessary to achieve optimal results. Delays of >3 h can produce substantial reductions in the degree of stress relief produced. If the parts cannot be transferred sufficiently quickly, a suitable refrigeration system will be required adding further to the process cost.

These are significant disadvantages and are the primary reasons why uphill quenching has not gained widespread use in the aluminum heat-treating industry. Nevertheless, there are some applications where its use does justify the cost. Thus, it continues to be used in these niche applications in the industry.

CONCLUSION

Uphill quenching is capable of providing substantial reductions in residual stress. In addition, because of the large reductions in residual stress, increased fatigue life and stress corrosion cracking properties would be expected without significant impact on tensile and yield strength.^[11,13,45] In addition, since uphill quenching typically imparts increased compressive stresses, substantially greater resistance to cracking is expected as well.^[7]

To obtain optimal reductions in residual stress, it is desirable to obtain maximum differences in process temperatures between cryogenic cooling and reheating. Typically, this is achieved with cryogenic cooling in LN₂ followed by high-velocity steam reheating. Attempts to use alternative cryogenic media such as dry ice or to use hot or boiling water do not produce enough reduction in residual stress to justify the process cost.

Table 9 Comparison of variations of the uphill quenching method^[13,36]

Comparative analysis of uphill process types			
Used method	Cooling temperature	ΔT	Stress relief (%)
LN ₂ to boiling perfluoromethyldecalin	−195.6°C [−320°F]	252.8°C [487°F]	>90
LN ₂ to low velocity steam	−195.6°C [−320°F]	117.8°C [244°F]	44
LN ₂ to high speed steam	−195.6°C [−320°F]	188.4°C [371°F]	82
Dry ice to high-speed steam	−37.8°C [−100°F]	103.9°C [219°F]	48
LN ₂ to boiling water	−195.6°C [−320°F]	43.4°C [110°F]	19
Dry ice to boiling water	−37.8°C [−100°F]	43.4°C [110°F]	19

In one case, it was shown that conducting the uphill quenching process in boiling perfluoromethyldecalin did produce even greater reductions in residual stress than high-velocity steam. This was reported to be a favored quenching process for the production of high-precision aluminum mirrors for aerospace application.^[36] However, the expected high cost typical of fluorocarbons precludes its use in most uphill quenching processes.

For thin parts, conventional quenching in aqueous polymer quenchant is a preferred lower cost alternative quenching medium relative to the use of uphill quenching.^[46,47]

Abstract

The current industrial production of aluminum from alumina is based on the electrochemical Hall-Héroult process, which has the drawbacks of high-greenhouse gas emissions, reaching up to 0.70 kg CO_{2-equiv}/kg Al, and large energy consumption, about 0.055 GJ/kg Al. An alternative process is the carbothermic reduction of alumina. Thermodynamic equilibrium calculations and experiments by induction furnace heating indicated that this reaction could be achieved under atmospheric pressure only above 2200° C. Lower required reaction temperatures can be achieved by alumina reduction under vacuum. This was experimentally demonstrated under simulated concentrated solar illumination and by induction furnace heating. By decreasing the CO partial pressure from 3.5 mbar to 0.2 mbar, the temperature required for almost complete reactant consumption could be decreased from 1800°C to 1550°C. Deposits condensed on the relatively cold reactor walls contained up to 71 wt% of Al. Almost pure aluminum was observed as Al drops, while a gray powder contained 60–80% Al and a yellow-orange powder contained only Al₄C₃, Al-oxycarbides and Al₂O₃.

Keywords: Alumina; Aluminum; Carbon; Carbon monoxide; Carbothermic reduction; Vacuum.

INTRODUCTION

Aluminum is the most abundant metallic element found in the Earth's crust, amounting to 8.3% by weight of the crust. Aluminum metal has been first isolated in 1825 by the Danish chemist Hans Christian Ørsted. This metal, particularly its alloys, has become of considerable importance due to its unique properties of lightweight, high-thermal and electric conductivity, and corrosion resistance.^[1] Because of the high calorific value of aluminum, 31 MJ/kg Al, a future important role could be that of an energy carrier and energy storage material. Thus, the well-known alkaline decomposition of aluminum or aluminum alloys, such as Al-Si to release hydrogen:

could be applied for hydrogen fuel cells in the transportation sector.^[23,24] The production of primary (new) aluminum is the largest in volume in the nonferrous metal industry. In 2010 the world primary aluminum production

reached 24 million metric tons, accounting for 1% of the world anthropogenic greenhouse gas emissions, while the production of iron and steel contributed 5.4%. Current aluminum production is based on two main stages, developed in the late 19th century:

- (a) The Bayer process for producing Al₂O₃ from a mixture of minerals composing the deposits of bauxite. A simplified overall equation describing this process is

in which in the above forward reaction, carried out in digesters, the alumina is solubilized to sodium aluminate at temperatures of 140–240°C, while most of the oxides of iron, silicon, and titanium remain insoluble, and are separated as “red mud.” The solution of sodium aluminate is then cooled to 45–70°C, resulting in the reverse reaction of Eq. 2, with precipitation of hydrated alumina, which then is calcined at 1150–1300°C to Al₂O₃.^[24] The Bayer process often requires a stage of mineral beneficiation, which involves the

removal of fines. It coproduces a strongly alkaline waste (red mud), which is a serious environmental hazard (major accident in Hungary, October 4, 2010), and also requires large areas. The Bayer process uses about 25% of the total energy consumption of aluminum production.

- (b) The Hall-Héroult electrolytic smelting process for converting Al_2O_3 to Al. This high-temperature electrochemical process in molten cryolite using sacrificial carbon anodes (releasing CO_2), prepared from calcined coke with pitch as binder, has the drawbacks of considerable environmental pollution due to perfluorocarbon (PFC) release, high-greenhouse gas emissions, reaching $0.70 \text{ kg CO}_{2\text{-equiv}}/\text{kg Al}$ even in modern smelters, and large electrical energy consumption, about 15.4 MWh (or 55.4 GJ) per metric ton Al. If the CO_2 emission from coal-fired electric power generation is included, the Hall-Héroult process may cause the emission of up to $8 \text{ kg CO}_{2\text{-equiv}}/\text{kg Al}$, while the Bayer process uses up to 0.035 GJ/ton Al .^[1,14] In the present study, thermochemical equilibrium calculations were made using the FACTSAGE and HSC computer codes.^[6,22] Reaction enthalpies were derived using the data of the National Institute of Standards and Technology (NIST).

REACTIONS AT ATMOSPHERIC PRESSURE

Considerable efforts had been applied to produce aluminum from alumina by the alternative process of the carbothermic reduction of alumina, according to the overall Eqs. 3 and 4,^[5,19,25,18,3,8,4,10]

Thermodynamic equilibrium calculations and experiments by induction furnace heating indicated that these reactions could be achieved under atmospheric pressure only above 2200°C .^[10] The reduction of alumina to Al under Ar and CH_4 at atmospheric pressure according to Eq. 4 had been studied by radio frequency generated induction-coupled plasma, at above $10,000^\circ\text{C}$. The reduction products collected on a water-cooled surface contained Al and Al_4C_3 .^[21] The drawback of the very high-reaction temperature is partly compensated by producing syngas as a valuable byproduct and by not requiring vacuum pumping.^[12] Experiments using mixtures of Al_2O_3 and charcoal under Ar at atmospheric pressure in a quartz-tube reactor heated for 30s pulses from an 18kW induction furnace resulted in the condensation on the cold region of the reactor tube of elementary Al, as well as variable amounts of Al_2O_3 , Al_4C_3 , and the oxycarbides Al_2OC and $\text{Al}_4\text{O}_4\text{C}$. In the best result in one of the experiments, the Al content

in the deposit was 29%.^[10,11] A moving-bed electric arc furnace for carbothermic reduction of Al_2O_3 with petroleum coke was patented, producing Al containing only 9–12% Al_4C_3 .^[15,16]

REACTIONS UNDER VACUUM

According to the Le Chatelier principle, the extent of a gas producing chemical reaction should be favored by a decrease in the total gas pressure. Thus, under vacuum conditions, the equilibrium of Eq. 3 should be shifted to the right and the onset temperature for the metal production should be significantly lowered. Thermodynamic equilibrium calculations indeed predict the advantage of much lower required reaction onset temperatures by alumina reduction under vacuum, as shown in Table 1.^[11,17] This had been experimentally demonstrated under simulated concentrated solar illumination and by induction furnace heating.^[27,7] The direct vacuum carbothermic reduction has also been applied to the alumina contained in bauxite.^[9,28,13] In a study of the vacuum carbothermal processing of low-iron bauxite, a mixture of calcined bauxite and charcoal heated up to 1600°C at an initial pressure of 0.01 mbar in a corundum reactor tube resulted in the condensation of $\beta\text{-SiC}$, $\text{Al}_4\text{O}_4\text{C}$, Al, Al_4C_3 , and $\alpha\text{-alumina}$ on the cold wall of the reactor, in a residue of $\alpha\text{-alumina}$, TiC, and FeO in the hot zone of the reactor.^[9] In a related study, the production of Al-Si alloys had been studied by the vacuum carbothermal reduction of bauxite tailings containing mainly Al_2O_3 , SiO_2 , and Fe_2O_3 in a graphite furnace at pressures down to 10^{-9} bar and temperatures up to 2000°C , resulting in the formation of an Al-Si-Fe alloy, as well as carbides, elementary Al, and Si. The proposed mechanism involves the intermediate formation and decomposition of carbides, in which the presence of Fe seemed to have a catalytic effect.^[28]

Table 1 Calculated onset temperatures for Al(g) production as function of vacuum pressure in the system $\text{Al}_2\text{O}_3 + 3\text{C}$

Pressure, bar	Temperature, K
1 bar	2258
0.5 bar	2190
0.1 bar	2037
0.01 bar	1855
1 mbar	1703
0.1 mbar	1575
0.01 mbar	1465
0.001 mbar	1370

INDUCTION FURNACE EXPERIMENTS

Experiments with induction furnace heating, using a 25 kW desktop Induction Heater, at temperatures of 1400–1800°C, an argon carrier gas flow rate of 100 ml/min, a pumping speed of 250 m³/h, and an average CO partial pressure from 0.03 mbar to 0.35 mbar were conducted. The experimental reactor was built at the Solar Research Unit, Weizmann Institute of Science. Details of an earlier experimental setup and of the reaction procedure had been reported.^[27] In addition to the gas chromatograph, the setup has now been fitted with an IR gas analyzer (Ultramat 23, Siemens, Germany), as shown in Fig. 1. Stoichiometric reaction mixtures were prepared from beech charcoal (Chemviron) and 10-μm alumina powder (Sigma-Aldrich). Sugar (sucrose, 10wt.%) was added as a binder. To prevent blowing losses, the mixture was pressed in reaction pellets. The pellets were then heated to 165°C, presumably resulting in caramelization of the sugar to sticky high-molecular weight compounds, which prevented the release of dust particles. Heating time up to the desired reaction temperature lasted 10–15 min and heating was stopped when the CO release reached zero. In tests at temperatures of about 1500–1600°C, with CO partial pressure 0.2–0.3 mbar, and at a temperature of 1800°C—with average CO partial pressure 3.5 mbar—the reactants were almost completely consumed in the forward reaction of alumina reduction, with only minor amounts of solids remaining in the reactor crucibles. At lower temperature or high-pressure residual amounts in the crucible were significantly larger and consisted of Al₄C₃, Al₄CO₄, graphite, and at the lowest test temperature, also, unreacted pellets covered by a carbide and oxycarbide layer (Table 2). Elementary aluminum could be observed as aluminum drops, or from 60–80% Al content in a gray powder (Fig. 2). A yellow-orange powder contained aluminum carbide, oxycarbide, and at lower

reaction temperature also corundum, which could be formed together with aluminum from volatile aluminum suboxide Al₂O released as a byproduct if the temperature of the forward reaction was not high enough. The content of elementary Al in the deposits (59–71 wt.%) was measured by XRD quantitative analysis of profile-fitted peaks (see Table 3), using a Rigaku Ultima III diffractometer (Cu target), with data analysis performed by Jade 9.1 software. In the XRD spectrum shown in Fig. 3, the products identified are indicated below the measured spectrum by the Powder Diffraction File (PDF) numbers and their major diffraction peaks, as listed by the ICDD (International Center for Diffraction Data). Aluminum vapors left the crucible and condensed on colder surfaces of the reactor, but which were still hot enough for the reverse reactions of carbonization and reoxidation of Al. The content of elementary aluminum at the deposition site depends on the rates of the reverse reactions and predominates in the outer layers of the deposit. The content of elementary aluminum at the deposition site depends on the rate of the reverse reaction.

DISCUSSION

A major issue involved in aluminum carboreduction in vacuum is the actual electrical energy consumed by the vacuum pumps, which is substantially higher than the theoretical work of isothermal compression. The minimum theoretical work in isothermal expansion of the product gases, assumed to be brought from atmospheric pressure P_0 to vacuum pressure P is

$$W = nRT_{\text{reaction}} \ln P_0/P [\text{kJ/mol Al}_2\text{O}_3] \quad (5)$$

where n is the increase in the number of gas moles formed per mole of aluminum oxide including the amount of argon

Corundum, Al ₂ O ₃	5.4

carrier gas moles, if any, $R = 8.314 \times 10^{-3} \text{ kJ K}^{-1} \text{ mol}^{-1}$ is the gas constant and T_{reaction} is the absolute temperature of the reaction. The total net enthalpy input can be estimated from

$$\Delta H = H_{2\text{al}}(T_{\text{reaction}}) + H_{3\text{CO}}(T_{\text{reaction}}) + H_{\text{kAr}}(T_{\text{reaction}}) - H_{\text{Al}_2\text{O}_3}(20^\circ\text{C}) - H_{3\text{C}}(20^\circ\text{C}) - H^{\text{kAr}}(20^\circ\text{C}) \quad (6)$$

The hypothetical heat input for the reaction of Eq. 3 to $2\text{Al}(\text{g}) + 3\text{CO}(\text{g})$ at $T = 1800^\circ\text{K}$ without carrier gas was calculated to be 2,242 kJ/mol Al₂O₃. The minimum work of expansion from normal pressure to $P = 10^{-4}$ bar is 689 kJ/mol Al₂O₃. The total theoretical energy input

would be 0.054 GJ/kg Al, comparable to that in modern smelters by the Hall-Héroult process of about 0.052 GJ/kg Al.^[1] At higher reaction temperature 2000°K and 1 mbar pressure, the total theoretical energy is 0.0522 GJ/kg Al, which also is similar to the energy consumption in the industrial process. However, the real pumping energy consumption can significantly exceed the theoretical work of exothermal expansion and at a CO partial pressure of less than 0.2–0.3 mbar (depending on amount of carrier gas used), the actual pumping energy would exceed the energy consumed in the industrial Hall-Héroult process, which in itself is at least two times higher than the theoretical figure, which is 0.023 GJ/kg Al (Beck 2011). The pumping energy was estimated (according to the Vacuum Technology Book 2011) for a dry vacuum system based on a Roots blower and a multi-stage Roots backing pump. As shown in Fig. 4, to attain a pumping energy lower than the energy consumption in the current industrial process, the operating pressure must be higher than about 0.2 mbar. In order that the total energy input into the process (pumping plus the process heat and the sensible heat to bring the reactants to the reaction temperature) will be similar

Fig. 3 Upper section: XRD spectrum of deposit on the relatively cold surface of the reactor. Bottom section: Identified products with PDF numbers and their major diffraction peaks

to the industrial process (curve 5 in Fig. 4), the operating pressure must be higher than about 0.2 mbar (curves 3a,b,c. in Fig. 4; curve 3b was taken as an example representing 1:1 molar ratio of argon as carrier gas to CO). In order that the total energy input into the process (pumping that consumes electricity plus the process heat and the sensible heat to bring the reactants to the reaction temperature, which is contributed by solar energy; see curves 4a,b,c in Fig. 4) will be competitive to the current industrial process, the CO partial pressure should be higher than 1 mbar. According to the thermodynamic estimations, this entails an increase of about 200°C in the reaction temperature compared to operating at about 0.2 mbar. That was proved experimentally when the forward reaction was successfully completed during 20 min as the CO partial pressure was increased from 0.18 mbar up to 3.79 mbar and the reaction temperature was increased from 1602°C to about 1809°C (see tests 3 and 7 in Table 2).

The main difficulty in the carbothermic reduction of alumina is of preventing the reoxidation or carbonization of the gaseous aluminum that condenses on the walls of the reactor where the temperature is still sufficiently high to promote the reverse reaction (e.g., the condensation temperature of aluminum vapors at 1 mbar pressure is 1546°C). XRD analyses of samples taken from different sites in the reactor confirm that the amount of elementary aluminum in the deposit strongly

Fig. 4 Real energy consumption for production of 1 kg Al/h as function of the CO partial pressure. 1-theoretical work for exothermal expansion; 2-net total process energy (chemistry plus sensible heat), 3-pumping energy; 4-total energy; 5-energy consumption in Hall-Héroult industrial electrolytic process (a-55.5 mol CO + 0 mol Ar/h, b-55.5 mol CO + 55.5 mol Ar, c-55.5 mol CO + 100 mol Ar)

depends on the temperature at the specific site. The problem could be that at a continuous irradiation of the reaction crucible to a high temperature (1800°C), the forward reaction of Eq. 3 is too fast relative to the rate of pumping out of the CO and of the Ar carrier gas. As a result aluminum vapor condenses on hotter areas and the residence time of the CO molecules is sufficient to allow them to react back. It is therefore important to design the pumping speed appropriately and in addition to the speed at the inlet of the pump, the resistance to flow in the connecting pipes, traps, etc., should be considered in order to obtain fast removal of the gases from the reactor. One possible approach would be to realize a reactor design, which maximally decreases the hot transition zone between the high-temperature reaction zone and the water-cooled area, where most of aluminum vapor should be condensed. Concentrated solar energy could be used to provide the energy required to preheat the reactor and the reactants to the operating temperature and to supply the endothermic energy required for the chemical reaction.^[18,17]

Wear Behavior of Aluminum Alloys at Slow Sliding Speeds

M. Ruiz-Andrés, A. Conde, J. de Damborenea, and I. García

Department of Surface Engineering, Corrosion and Durability, National Center for Metallurgical Research (CENIM-CSIC), Madrid, 28040, Spain

Abstract

The investigated slow sliding speeds presented in this work enable the understanding of the wear behavior on aluminum alloys and could possibly facilitate the completion of the previously proposed wear mechanism map for aluminum at this slow sliding speed range. Dry sliding block-on-ring wear tests were carried out on aluminum alloys, AA5754 (Al-Mg), AA6082 (Al-Mg-Si), and AA7075 (Al-Zn-Cu), at a very slow sliding speed range (<0.01 m/s). A bearing steel ring of AISI 52100 was used as the counterbody. Tests were performed at varying contact pressures, 20, 100, and 140 MPa, and sliding speeds ranging from 0.001 to 1.5 m/s. The wear tracks and debris collected were examined by scanning electron microscopy (SEM), energy-dispersive spectroscopy (EDS), and X-ray diffraction (XRD), with the aim of analyzing their morphology and composition. At relatively slow sliding speeds (>0.01 m/s), the specimens exhibited a wear process placed at the mild wear regime, characterized by oxidation and delamination mechanisms of both the aluminum specimen and the steel ring. However, at very slow speed range (<0.01 m/s), an increase in the wear rate and the friction coefficient is observed for all of the aluminum alloys, thus suggesting that an alternative wear mechanism could be taking place.

Keywords: Aluminum; Unlubricated wear; Wear mechanisms.

INTRODUCTION

Aluminum alloys are known for their suitable mechanical properties, mainly due to their high strength-to-weight ratio.^[1,2] Therefore, multiple experimental studies on dry sliding wear of aluminum alloys have been conducted in recent decades due to the interest in the ever-increasing use of light aluminum alloys and composites in engineering applications.^[3–7] However, it is generally agreed that aluminum alloys present a low sliding wear resistance when mated against several materials.^[8–11]

The first wear mechanism map for aluminum alloys that allowed a qualitative prediction of wear behavior on a broad range of loads and sliding speeds was proposed by Antoniou and Subramaniam.^[12] Later on, Y. Liu, et al.^[13] performed a quantitative wear mechanism map for aluminum alloys. All of these maps were based on the primary wear mechanisms map set forth by Lim and Ashby^[14,15] for steels.

Zhang, et al.^[16] carried out wear tests on various aluminum alloys, sliding on air and under nonlubricated conditions. They published an empirical wear mechanism map as a function of applied load and sliding speed, showing that the transition from a mild to severe wear regime is determined by wear mechanisms changes, such as mechanical mixing–oxidation, delamination, and galling.

In aluminum alloys, and in other engineering materials in general, the transition from a mild to severe wear regime depends largely on the surface temperature rise due to the heating produced by friction under dry sliding conditions, specifically, when this temperature exceeds 0.4 times the melting point.^[15,17] Many studies show that the temperature rise at local contact areas can influence wear and friction during the wear test.^[18–21] In addition, Alpas and coworkers^[16,23–25] stated that any transition that occurred in the wear rate also depended on the temperature reached during sliding.

Sliding wear damage of metals is usually classified as either mild or severe wear. The mild wear term is used to refer to damage localized to the contact areas. Several studies^[26,27] propose two different sub-regimes within this mild wear regime for aluminum alloys. The first subregime is characterized by a mixing–oxidation behavior that occurs at low sliding speeds. In this case, the worn surfaces are covered by a mechanically mixed and oxidized tribolayer. In the second subregime, the formation of debris by adhesive wear^[16] prevails. Metallic flake-like debris is produced as a result of metal transfer and back-transfer processes between the aluminum and the counterbody. The mechanism operating within the mild regime acts on the majority of it and the transition between the subregimes occurs gradually as the operating conditions change. As a consequence, a gradual change in

the appearance of the worn surfaces and the morphology of the debris collected is observed from mixing-oxidation to adhesive.^[16]

Conversely, so-called severe wear involves massive surface damage, characterized by a large material transfer and back-transfer between the sample and the counterbody.^[28,29] The transition from a mild wear regime to a severe wear regime begins when the surface temperature at the contact area exceeds the recrystallization temperature of the material—around $0.4 T_m^{[30]}$ —and leads to a significant increase in the wear rate.

Most of these works on the dry sliding wear of aluminum alloys and composites have been performed in a wide range of sliding speeds, but hardly any have focused on the very slow sliding speed interval. In this work, wear tests were performed in a very slow sliding speed range in order to make possible the completion of the wear mechanism map for aluminum alloys previously proposed by Zhang and Alpas.^[22] Three aluminum alloys representative of the most used alloys, namely, Al-Mn non-heat-treatable AA5xxx, Al-Mg-Si AA6xxx, and high strength Al-Zn AA7xxx, were selected for this work.

EXPERIMENTAL METHODOLOGY

Several commercial wrought aluminum alloys, namely, AA5754 (Al-Mg alloy), AA6082 (Al-Mg-Si alloy), and AA7075 (Al-Zn alloy), were studied under wear testing. The former is a non-heat-treated alloy in H111 temper conditions with a hardness of 57 HV, and the other two alloys are heat-treated alloys both in T6 temper conditions with 93 HV (AA6082) and 175 HV (AA7075). The aluminum alloys were supplied with a sheet form thickness of 1.5 mm. The sheets were cut into $6.35 \times 15.8 \text{ mm}^2$ coupons. The larger dimension was aligned with the manufacturing rolling direction of the sheet. Therefore, the sliding direction during the wear test was parallel to the rolling direction of the sheets. The average surface roughness (R_a) of each aluminum alloy measured in each sliding direction was $0.16 \pm 0.01 \mu\text{m}$, $0.09 \pm 0.01 \mu\text{m}$, and $0.15 \pm 0.03 \mu\text{m}$ for AA7075, AA 6082, and AA5754, respectively. The coupons were firmly fixed to a standardized steel block by an epoxy adhesive. AISI 52100 bearing steel (100Cr6 steel, 62 HRC) rings were used as counterbodies. The outer diameter of the rings was 35 mm. The surfaces of both block and ring were degreased with a commercial cleaner, rinsed in tap water followed by deionized water, and dried by blowing warm air on them immediately before wear testing.

The wear tests were conducted in a Bruker-CETR-UMT-2 microtribometer using a block-on-ring configuration according to the ASTM G77-05 standard test method in which the ring was rotating on a horizontal axis. Tests were performed in ambient air of 50% relative humidity, without lubrication and at room temperature,

for a total sliding distance of 200 m. In accordance with Hertzian theory of nonadhesive elastic contact for line contacts (the length of the contact line is equal to the block width, 6.35 mm), initial contact pressures of 20, 100, and 140 MPa—corresponding to 2.58, 58.05, and 110 N, respectively—were applied. According to the classical criteria for elastic regime, the asperities deformation can be considered elastic if the contact pressure is below 0.4 times the hardness value of the softer mating material.^[31] The maximum load applied was 110 N, which corresponds to a maximum contact pressure of 140 MPa and a mean contact pressure of 110 MPa, taking the following values for the AA 7075 block (E 72 GPa, $\sqrt{0.33}$) and the 100Cr6 ring (E 210 GPa, $\sqrt{0.3}$). Therefore, the mean contact pressure of 110 MPa is lower than 0.4 times the hardness of the softer material of the pair (AA 7075), which corresponds to 224 MPa. The other two Al alloys—AA5754 and AA6082—present similar results; that is, $P_m < 0.4H$. Consequently, the operational parameters chosen to carry out this work are in the elastic regime for asperities deformation. A sliding speed range between 0.001 and 1.5 m/s was used. For this range of speed, a steady-state temperature distribution is assumed for both mating bodies as the Peclet number is lower than 1.^[14,15] Wear tests were performed in triplicate and results are provided by means of the average value and standard deviation.

The aluminum alloy wear volume loss was determined by means of the width of the scar after the completion of each test. The mathematical expression used was provided by ASTM G77-05 as follows:

$$\text{Scar volume} = \frac{D^2 \cdot t}{8} \left[2 \cdot \sin^{-1} \left(\frac{b}{D} \right) - \sin \left(2 \cdot \sin^{-1} \left(\frac{b}{D} \right) \right) \right],$$

where t is the block width (mm), D is the ring diameter (mm), and b is the average scar width (mm).

The aluminum alloy wear tracks were examined by scanning electron microscopy (SEM) equipped with an energy-dispersive spectroscopy (EDS), in order to analyze the wear processes and the fundamental mechanisms. Wear debris was collected and examined by SEM, EDS, and X-ray diffraction (XRD) to identify their composition and phases. XRD analyses were performed using a Cu-K α monochromatic radiation with a wavelength of $\lambda = 1.54 \text{ \AA}$.

Some specimens were cut after the wear tests to show the cross section beneath the wear track. Hardness measurements at several depths of the wear track were performed using a NanoTest 550 Micro Materials Ltd nanoindenter with a Berkovich diamond tip. Tests were carried out at an indentation depth of 840 nm. The local hardness and elastic modulus results were estimated using the loading and unloading curves via the standardized Oliver-Pharr methodology.^[32]

RESULTS

Effect of Sliding Speed and Contact Pressure on the Coefficient of Friction

The average values of the coefficient of friction (COF) for each alloy (AA5754, AA6082, and AA7075) as a function of sliding speed and contact pressure are shown in Fig. 1. At 20 MPa, the COF values for the AA5754 alloy are higher than those measured in the other two alloys (AA6082 and AA7075). Some differences can be observed among the mean COF value trends in the three studied alloys, although they should not be considered statistically significant (Fig. 1a). The COF values for AA5754 decrease steeply, whereas the COF values for AA7075 decrease less sharply to 0.1 m/s. At 0.5 m/s, the COF values increase slightly and drop again at speeds higher than 1 m/s. Conversely, the COF values for the AA6082 alloy do not display the same decreasing trend within the analyzed sliding speed range.

COF values recorded during the tests performed at higher contact pressures of 100 and 140 MPa, respectively, are shown in Figs. 1b,c. In both cases, the COF values for

AA5754, AA6082, and AA7075 tend to slightly decrease at a sliding speed up to 0.5 m/s, where the COF values clearly decrease. Although this diminishing trend may be not statistically significant, this variation in the trend for the COF values suggests that a change in the wear mechanism might take place. It is noteworthy that, as occurred at 20 MPa, the COF values for AA5754 are higher than the values measured for AA6082 and even higher than those obtained for AA7075, which displays the lowest values.

The influence of the contact pressure on the COF of the AA7075 alloy at the slowest sliding speed evaluated, 0.001 m/s, can be seen in Fig. 2. Initially, the COF values are higher and tend to gradually decrease down to 50 MPa. Thereafter, the COF remains steady regardless of the contact pressure applied. This result is in agreement with those shown in Fig. 1, which shows that for any sliding speed, the higher the contact pressure, the lower the COF values.

Effect of the Sliding Speed and Contact Pressure on Wear Rate

The wear rate for the three aluminum alloys studied (AA5754, AA6082, and AA7075) at different sliding

Fig. 1 Coefficient of friction versus sliding speed diagram for AA5754, AA6082, and AA7075 at contact pressures of (a) 20 MPa, (b) 100 MPa, and (c) 140 MPa

Fig. 2 Coefficient of friction versus contact pressure diagram for AA7075 at a sliding speed of 0.001 m/s

speeds and contact pressures is shown in Fig. 3. At the lower contact pressure, 20 MPa, the wear rate values of the three aluminum alloys slightly decrease with sliding speed (Fig. 3a). The wear rate of the AA5754 and AA7075 alloys presents a stronger dependence on the sliding speed than the AA6082 alloy does. However, the minimum wear rate value is reached at different sliding speeds for each aluminum alloy. In the case of the AA5754 and AA7075 alloys, the minimum wear rate values are reached at 0.5 and 1 m/s,

respectively. Once the minimum is reached, the wear rate increases concurrently with the sliding speed. In alloy AA6082, the minimum wear rate value is reached at the highest sliding speed; it should be noticed that wear rate varies approximately from $5.03 \cdot 10^{-3}$ to $8.18 \cdot 10^{-5} \text{ mm}^3/\text{m}$.

Figure 3b shows the wear rate evolution as a function of sliding speed when the contact pressure is 100 MPa. The wear rate exhibits a strong dependence on sliding speed in the three aluminum alloys tested. The wear rate values decrease with sliding speed, indicating the existence of a threshold value from which the wear rate values increase with a steep slope. Likewise, it is interesting to note that the effect of sliding speed on the wear rate is similar regardless of the aluminum alloy analyzed and the minimum wear rate is reached at the same sliding speed, 0.5 m/s. At 100 MPa, the wear rate varies from $4.36 \cdot 10^{-2}$ to $1.76 \cdot 10^{-3} \text{ mm}^3/\text{m}$, which is approximately one order of magnitude higher than the wear rate estimated at 20 MPa.

Finally, Fig. 3c shows the evolution of the wear rate versus sliding speed when a contact pressure of 140 MPa is applied. At the higher contact pressure evaluated, the behavior is similar to that obtained at 100 MPa. For the three aluminum alloys, the wear rate decreases with sliding speed, reaching the minimum value at 0.5 m/s. At higher sliding speeds, the wear rate increases again. These results cover wear rate values from $8.50 \cdot 10^{-2}$ to $2.37 \cdot 10^{-3} \text{ mm}^3/\text{m}$.

Fig. 3 Wear rate versus sliding speed diagram for AA5754, AA6082, and AA7075 at contact pressures of (a) 20 MPa, (b) 100 MPa, and (c) 140 MPa

According to the wear rate criterion proposed by Zhang and Alpas,^[16] two wear regimes could be identified in Fig. 3 based on the wear damage caused on the surfaces of the three aluminum alloys; that is, a mild wear regime and a severe wear regime.

At a contact pressure of 20 MPa, the wear damage is low and less extensive on the surfaces. Based on this criterion, a mild wear regime thus occurs at these conditions in the three aluminum alloys.

At 100 MPa, the wear rate values increase more than one order of magnitude with regard to 20 MPa. Firstly, severe wear is exhibited at slow sliding speeds ranging from 0.001 to 0.05 m/s. In this case, both the damage of the worn surfaces and the amount of material loss are perceivable to the naked eye. From 0.05 m/s onwards, the wear rate is significantly lower. The amount of material removed drops and is directly related to a change in the wear regime from severe to mild wear. Within this mild wear regime, a variety of trends are also observed. From 0.05 to 0.5 m/s, the wear rate decreases down to a clearly observed minimum at 0.5 m/s. From this sliding speed onwards, the wear rate increases again but the material loss is still low.

Finally, at 140 MPa, the material loss is in general higher than that obtained at 100 MPa and at other sliding speeds, with a wear damage that is easily noticeable to the naked eye. As a consequence, extensive damage is shown on the surfaces of the three alloys. However, some differences are observed depending on the aluminum alloy as a function of sliding speed. In the case of the AA5754 and AA6082 alloys, a severe wear regime is exhibited. Alloy AA7075 experiences severe wear according to the amount of material removed at the speed range from 0.001 to 0.1 m/s. Conversely, from 0.1 m/s onwards, the wear rate drops and enters the mild wear regime and then goes down to 0.5 m/s, where the minimum wear rate value is reached. From 0.5 m/s onwards, the wear rate increases again up to the highest sliding speed, 1.5 m/s. Despite this increase, the measured wear rate values still remain within the mild wear regime.

As previously described in Fig. 3, the behavior of the aluminum alloys is similar regardless of the contact pressure applied at the very slow sliding speeds. The results shown in the case of the alloy AA7075 are therefore assumed to be representative of the behavior of the other two aluminum alloys studied in this work. Figure 4 shows the influence of contact pressure on the wear rate of the alloy AA7075 alloy at a very slow sliding speed of 0.001 m/s. The wear rate values increase gradually with contact pressure. The wear rate range is about two orders of magnitude higher, from $1.5 \cdot 10^{-3} \text{ mm}^3/\text{m}$ at 20 MPa to $8.50 \cdot 10^{-2} \text{ mm}^3/\text{m}$ at 140 MPa. Therefore, according to the material loss criterion at a very slow sliding speed, severe wear takes place in the aluminum alloys.

The literature indicates that a change in the wear rate curve slope could indicate transitions between wear

Fig. 4 Wear rate versus contact pressure diagram for AA7075 measured at a sliding speed of 0.001 m/s

regimes.^[10,26,33] Therefore, it seems clear that no transition occurs at the slowest sliding speed range evaluated in this work, thus showing that the wear process takes place in only one wear regime, the severe wear regime.

Characterization of Worn Surfaces and Wear Debris

A preliminary study of the steel rings was carried out to evaluate their degree of wear during the tests. Figure 5 presents the optical microscope images of the surfaces for the AISI52100 rings after sliding against AA7075 at 100 MPa and at three sliding speeds, namely, 0.001, 0.1, and 1.5 m/s. One can note the different surface appearance as a function of sliding speed. As the sliding speed increases, the dark tribolayer that covers the contact area tends to diminish. For instance, at 0.001 m/s, it can be observed that the worn surface is almost covered by a dark tribolayer, whereas there is no tribolayer at 1.5 m/s. The average roughness measurements taken on the steel ring surfaces vary between approximately 180 and 220 nm, regardless of the sliding speed applied. Therefore, it seems reasonable to assume that the wear of the rings can be considered negligible.

As previously discussed, at a contact pressure of 100 MPa, severe and mild wear regimes are both markedly distinguished by the wear rate values as a function of sliding speed for the three aluminum alloys. Because the three studied alloys present similar morphologies of their wear tracks and debris when tested under the same load and sliding speed conditions, for the sake of clarity the following results are detailed using only images taken for AA7075.

Some clear differences in the SEM images (Fig. 6) of the worn surfaces for the alloy AA7075 analyzed at 100 MPa and 0.001, 0.1, and 1.5 m/s sliding speeds are observed. In Fig. 6a, at 0.001 m/s, the wear track displays longitudinal grooves parallel to the sliding direction. Moreover,

Fig. 5 Optical microscope images of worn surfaces for AISI52100 rings tested against AA7075 at 100 MPa and at sliding speeds of (a) 0.001 m/s (b) 0.1 m/s, and (c) 1.5 m/s

shallow craters are observed along the wear tracks. The literature describes both characteristics as typical of a mild wear regime.^[34] However, the worn surface exhibits a large amount of debris piled up along the track and the wear rate values are higher than $6 \cdot 10^{-2} \text{ mm}^3/\text{m}$, suggesting a wear process within the severe wear regime.^[16] The EDS analysis on this worn surface indicates a surface containing oxygen, aluminium, and iron (Fig. 6b). The presence of aluminum–iron oxides could be a consequence of the mechanical mixing of the removed and transferred material during the test.

The worn surface of alloy AA7075 tested at 100 MPa and 0.1 m/s displays (Fig. 6c) longitudinal grooves along

the wear track parallel to the sliding direction. Moreover, debris is observed throughout the worn surface. The EDS analysis of the wear track again reveals the presence of oxygen, aluminium, and iron, also indicating the presence of an aluminum–iron oxide (Fig. 6d). As occurs in the case of the slowest sliding speed, the worn surface and the debris appearance correspond to a mild wear regime.

Finally, Fig. 6e presents the damage caused at 100 MPa and the higher speed, 1.5 m/s. The surface depicts extruded ridges, removal of material, and abrasion marks related to ploughing in the sliding direction. The worn surface shows evidence of noticeable surface damage with a metallic and shiny appearance related to severe plastic deformation. The lack of fine dark colored debris on the wear tracks, as occurs at slower sliding speeds, is interesting. Figure 6f shows the EDS analysis of the worn surface, which confirms the main presence of aluminum, with lower contents of iron and oxygen. In this case, the ratio Al/Fe is half of the ratio measured at the lower sliding speeds.

The debris produced during each test was collected and then analyzed by SEM. At 100 MPa and 0.001 m/s, a great amount of debris is clearly visible to the naked eye. The powder has an appearance of fine dark particles mixed with larger flake-like particles with a metallic shine. At higher magnifications, SEM analysis reveals fine particles of $\sim 5 \mu\text{m}$ (Fig. 7a). Flake-like particles in a lower quantity are also observed. The size of these flakes particles is about $400 \mu\text{m}$ (Fig. 7a). EDS analysis of this debris shows oxygen, aluminium, and iron species due to the material transfer from the ring to the block during the tests. The XRD diffractogram corresponding to the debris is shown in Fig. 7b. The diffraction peaks are placed at 2θ values of 38° , 44° , 65° , and 78° and correspond to the planes (111), (200), (202), and (311) of Al, respectively. Additionally, a small diffraction peak is observed at 36° , which could correspond to either the (202) plane of magnetite (Fe_3O_4) or to an aluminum/iron oxide (AlFe_2O_4).

The SEM image of the debris produced at 100 MPa and 0.1 m/s is shown in Fig. 7c. Only fine particles ($< 5 \mu\text{m}$) are observed. The EDS analysis presents a composition similar to that at lower sliding speeds, revealing the presence of oxygen as well as aluminum and iron. The XRD diffractogram does not show a clear peak, thus suggesting that the debris of the alloy AA7075 produced at these conditions is amorphous (Fig. 7d).

Finally, the analysis of the collected debris produced during the wear test at 100 MPa and 1.5 m/s reveals that there are only flake-like shape particles with a shiny appearance (Fig. 7e). This debris morphology is related to an adhesive wear mechanism that takes place with high material transference.^[4] The corresponding diffractogram in Fig. 6f displays several peaks at 38° , 44° , 65° , and 78° , which correspond to the Al planes (111), (200), (202), and (311), respectively, without traces of magnetite or other aluminum–iron oxides.

Fig. 6 SEM images of worn surfaces and EDS spectra for AA7075 measured at 100 MPa and at sliding speeds of (a)–(b) 0.001 m/s (c)–(d) 0.1 m/s, and (e)–(f) 1.5 m/s

DISCUSSION

At the relatively low contact pressure of 20 MPa, almost no debris is generated during the tests and a low level of damage is produced on the worn surfaces regardless of the sliding speed used. Notwithstanding, the contact surfaces are partially covered by a dark colored layer, suggesting the presence of some kind of iron or aluminum–iron oxide as a result of the transfer process. The results of the wear track morphology and debris (Fig. 8) are thus in agreement with the wear rate criterion followed,^[16] indicating that a mild wear regime takes place.

Conversely, the wear mechanism changes when the tests are performed at the highest contact pressures (100 and 140 MPa). Similar extensive surface damage is obtained in both cases.

More specifically, at 100 MPa the wear rate can be grouped into two different regions depending on the sliding speed, thus suggesting distinct wear modes. In Fig. 3b, from 0.001 to 0.05 m/s it can be noted that a substantial amount of material is removed. The wear rate indicates a high degree of damage related to the severe wear regime,^[35]

but the worn surface appearance and the debris features are typical of a mild wear regime.^[16] For sliding speeds above 0.5 m/s, a clear variation in the morphology is observed, although the wear rate remains in the mild wear region. However, visible is the increasing evolution of the wear rate results. Therefore, it seems reasonable to assume that the wear rate increases even at higher sliding speeds and consequently enters the severe wear regime.

As is well known, heat input is sufficient to promote a transition between wear regimes. In this sense, both the contact pressure and the sliding speed are also relevant parameters during surface heating. Some authors have reported that when a critical temperature—the recrystallization temperature—is achieved, the transition from mild wear to severe wear occurs.^[14,36] Moreover, Mahato, et al.^[33] coined the term “post severe oxidative wear regime” to refer to a wear mechanism exhibited at high sliding speeds showing wear rates corresponding to a severe regime but with worn surfaces covered by aluminum oxides.

In this work, however, it does not seem reasonable to consider that the surfaces have experienced heating during the wear tests performed because the mild wear

Fig. 7 SEM images and XRD diffractograms of wear debris collected from AA7075 at 100 MPa and at sliding speeds of (a)–(b) 0.001 m/s (c)–(d) 0.1 m/s, and (e)–(f) 1.5 m/s

morphology of the damage occurs at very slow sliding speeds (0.001 to 0.05 m/s) and 100 MPa. Moreover, solving the equation described elsewhere,^[36] the flash temperatures have been estimated for the sliding speeds and the pressure contact evaluated. As can be seen in Fig. 9, the temperature reached during the wear tests can be considered practically negligible in relation to the sliding speed range tested.

The relation of the wear rate to the sliding speed for aluminum alloys was explained by several authors as a consequence of two effects that compensate for each other.^[16,37] On the one hand, strain hardening takes place, thus reducing the wear rate as the sliding speed increases. On the other hand, this effect is counterbalanced by the softening of the worn surfaces as a result of frictional heating. Figure 10 shows the hardness and elastic modulus measured on the cross sections corresponding to the wear tracks of AA7075 after tests performed at sliding speeds of 0.001, 0.05, and 1.5 m/s. It can be observed that

the hardness increased in all cases compared to the initial value. However, it should be noted that there is no significant hardening as the sliding speed increases from 0.001 to 0.5 m/s. On the contrary, a softening effect on the aluminum alloy surface is observed (Fig. 10), where a decrease in the hardness and the elastic modulus of the AA7075 surface at 1.5 m/s is clearly perceived.

The above evidence suggests, therefore, that the transition from severe to mild wear observed at very slow sliding speeds is dependent on a critical mechanically mixed tribological layer generated on the contact areas instead of as a consequence of strain hardening. Initially, in the very slow sliding speed range (0.001–0.05 m/s), this layer is not thick enough to act as a protective layer. As a result, severe wear damage takes place.

At even higher sliding speeds, ranging from 0.1 to 0.5 m/s, the presence of the mechanically mixed tribo-layer is more consistent and behaves as a lubricant, thus

Fig. 8 SEM images and EDS spectra of (a)–(b) worn surface and (c)–(d) wear debris collected from AA7075 at 20 MPa and sliding speed of 0.1 m/s

diminishing the wear damage and a mixing–oxidation mild wear regime starts to prevail. This tribolayer covers the worn surface and consists of a mechanical mixture of amorphous oxide particles containing aluminum and iron from both the specimen and the counterbody, respectively.

Finally, above 0.5 m/s, the worn surface shows massive surface damage without oxidized particles on the track. Moreover, the debris collected is made up of large aluminum particles, which are typical features of a severe wear

regime. However the wear rate is still low and more suitable to be considered in the mild wear regime. In this case, due to a softening effect on the surface layers, the wear rate starts to increase as the sliding speed increases.

The results obtained in the present work might make it easier to complete the wear mechanism map for aluminum at a very slow sliding speed interval, an aspect that has been scarcely studied.

CONCLUSIONS

The wear behavior of AA5754, AA6082, and AA7075 aluminum alloys against AISI 52100 steel at a very slow sliding speed interval was studied by means of block-on-ring wear tests. At the load and sliding speed range studied there is no significant difference between the three aluminum alloys. At the lowest contact pressure applied (20 MPa), only the mild wear regime prevails. Conversely, at the highest contact pressures evaluated (100 and 140 MPa), the results obtained are more complex. At 100 MPa and at a sliding speed range from 0.001 to 0.05 m/s, the wear rate is severe, whereas at sliding speeds above 0.05 m/s, mild wear takes place according to the wear rate criterion followed. Similar behavior is shown for the wear rate results at 140 MPa.

On the other hand, at 100 and 140 MPa, there is clear change in the behavior of the wear rate as a function of

Fig. 9 Flash temperature values measured at 20, 100, and 140 MPa in the sliding speed interval from 0.001 to 1.5 m/s

Fig. 10 Representation of (a) ultramicrohardness and (b) elastic modulus as a function of the distance from the surface of AA7075 at 100 MPa

sliding speed at approximately 0.5 m/s for the three aluminum alloys studied. Below this sliding speed, the wear rate decreases as the speed increases, and the worn surface appearance along with the debris morphology suggest an oxidative process, whereas at speeds above 0.5 m/s, the wear rate increases as the speed increases, the worn surface shows massive surface damage, and the debris consists of large aluminum particles.

This behavior seems to depend on a compromise between a mechanically mixed tribological layer generated on the contact areas and a softening effect due to frictional heating instead of the compromise between strain hardening and softening that was previously proposed.

Weldability: Effect of Alloying Element Sc, Mn, and Zr on Alloys of the Al-Mg-Sc-Mn-Zr System

V. I. Lukin

Research Institute of Aviation Materials

Abstract

Scandium in aluminum alloys behaves as the most efficient modifier of the structure of the material and as an agent suppressing recrystallization. This unique behavior of scandium in alloys of the Al-Mg system greatly increases the strength characteristics, whilst retaining on a higher level the ductility and processing properties of deformed semi-finished products. This article describes the effect of complex alloying the Al-6.3% Mg alloy with scandium, manganese and zirconium on the weldability and strength properties of the material is of considerable scientific and practical importance. Investigations.

Keywords: Ductility; Fusion zones; Hot-cracking; Scandium; Toughness; Weldability.

Scandium in aluminum alloys behaves as the most efficient modifier of the structure of the material and as an agent suppressing recrystallization. This unique behavior of scandium in alloys of the Al-Mg system greatly increases the strength characteristics, whilst retaining on a higher level the ductility and processing properties of deformed semi-finished products. This is very important when producing complicated welded three-dimensional structures.

This effect is explained by the fact that during interaction with aluminum, Sc forms a number of intermetallic high-strength joints of the Al_3Sc type, whose particles are distributed in the matrix with a higher density, are spherical, are fully coherent with the matrix and efficiently inhibit the migration of grain boundaries, and slow down and in many cases prevent the process of recrystallization in deformed alloys.^[1,2] Manganese and zirconium have a similar anti-recrystallization effect, ensuring the formation of the subgrain structure of semi-finished products and supporting more extensive generation of main hardening phases. Manganese and zirconium are used for additional alloying of industrial aluminum alloys.

Thus, examination of the effect of complex alloying the Al-6.3% Mg alloy with scandium, manganese, and zirconium on the weldability and strength properties of the material is of considerable scientific and practical importance.

Investigations were carried out on 2 mm sheets produced by the following technology. A 40×12 mm strip was pressed at 400°C from a 70 mm diameter ingot after homogenizing annealing at 360°C (12 hr). The strip was then rolled at 350°C in the direction normal to that of pressing to a thickness of 6 mm. After annealing at 350°C

(2 hr), cold rolling was carried out in the same direction to a thickness of 2 mm. Prior to welding, the sheets were annealed at 350°C (2 hr) with cooling in air.

The susceptibility of the examined alloys to hot cracking during welding was determined by the method developed at the N E Bauman Higher Technical School in Moscow using LTP-1-6 equipment with forced tensile deformation of the specimen during welding carried out without filler material. Specimens for the mechanical tests were welded manually with filler material of the same composition as that of the welded material.

The dependence and the mechanical properties and weldability of the alloys on the scandium, manganese, and zirconium content was described by regression analysis of a complete factorial model of the second order with respect to three variables.^[3] The model of the system was represented by the following polynomial:

$$Y = b_0 + b_1x_1 + b_2x_2 + b_3x_3 + b_{12}x_1x_2 + b_{13}x_1x_3 + b_{23}x_2x_3 + b_{11}x_1^2 + b_{22}x_2^2 + b_{33}x_3^2$$

where Y is the required response function; b_0 – b_{33} are coefficients; x_1 – x_3 are the content of scandium, manganese, and zirconium in the alloy.

To determine the coefficients b_0 – b_{33} , an experiment plan was constructed on three levels containing the results of examination of 15 compositions. Response functions were the mechanical properties of the parent material in the transverse direction (σ_B – tensile strength, $\sigma_{0.2}$ – yield strength, δ – relative elongation, KCU – impact toughness), hot cracking susceptibility of the alloys in welding (A_{cr} and the mechanical properties of welded joints in the

transverse direction (σ_{Br} – tensile strength of the welded joint characterizing fracture through the fusion zones, σ_{Be} – tensile strength of the cast zone of the welded joint characterizing the fracture through cast zones, α – bend angle of the welded joint, KCU_c – impact toughness in the weld center, KCU_m – impact toughness in the melting zone).

The properties of the parent metal and welded joints and their susceptibility to hot cracking in welding are presented in Table 1.

The regression coefficients were calculated on the basis of the condition to ensure the minimum sum of the squares of deviations of the response functions predicted by the model for different points of the examined area, from their actual values at these points (by the method of least squares). The values of the coefficient of the polynomial, calculated from different response functions, are presented in Table 2.

Analysis of the regression models shows that the susceptibility of the Al-6.3% Mg alloy to hot cracking during welding decreases when alloying with scandium irrespective of the manganese and zirconium content (see Fig. 1 position a). The critical strain rate increases from 6–7 (for alloys without scandium) to 16–18 mm/min (at 0.8% Sc). When the alloy contains $\leq 0.2\%$ Zr, its hot brittleness slightly decreases in the presence of $\leq 0.3\%$ Sc (A_{cr} increases by 2–3 mm/min and has almost no effect on this parameter at a higher scandium content), at $> 0.2\%$ Zr, the hot brittleness of the alloys containing 0.3% Sc decreases and the susceptibility to hot cracking increases at a higher scandium content. In the presence of $\leq 0.6\%$ Mn, the hot brittleness of the alloys containing $\leq 0.3\%$ Sc decreases

(A_{cr} increases by 2 mm/min), and the susceptibility to hot cracking increases by approximately the same value in the alloys containing $> 0.3\%$ Sc. This relationship is observed irrespective of the zirconium content of the alloy.

The region of the maximum values of the strength of the parent metal (see Fig. 1 position b) and of the welded joint (see Fig. 1 position c) consist of compositions containing 0.4–0.6% Sc, 0.2–0.3% Zr and 0.4–0.6% Mn. In comparison with the initial condition of the alloy without Sc, Mn, and Zr, the strength of the parent metal increases from 300 to 400 MPa and that of the welded joint from 250 to 420 MPa. The strength of the parent metal and the welded joint is almost independent of the zirconium content of the alloy, but rapidly increases with increasing scandium content and only slightly (by 30–40 MPa) with increasing manganese content.

With increasing scandium content, the ductility of the welded joint (see Fig. 1 position d) decreases irrespective of the manganese and zirconium content. The bend angle of the welded joint decreases from 170 to 100° when the Sc content is increased from 0 to 0.8%. At $\leq 0.2\%$ Zr, alloying with manganese slightly increases the ductility of the welded joint (bend angle increases by 20–30°). When the alloy contains $> 0.2\%$ Zr, the ductility of the welded joint decreases with increasing manganese content.

These relationships confirm the conclusions^[4,5] according to which alloying with scandium is highly promising in developing materials with high values of weldability, strength, technological properties, hot cracking resistance and special filler materials increasing these characteristics when welding high-strength aluminum alloys of the Al-Mg, Al-Mg-Li, Al-Cu-Li and other systems.

Fig. 1 Dependence of A_{cr} (a), σ_B (b), σ_{Br} (c) and α (d) in Al-6.3% Mg-0.2% Zr alloy on scandium and manganese content

These results were used to develop Sv-1587 filler wire of the Al-Mg-Sc-Zr system (Author's cert No. 1526261, USSR), which has given satisfactory results in welding deformed, semi-finished products of aluminum alloys of the manganese-aluminum group.

CONCLUSION

Alloying the Al-6.3% Mg alloy with scandium greatly increases the strength of the welded joint and reduces its hot brittleness during welding. The ductility and impact toughness of the welded joint remains high.

Weldable Aluminum Alloys in Aerospace and Transportation

Alexey Sverdlin

IMET, Bradley University, 2119 W. Raleigh Ct, Mequon, Wisconsin, 53092, United States

Abstract

Fabrication of high-strength aluminum alloys with the application of welding is one of the most important directions for increasing efficiency and performance characteristics of the aircraft. Today, the aerospace industry has accumulated extensive experience in the application of welded aluminum alloys. Of course, the individual structural elements are made of steel, titanium alloys, or composite materials, which increase the reliability and functionality of the designs in general.

Keywords: Alloying elements; Al-Mg-Li; Aluminum alloys; Al-Zn-Mg-Zr; Corrosion resistance; Cracking sensibility; Density; GMAW; HAZ; Heat treatable; Non-heat-treatable; Weldability.

MODERN ALUMINUM ALLOYS

In the United States and Russia, heat-treatable high-strength aluminum alloys of Al-Zn-Mg-Cu system and medium-strength Al-Mg-Cu system have been used successfully in the manufacture of aircrafts and transportation. Tables 1 and 2^[1] show properties of some American- and Russian-wrought weldable aluminum alloys, and Tables 3 and 4^[2] represent composition and weldability of selected non-heat-treatable and heat-treatable cast aluminum alloys.

The heat-treatable aluminum alloys provide good strength and toughness in engineering applications while maintaining the low density and corrosion resistance of aluminum.^[2] These attributes allow the heat-treatable alloys to be used in a wide variety of applications, which include the aerospace, transportation, shipbuilding, tankage, piping, and appliance industries. The majority of these alloys can be welded by the conventional arc welding processes [gas metal arc welding (GMAW) and gas tungsten arc welding (GTAW)], resistance spot and seam welding processes, as well as the high-energy processes, such as laser-beam welding and electron-beam welding.

Selecting of the proper filler material to get the desired performance of weldments is the most important issue. Most alloys and alloy combinations can be joined using any one of several filler alloys, but only one filler may be optimal for a specific application. Table 5 lists the chemical composition of standard aluminum filler alloys.

The primary factors commonly considered when selecting a welding filler alloy are^[2] as follows:

- Ease of welding or freedom from cracking.
- Tensile or shear strength of the weld.
- Weld ductility.
- Service temperature.

- Corrosion resistance.
- Color match between the weld and base alloy after anodizing.

In this article, sensitivity to weld cracking will be taken into consideration. Weld crack sensitivity is most easily controlled by influencing the composition of the weld. Most of the filler alloys shown in Table 5 are high in solute to reduce crack sensitivity. The non-heat-treatable aluminum alloys can be welded with a filler alloy of the same basic composition as the base alloy. Typically, alloys used as filler for welding heat-treatable aluminum alloys have a lower melting temperature than the base alloy.

A simple inverted “T” fillet weld test^[3,4] can be used to determine the compatibility of a filler alloy with a base alloy. It is a measure of weldability in terms of resistance to weld metal hot cracking. Typical weld cracking results obtained from the fillet weld tests [more below] are shown in Fig. 1.

Those results show the following:

- The high-purity 1xxx series alloys and 3003 are easy to weld with base alloy filler, 1100 alloy, or an aluminum–silicon alloy filler, such as 4043.
- Alloy 2219 exhibits the best weldability of the 2xxx series base alloys and is easily welded with 2319, 4043, and 4145 fillers.
- Al-Si-Cu filler alloy 4145 provides the least susceptibility to weld cracking with 2xxx series wrought copper-containing alloys, as well as Al-Cu and Al-Si-Cu alloys.
- The cracking sensibility of Al-Mg alloy welds decreases as the magnesium content of the weld increases above 2%. The high-magnesium content aluminum filler alloys 5356, 5183, and 5556 can be used to weld the Al-Mg wrought and cast aluminum alloys with relative ease, using the GTAW process.

A356.0	7.0			0.35			
A357.0	7.0			0.58		0.12	0.55 Be

- The 6xxx series base alloys are most easily welded with the Al-Si-type filler alloys, such as 4043 and 4047.

- The 7xxx series (Al-Zn-Mg) alloys exhibit a wide range of crack sensitivity during welding. Alloys 7005 and 7039, with a low (<0.1%) copper content, have a narrow melting range and can be readily joined with the high-magnesium content filler alloys 5356, 5183, and 5556. The alloy 7005 has been developed with welding in mind. Following welding, this alloy ages naturally at room temperature thus regaining an appreciable amount of its original strength. This higher strength of the welded parts presents the most significant advantage of 7005 over 6061.
- The non-heat-treatable alloys, in the as-welded condition, retain approximately 90% of their ultimate tensile strength and 60% of their yield strength. It is important to note that the elongation remains relatively high.

Figure 2^[5] shows in the simplified way the ultimate tensile strength, the yield strength in ksi, and elongation in percent, and Fig. 3 presents the welded properties based upon averages and should be expected in production by properly trained welders using GMAW and Table 6 presents the potential applications of those alloys. The percent figure shown inside the cross-hatched area expresses its size in relationship to the size of the area of the unwelded material. The smaller this figure, the larger the metallurgical notch effect in the weld seam. The larger this figure, the higher the efficiency of the joint with respect to energy absorption, a feature mandatory in all cases where dynamic loading prevails. An ideal material would be one having identical properties both in the unwelded and in the welded condition. However, that loss

Fig. 1 Relative crack sensitivity ratings of selected aluminum (base alloy/filler alloy) combinations^[2]

Fig. 2 Evaluation scheme for weldability

of strength is limited to the HAZ, usually 1 in. to either side of the weld seam.

Aerospace and space industry has traditionally been a pacemaker for development and introduction of new materials systems and production technologies. The key driving forces for materials development are weight reduction, application-specific performance improvement, and reduced cost. Application of advanced engineering materials has significant impact on both economical and ecological issues. Lithium-containing aluminum alloys constitute a relatively new generation of high-performance, light-weight aviation alloys that are being considered for a variety of applications requiring welded construction. As with other aluminum alloys, there are a number of weldability issues associated with these alloys, including resistance to defect formation during fabrication, mechanical property degradation, and service performance.

ALUMINUM ALLOYS WITH LITHIUM AND THEIR WELDABILITY

Aluminum–lithium alloys initially were not designed with weldability in mind with the exception of the Weldalite 049 alloys,^[8–11] since mechanical fastening was the primary joining process in aerospace applications. Welded structure gives weight savings (elimination of rivets, sealants, rubbers, and glues), less use of labor in manufacture, and reliability in performance due to uniform distribution of stresses in joint elements as compared with riveted or bolted joints.^[12]

Reduced density and increased elastic modulus along with very good cryogenic toughness and ductility (Table 5) make Li-containing aluminum alloys an attractive alternative relative to more conventional precipitation-hardenable aluminum alloys, such as 2014, 20124, 2219, 6061, and 7075.^[8–10] It is known that every 1 wt% Li in aluminum decreases the density^[4,5,11] by about 6%. Figure 4^[6] shows the effect of Al–Mg–Li alloys. Pickens^[6,13] states that for an Al–Li alloy, structural weight savings in airplanes, cars, and trains would be in the range between 10% and 16%. The use of high-strength aluminum–lithium alloy in welded hermetically sealed structures, e.g., in fuel tanks for MIG-29 aircraft, permits to reduce their own mass by 12%–15%. Figure 5^[6] illustrates the specific yield strength for some commercial aluminum alloys with lithium and some conventional aerospace aluminum alloys.

Commercial applications in production include aircraft parts such as leading and trailing edges, access covers, seat tracks, and wing skins. Figure 6^[2] illustrates the present and potential uses of aluminum–lithium alloys on

Fig. 3 Strength comparison diagram

a generic commercial transport and thereby serves a summary of alloys and tempers that are in production or under evaluation.

Certain types of military aircraft parts such as F22A Raptor, RQ-4 Global Hawk, or MQ-1C Gray Eagle (American military aircrafts) and Su-27, T-50 PAK FA, or F-22 (Russian military aircrafts) (Fig. 7) are likely candidates for the use of Al-Li alloys. Steady progress has been made in using superplastic-formed aluminum–lithium

sheet parts^[15] and conventionally formed 2090, 2091, and 8090 sheet^[16–23] for structures and wing skins and for plate parts.

Classification of the alloys based on chemical composition, as details below:

- Al-Cu-Li with the small amounts of Mn and Cd (2020 and VAD23).
- Al-Li-Mg (Russian alloys 1420, 1421, and 1423).

Table 6 Applications of some welded aluminum alloys

Alloy	Application
5052	It is an alloy with a long-standing record of highly successful welded applications and still remains best suited for numerous applications where strength alone is not the predominant requirement. In early 1950, it was the only Al-Mg alloy offered by the American aluminum industry. It has been used in pleasure craft hulls, houseboats of 50–60 feet length, pontoon boats, truck fuel tanks, stationary and movable storage tanks, pressure vessels, and components for road tankers.
5083	It combines high mechanical properties with very good ductility. It is used in constructing railroad hopper and gondola cars, overhead cranes, and cryogenic vessels. It has been used for off-highway dump bodies. However, its application is restricted to an operating temperature not exceeding 150°F. A welded highway bridge was built in the late 1950.
5086	It is often specified by the Navy for welded structures where a single failure may result in hazard to personnel or critical ship components. This alloy is suggested for boat hulls and in all cases where high energy absorption may be required in service. It is also being used in large size dump bodies for off-highway service. It should not, however, be used for continuous operating temperatures higher than 150°F.
5454	It is suitable for the variety of applications and for structures where temperatures higher than 150°F may be prevalent. Hot asphalt road tankers, gasoline and oil road tankers (delivery tank trucks), as well as dump truck bodies have been constructed from this alloy.
5456	It presents the highest static properties among the Al-Mg alloys in the unwelded as well as in the welded condition. However, for dynamically stressed structures with weldments in highly stressed areas, the dynamic strength characteristics should be carefully compared with the static strength properties. The alloy is also restricted to applications not exceeded 150°F operating temperatures.
6061	It is a heat-treatable alloy frequently being used for extrusions in combinations of sheet/plate/extrusion structures, often as stiffening members for sheet panels or support members of a sheet/plate structure. It should be noted, however, that the welded properties of 6xxx series alloys are appreciably lower than their unwelded properties. Only post-welded heat treatment does almost entirely restore the original ultimate and yield strength. However, the elongation is reduced so much, that the joint could be termed as being brittle.
6063	It is an extrusion alloy and is widely being used for secondary structures, mostly mechanically joined, but it is readily weldable.
7005	It is a heat-treatable alloy of the Al-Mg-Zn system, basically available in the form of extrusions. It may be specified in sheet/plate/extrusion combinations if strength requirements warrant the higher welded properties available in this alloy over 6061. Service conditions may require special attention to the metal surface protection. 7005 extrusions can be used in combination with 5xxx and 6xxx series sheet and plate alloys.

Fig. 4 Elastic modulus of Al-Mg-Li alloys depends on lithium content^[8]

- Al-Li-Cu-Mg-Zr (2091, 8090, Weldalite 049, 2094, 2095, 2195, 2196, 2197, 2198, 2099, 2199, 2055); some of these alloys contain small amounts (~0.5%) of Ag.

Table 7 lists typical compositions of some commercial aluminum alloys with lithium. Minor additions of other elements such as Zr, Cd, and Mn are used to modify microstructure and mechanical properties of Al-Li alloys.

Table 8^[2] represents the mechanical properties of some aluminum–lithium alloys after the artificial aging.

The first-generation Russian alloy 1420 and the third-generation Western alloy 2195 were developed specifically

Fig. 5 Yield strength (σ_y) and σ_y /density ratio for various Al alloys^[6, 9, 11, 12]

Fig. 6 Use of aluminum–lithium alloys in a commercial aircraft

for weldability. Other Al–Li alloys with superior combinations of strength and toughness are considered non-weldable.^[6,7] Past studies have concentrated on studying the weldability of 1420, 1441, 2090, 2195, and 8090 alloys. Of these, 1420, which was derived from an Al–5Mg weldable

alloy, was reported to be resistant to hot cracking.^[12,25] In order to evaluate a material's overall weldability, it is necessary to consider a number of factors. In aluminum alloys, and aluminum with lithium in particular, the following four factors typically dictate weldability:

- Mechanical property degradation or loss of weld joint “efficiency”.
- Susceptibility to cracking during fabrication, usually due to solidification or liquation cracking mechanisms.
- Porosity formation.
- Resistance to corrosion.

Precipitation-hardenable aluminum alloys exhibit lower tensile strength and ductility in the as-welded conditions. In general, improvement in the weld fusion zone integrity can be accomplished by modifying the composition and microstructure through the proper selection of filler metals and welding parameters. Considerable work has been undertaken to measure and optimize the mechanical properties of a number of commercial alloys, including alloys 01420, 8090, 2090, and Weldalite 049. Tensile strength and welded joint are illustrated in Figs. 8–11.^[6]

In general, the as-welded joint efficiency (ratio of weld strength to base metal strength) ranges from 50% to 80%, while Pickens^[14] states that efficiencies up to 100% can be achieved for welds that are solution annealed and aged after welding.

In the case of alloy 8090 (Fig. 9),^[6] improved joint efficiencies with the GTAW process are achieved using solution heat treatment and aging after welding. The highest joint strengths are obtained using 5000 series filler metals, such as 5356, or with a filler material (8090). Joint efficiencies are generally lower than those achieved in 1420 alloy weld.

Similar data are compiled in Fig. 10^[6] for alloy 2090 using both the GTAW and EBW processes. The tendency toward increased joint efficiency is again apparent when post-weld solution heat treatment and aging are employed. Welds produced with EBW exhibit finer microstructure in

**Fig. 8** Weld joint strength and efficiency for Soviet 01420 alloy using various processes and filler metals^[9–11]

the fusion zone and narrower HAZ compared with welds produced using GTAW.

As shown in Fig. 11^[6] Weldalite 049 alloys seem to achieve high strength using filler alloys with increased copper such as 2319 coupled with post-welding solution

heat treatment and aging. Welds made using the EBW process also exhibit high strength. Mechanical tests also revealed the tendency of increased weldment strength and toughness at cryogenic temperatures in this alloy.^[14]

Fig. 11 Weld joint strength and efficiency for alloy Weldalite 049 using various process and filler metals^[8,13,14]

The results of the study of weldability of American Al-Li 2096 and 2195 with comparison of the Russian alloy 1460^[24, 26, 27] have been shown in Tables 9–12. Those experiments carried out on the specimens that have been cut out from sheets of the specified alloys with the size of 150×200mm and with the thickness of 3mm, and from forgings with the thickness of 50mm. Welding carried out after the completing the heat treatment of a material including quenching and artificial aging. Before welding, welded edges of samples have been cleaned by brush on distance of 10–15mm from a joint. The GTAW with a filler wire of 2mm in diameter have been used for this study. For The mixture of two inert gases such as argon (60%) and helium (40%) with the flow of 12–14L per minute has been used to protect the liquid metal. A penetrated material was protected using pure argon with consumption 2–3 L/min, supplied into a forming backup plate. After welding, the X-ray control of weldments has been applied.

To evaluate the capacity of a metal or combination of metals to be welded into a suitably designed structure

test” and “the fish-bone test” were applied. The Moscow State Technical University technique was used to evaluate the critical rate of deformation.

The analysis of the data shows that the alloys containing lithium possess lower resistance to the hot cracks formation at welding than traditional aluminum alloys without lithium. Among alloys with lithium the aluminum alloy 1460 has the highest resistance to the hot cracks formation. Using the filler wire from alloys 1201 and 2219 will increase the resistance to hot cracks formation at alloys 2096 and 2195. Using the filler wires SvAMg63 and Sv1217 for welding aluminum alloys 1420 and 1460 completely excludes occurrence of the hot cracks.

Table 7 shows the mechanical properties of the welded joints of the investigated alloys. The analysis of the received data shows that the tensile strength of welded joints of an alloy 2096 is lower than an alloy 2195. The failure of the weldments took place at the HAZ—and for the alloy 2195—at the distance of 7–9 mm from the HAZ. Welded joints made of aluminum alloys 1420 and 2195 had the highest value of the tensile strength. The tensile strength of the welded joints made from other aluminum alloys is reduced in the following order: 1460–2096 and AMr6–1201. Weldments made from aluminum alloys 2096 and 2195 show the lowest percent of elongation. Weldments made from aluminum alloy 1460 showed the best combination of plasticity and tensile strength among alloys of systems Al–Cu–Li and Al–Cu–Li–Mg.

The analysis of a macrostructure of welded joints of alloys 2096, 2195, 1460, 1420, and 1201 has shown that it is characterized by the increased section in the HAZ. The similar configuration is defined by the shape of the groove and thermal characteristics of the investigated alloys of a back support lining.

These results show that there is an opportunity to create weldments from various aluminum alloys in combinations of AMg6+1460 and 1460+1201, which will allow to solve tasks of creation of the combined designs.

Fatigue life for all alloys of Al–Cu–Li system is 1.3–2 times more than for all the known standard wrought aluminum alloys. However, all Al–Cu–Li alloys show worse weldability than the standard aluminum alloys, such as AMg6, 01545K, and 01570 (Figs. 12–14).^[28–34] In addition, ductility of Al–Cu–Li alloy welds is significantly (3–6 times) lower than for standard aluminum alloys (8–10 times).^[28]

During welding, high-strength aluminum alloys have demonstrated an affinity for solidification cracking. Although process parameters such as by changing solidification rate may affect crack sensitivity, the conditions

Fig. 12 The fatigue curves of weldments (GTAW, 1—alloy 01570, 2—alloy 1420, 3—alloy 01460, 4—alloy 1201). Tested at 273 K

Fig. 13 The fatigue curves of aluminum alloy 01460 (1, 2, 4, 6) and aluminum alloy 1201 (3, 5, 7) depend on temperature of the test: 1, 3—4.2 K; 2—20 K; 4, 5—77 K; 6, 7—273 K

Fig. 14 The fatigue curves of aluminum alloy 01460 (1, 3, 4) and aluminum alloy 1201 (2, 5) depend on the semi-products and texture. Specimens tested at temperature of 4.2 K. 1—sheet 0140, longitudinal direction; 2—sheet 1201, longitudinal direction; 3—plate 01460, longitudinal direction; 4—plate 01460, lateral direction; 5—plate 1201, longitudinal direction

are primarily influenced by the characteristics of the solidifying network, which is determined by the weld composition. Hence, the sensitivity of a base metal to weld cracking must also consider the filler alloy since it also contributes to weld metal composition.

Inverted “T” weld cracking tests were used to determine weld crack sensitivity.^[35] Discontinuous, GMAW

Table 13 Inverted “T” discontinuous welding test results (2090-T8E41 alloy)

Filler alloy	Total crack length	
	(cm)	(in.)
4043	29.7	11.7
	32.8	12.9
5556	50.8	20.0
	46.0	18.1
2319	20.8	8.2
	18.3	7.2
4047	6.1	2.4
	0.2	0.1
4145	5.1	2.0
	5.3	2.1

Total weld length—50.8 cm (20.0 in.)

fillet welds were produced on both sides of the joint and were subsequently dye penetrant inspected. The total crack lengths of both fillet welds were then measured to indicate relative crack sensitivity. Results of replicated inverted “T” tests are shown in Table 13.

Filler alloys 4047, 4145, and 2319 produced the least amount of weld cracking during testing. The results of these tests indicated that 2090-T8E41 welded with 4047 or 4145 is comparable to 6061-T6 welded with 4043. A slightly higher crack sensitivity was observed for 2090-T8E41 welded with 2319 when compared to 2219-T87 welded with 2319 filler alloy.

Al-Li alloys had other problems as well. Because they contain greater-than-equilibrium amounts of lithium, they are expensive to manufacture and difficult to process. Keeping flatness within tolerance proved difficult. With rare exceptions, Al-Li proved difficult to weld because heating drove lithium out of solution and weakened the joint. Despite these humbling experiences, engineers have found ways to tame their materials. In fact, Al-Li has carved out a niche for itself in several aerospace applications, and more are on the way.

The most impressive use is the Space Shuttle SLWT. As tall as a 15-story building and as broad as a silo (27.6 feet in diameter), the tank is composed of nearly a half-million steel, titanium, and aluminum parts. The previous design could handle the stress and still weigh only 66,000 lb. The redesigned aluminum-lithium SLWT weighs even less, 58,500 lb. More important is the switch to Weldalite Al 2195, from a more conventional Al 2219. According to NASA, the new Al-Li alloy is 30% stronger and 5% less dense than Al 2219.

Al-Li has shown up in several other areas. One of the most critical is a thick primary structural bulkhead on the F-16. It is designed to buttress the area where the empennage joins the aft fuselage. Lockheed Martin also uses Al-Li on the F-16 center fuselage longeron and the engine access door stiffener attached to the ventral fin.

EH Industries uses Al-Li in its EH101 helicopter and its Merlin variant. The fuselage consists largely of Al-Li, with aluminum and Al-Li sandwich panels. EH uses 8090 sheet.

ALUMINUM ALLOYS WITH SCANDIUM AND THEIR WELDABILITY

Aircraft construction today is characterized by the quest for innovative materials and production technologies that make weight saving and thus cost-reducing structures possible. From this standpoint, scandium-reinforced aluminum alloys represent a new generation of high-performance alloys that display numerous advantages over high-strength aluminum alloys. Scandium-reinforced alloys are approximately 25% stronger than other high-strength alloys, exhibit significant grain refinement, strengthen welds, and eliminate hot cracking in welds. These alloys also exhibit a good resistance to corrosion as shown by recent studies.^[36] A review of their mechanical, microstructural, and corrosion characteristics shows that scandium-reinforced alloys can be usefully employed in aerospace, sports, transportation, and process industries. The information on scandium-reinforced alloys is scanty; very little has been published on the mechanical, microstructural, and corrosion behavior of these alloys. The following fills this gap (Figs. 15, 16).

An Al-Mg-Sc alloy is characterized by very low density comparable with that of the Al-Li alloys. The Al-Mg-Sc alloy is very corrosion resistant and exhibits excellent damage-tolerant properties with respect to crack propagation. This is significant particularly for the upper fuselage area which is subjected to especially large tensile stresses with consequence that cracks can propagate here more quickly. In addition, the alloy has very good welding properties. This is particularly interesting for Airbus because

laser-welded 6xxx series alloys are already being used for the lower fuselage area of A318, A340, and A380. Laser welding allows very high welding speeds, and in addition production costs are reduced compared with components that were traditionally riveted. Matthias Miermeister mentioned that parts can be welded flat without any prior treatment with aluminum–magnesium–scandium alloys. Those alloys offer a weight saving of 27%. There are also significant weight savings compared with conventional 6xxx series alloys.

The development of Al-Sc alloys first flourished in the Soviet Union, where military demand was the main driving force. At the time of the Soviet Union breakup, scandium alloys were on the verge of major application in MIG-29 fighters because of their advantages over the low density and high strength of Al-Mg, Al-Li, and other recent alloys.

Fig. 15 The Al-Mg-Sc alloys offer significantly improved damage tolerance compared with aluminum alloys that are representative of today's state of the art

Fig. 16 Comparison of weights of Al-Mg-Sc alloys with conventional aluminum alloys

Fig. 17 The ultimate tensile strength of a 7xxx series weldment is considerably higher when a scandium-modified 5xxx aluminum filler metal is used compared to a conventional 5356 filler material. The difference is even more pronounced when the base metal is also modified by scandium

Scandium, with its unique strength and weight-saving characteristics, has been introduced as a potent alloying element in several aluminum alloys (e.g., 5052 and 7075) in recent years, bringing about dramatic improvements in their mechanical and physical characteristics. It has been possible to achieve an ideal combination of strength, density, and thermal stability because of the unique precipitation hardening characteristics of scandium. These alloys are gaining a wide popularity in aeronautical, automotive, and transportation industries.

Scandium-reinforced aluminum alloys offer design engineers several significant advantages over other high-strength aluminum alloys,^[36] including the following:

- Inhibition of recrystallization. Transition metals such as zirconium, chromium, manganese, vanadium, or titanium are not very effective at inhibiting recrystallization because most of the high-strength and precipitation-hardenable aluminum alloys are solution heat treated at temperatures well above their recrystallization temperatures. Welding studies on Al 7xxx by conventional filler

alloys and scandium-modified fillers have shown the capability of scandium to convert non-weldable alloys to alloys with a promising degree of weldability (Fig. 17). In addition, the weldment tensile strength of Al 7xxx is significantly improved when welded with modified 5xxx alloys versus conventional 5xxx filler (Fig. 19).^[37,38] Strength is further improved when scandium is added to Al 7xxx. Because of these advantages, the scandium-modified aluminum alloys have a promising potential for military and commercial aerospace applications including bulk heads, heat shields, sheet for upper skin, fuel and exhaust systems, and in automotive and transport systems. The addition of scandium also improves fatigue life.^[6] Medium- to high-strength Zr-Mg-Al alloys failed at 16,000 cycles, indicating their limitation for intended applications. Surprisingly, the fatigue life was increased to 25,000 cycles with a scandium-modified filler temperature of aluminum alloys to above 600°C, well above the temperature range of heat-treatable aluminum alloys. It has been observed that the addition of scandium with zirconium is more effective than the addition of scandium alone.^[39]

- Small additions of scandium in the range of 0.2–0.6 wt% bring about a high-specific strengthening effect.^[3] An Al-5.25Mg alloy containing 2.5% scandium showed a yield strength of 365 MPa, more than double the strength of the scandium-free alloy. Scandium provides the highest increment of strengthening per atom percent of any alloying element when added to aluminum.^[4] Al-Mg-Sc alloys are capable of developing strength and metal (Fig. 18). In a Houldcroft (fish-bone test) welding test, cracking was significantly reduced by a scandium-modified filler metal. When both the filler and base metal are modified by scandium, cracking is eliminated (Fig. 19).^[38] Fracture toughness is similar to that of Al 2024-T3 alloy. The effect of scandium addition on the yield strength of conventional and scandium-modified experimental 7xxx alloys is shown in Fig. 20.^[39]

Fig. 18 The fatigue life of a high-strength aluminum–magnesium–zinc alloy almost triples when it is welded by a scandium-modified 5xxx series filler metal

Fig. 19 As shown by crack length in millimeters, the Houltcroft test greatly favors the scandium-modified versus conventional filler metal in the welding of a 7xxx series aluminum alloy

- Scandium has the ability to refine grain size. It is a strong modifier of cast structure, and the addition of scandium makes it possible to obtain continuously cast billets with a non-dendritic structure.^[40]
- Reduction and elimination of hot cracking in welds. The scandium modification of welding filler alloys as well as base alloys is capable of preventing hot cracking. Aluminum alloy 2618 is known to be hot-crack sensitive, and, when welded with conventional filler, it develops a high level of cracking.^[40] However, its cracking susceptibility was reduced when the conventional filler was replaced with scandium-modified filler.

According to the AA (Aluminum Association) designation system, aluminum of 99% purity or higher is classified as a 1xxx alloy. These alloys are used for packaging, electrical conductors, heat exchangers, and architectural applications.^[41,42] It is possible to add significant amounts of Sc to aluminum alloys within the 1xxx classification. The 1xxx alloys are categorized as unalloyed and non-heat treatable, but an adding Sc will give a precipitation hardening potential in these alloys. It is thus appropriate to consider whether otherwise unalloyed Al with Sc should

Fig. 20 The yield strength of conventional and scandium-modified experimental 7xxx alloy in the initial and cold worked 84% and heat-treated conditions

still fall within the 1xxx series or whether the 8xxx series should be used. Some properties that may be obtained in binary Al-Sc alloys^[43] are presented in Table 14.

With the passage of time and new developments, scandium has found a wide range of applications. A leading sports company successfully employed scandium alloys in the production of softball and baseball bats. This success was followed by the manufacture of mountain and road bicycle frames and components. The bicycle frames showed a 12% reduction in weight, a 50% increase in yield strength, and a 24% improvement in fatigue life over the best-selling aluminum bicycle.

Potential aerospace applications include bulk heads, heat shields, forgings and extrusions for seat tracks, wheels, running gear, and fuel and exhaust systems. Scandium alloys are promising for automotive and air transportation applications because of their capability of weight reduction on critical moving parts. Scandium alloys could also be used in wheels, bumpers, frames, pistons, and air bag canisters. The aluminum scandium welding wire provides a very strong bonding while welding aluminum. This alloy could also be used in the cylinders of diesel engines for power boats. Because of the good corrosion resistance shown by recent studies, scandium alloyed with aluminum could also be used in a saltwater environment (e.g., heat exchanger tubes in desalination plants). The potential of scandium alloys is highly promising, but, like new technologies, it is going to take time and painstaking research and development efforts to convince the designers to use these alloys in a wide spectrum of applications.

AL-ZN-MG ALLOYS WITH ZIRCONIUM AND THEIR APPLICATION

High-strength heat-treatable and weldable aluminum alloys based on the Al-Zn-Mg system are used extensively for structural application in the aerospace industry.^[53] In recent times, the aerospace industry has

Table 14 Literature data on the effect of Sc on the strength of the various classes of wrought aluminum alloys^[43–52]

Alloy system	Alloy	Yield strength (MPa)	Tensile strength (MPa)	Products

developed substantial growing interest in new aluminum alloys with small zirconium and scandium, due to the fact that of all microalloying additions to Al, Zr and Sc offer the greatest potential for developing new lightweight structural materials with excellent mechanical properties, corrosion resistance, and weldability. The difficulty of developing high-strength, fatigue- and fracture-resistant

welds in aerospace aluminum alloys, such as highly alloyed 7xxx system, has long inhibited the wide use of welding for joining aerospace structures.^[54] The welding of these aluminum alloys has always represented a great challenge for designers and technologists because of the poor solidification microstructure and porosity in the fusion zone. Also, the loss in mechanical properties as compared to the

base material is very significant. These factors make the joining of these alloys by conventional welding processes unattractive.

All the commercial aluminum alloys that comprise this group contain more zinc than magnesium. There are a few commercial alloys with Zn:Mg < 1, but they have been considered with the aluminum–magnesium alloys because their behavior and structure are much closer to those of aluminum–magnesium alloys than of aluminum–zinc–magnesium. Al-Zn-Mg alloys can be used for both castings and wrought products, but because of the poor castability, the bulk is in the form of wrought products. Table 15 shows the composition limits of the alloys in commercial use.

Zinc and magnesium are the main alloying elements: high Zn:Mg ratios produce the best strength and response to heat treatment, together with the highest susceptibility to stress corrosion. Low ratios produce the best weldability and the lowest quench sensibility.

The high-strength self-quenched alloy V92Zr system Al-Zn-Mg has been developed in the former USSR in 1960. The major alloying elements are 4.2 wt% Mg, 3.2 wt% Zn, 0.6 wt% Mn, and 0.15 wt% Zr. The most acceptable filler wires to weld this alloy are V92W, alloys AMg6, AMg4Zr,

and No.11 (Al-Zn-Mg). This alloy can be used in the aircraft production. Prolonged heating at 50°C–70°C can lead to substantial structural changes in precipitation hardening of aluminum alloys.

Authors studied^[55,56] the effect of prolonged low-temperature heating on the mechanical properties, sensitivity to cracks in impact bending, and corrosion resistance of semifinished products and weldments of aluminum alloys V92Zr after solution treatment and aging at the room and elevated temperatures.

The study has been carried out on the welded joints after the prolonged heating at 70°C for 1000 and 3000h. The specimens from the extrusions, forgings, and sheets 2.5 and 5 mm thick were cut off and welded using an automatic GMAW process with various fillers (V92w, #11, AMg6, and AMg4Zr.^[56] Chemical composition of these fillers is shown in Table 16. Before heating, the specimens were aged at 20°C and at 60°C for 24 h+200°C for 1.5 h. It can be seen from the data in Table 17 that prolonged heating has different effects on the properties of welded joints aged at room temperature and after artificial aging (60°C for 24 h+200°C for 1.5 h).

Heating at 70°C for 1000h increases the ultimate tensile strength of the welded joints, particularly those welded with filler wires V92w and # 11 (by 50–70 MPa), and to a lesser extent (by 20–30 MPa) those welded with AMg4Zr and AMg6. After artificial stepped aging, however, heating leads to a slight increase in the strength (15 MPa), evidently due to the coalescence of metastable phase and the formation of a fairly stable structure after this treatment. Failure of the samples occurs mainly in the zone of fusion; only in the case of aging at 60°C for 24 h+200°C for 1.5 h after welding, does failure occur more often at a distance of 15–20 mm from the center of the weld.

The change in the bending angle and the impact toughness match the change in tensile strength. The bending angle decreases (by 10–25°) as the result of heating after aging at 20°C, but only slightly (1–4°) after stepped aging. The impact toughness in the center of the weld and in the fusion zone also decreases after aging at 20°C but remains somewhat higher than after stepped aging. The bending angle and the impact toughness of joints welded with filler wire # 11, AMg6, and AMg4Zr are the same and 50%–100% higher than for joints welded with V92w.

60°C 24 h+200°C 1.5 h	60°C 24 h+200°C 1.5 h	417	Fusion zone	21	5.8	4.3
	60°C 24 h+200°C 1.5 h+70°C 1000 h	430		18	4.5	3.4

High-temperature aging, inducing more complete decomposition of the solid solution, may improve the stress corrosion resistance after heating. The investigation confirmed the positive effect of high-temperature tempering at 200°C for 2–4 h and 210°C for 2 h on the resistance to stress corrosion. No failures occurred in tests for 4 months. The susceptibility to stress corrosion was lowest for joints welded with filler wire No.11 and higher (about 40 days to failure) for joints welded with AMg6. This is evidently due to the large chemical heterogeneity of the transition zone in joints welded with AMg6 and also the formation of a continuous network of β -phase at elevated temperatures (200°C–210°C).

APPLICATIONS OF ALUMINUM ALLOYS

Aerospace

The aerospace and space sector has traditionally been a promoter for the development and application of advance engineering materials.^[57] The key driving forces for materials development are weight reduction, application-specific performance improvement, and reduced cost. Weight reduction is most effectively done by reducing density. Furthermore, weight reduction of an individual component can generate a snowball effect if, for example, the airframe and the engine of an aircraft are re-optimized allowing the use of less stringers (using panels), a down-sized engine, a smaller wing, etc. As a rule of thumb, each

pound of direct weight saved in a primary structure results in nearly another pound saved indirectly in another part of the aircraft.

Ever since the launch of Sputnik a half-century ago, aluminum has been the material of choice for space structures of all types. Chosen for its lightweight and its ability to withstand the stresses that occur during launch and operation in space, aluminum has been used on Apollo spacecraft, the Skylab, the space shuttles, and the International Space Station. Aluminum alloys consistently exceed other metals in such areas as mechanical stability, dampening, thermal management, and reduced weight.

In 1986, Molniya research and production association (Russia) began designing a multipurpose aviation/space system that could handle a large spectrum of tasks in space. This system consists of a carrier plane on which is installed a multipurpose space plane. The space plane has replaceable modules, an external fuel tank filled with cryogenic components, and disposable ascent unit that carries a payload. Among the many problems associated with the development of the cryoplane, one of the most complicated is the selection of materials for the fuel tank. Most aluminum alloys are incapable of operating at cryogenic temperatures, because these conditions sharply decrease their strength and plasticity, and increase their sensitivity to stress concentration. Among weldable aluminum alloys, only alloy 1201 of the Al-Cu-Mn system is capable of operating at such low temperatures. Its American analog, alloy 2219, was used for cryogenic tanks on the U.S. Space Shuttle system. Later, Russian Al-Li alloy 1460 has been used at the cryogenic tanks for TU156 aircraft.

Today, in the United States and Russia, heat-treatable high-strength aluminum alloys Al-Zn-Mg-Cu and medium-strength Al-Mg-Cu alloys are used in the manufacture of aircraft parts. In modern aircraft, aluminum alloys, such as Al-Mn, Al-Mg, Al-Cu, Al-Cu-Li, Al-Mg-Si, are used literally everywhere: in the fuselage, in the trims, in wing panes, in the rudder, in the tie-down systems, in the exhaust pipes, in the feeding blocks, in the refueling hoses, in the door and floors, in the frames of pilot and passenger seats, in the fuel nozzles, in the hydraulic systems, in the cabin pillars, in ball bearings, in the instrumentation in the cockpit, in the engine turbines, and in lots of other places.

Over 70% of the structural weight of modern civil aircraft, like the Airbus A330/A340, or the Boeing 777, is attributable to high-strength aluminum alloys. Most visible parts are the fuselage and the wings. The challenge from carbon fiber-reinforced plastics not only led to the development of new alloys and processing techniques, such as aluminum–lithium alloys, powder metallurgical alloys, or metal-matrix composites, but also stimulated the improvement of conventionally processed aluminum aerospace alloys as well as the introduction of near-net-shape technologies. New developments in the area of Al alloys are focused on either improving the performance of the material or reducing the cost of the final component. In most cases, progress is judged by comparing the advances in performance with the properties of the two most dominant aerospace variants, the damage-tolerant Al-Cu base alloy 2024 and the high-strength Al-Zn-Mg-Cu base alloy 7075.

The composition of aluminum alloys used in aircraft has changed, airplanes have gotten better, but the main goal of aircraft designers remains the same: build a plane that is as light as possible with the maximum possible capacity that uses the least possible amount of fuel and whose body doesn't rust over time.

The key aluminum alloys used in aviation are the 2xxx, 3xxx, 5xxx, 6xxx, and 7xxx series. The 2xxx series is recommended for use in high-temperature environments and in environments with an increased yield coefficient. The 7xxx alloys are used for lower-temperature environments in parts exposed to increased loads and in parts that need to deliver high corrosion resistance under high voltage. 3xxx, 5xxx, and 6xxx alloys are used in low load parts, as well as in hydraulic, lubrication, and fuel systems.

The most widely used alloy is 7075. It consists of aluminum, zinc, magnesium, and copper. It is the strongest of all aluminum alloys and comparable in that respect with steel, however it weighs only a third of what steel weighs.

Al-Zn-Mg-Cu high-strength aluminum alloys hardened by heat treatment and Al-Mg-Cu average- and high-strength aluminum alloys are successfully used for aircraft equipment production in Russia. They are structural material for skin and inner set of airframe components (body, wing, keel, etc.).

1420 alloy pertaining to Al-Zn-Mg system is used for airliner welded body design. Usage of aluminum–magnesium corrosion-resistant welded alloys (AMr5, AMr6) and Al-Zn-Mg alloys (1915, B92, 1420) is provided for hydroplane production. Aluminum welded alloys have undeniable advantage when designing space technology items. High strength-to-weight ratio and stiffness-to-weight ratio of the material are provided for the manufacture of missile tanks, inter-tank, and nose parts with high directional stability. Among the advantages of aluminum alloys (2219 and others) is their operability under cryogenic temperatures in contact with liquid oxygen, hydrogen, and helium. These alloys are capable of the so-called cryogenic hardening, i.e., strength and ductility increase simultaneously with the decrease in temperature. 1460 alloy pertains to Al-Cu-Li system and is most promising for design and manufacture of tank structures with regard to cryogenic type of fuel—compressed oxygen, hydrogen, or natural gas.

Aircraft are assembled from sheets and extrusions that are held together by rivets. The number of rivets in a single aircraft can reach millions. Some models use pressed panels instead of sheets, and if a crack appears, it can only reach the boundary of such a panel. For instance, the wing of the world's largest cargo plane AN-124-100 Ruslan (Russia), which can carry up to 120 tons of cargo, consists of eight pressed aluminum panels each 9 m wide. The wing is designed in such a way that it will continue to perform its functions even if the panels get damaged.

In the late 1970s, higher strength versions of 2024 were required for the Boeing 757/767 aircraft without sacrificing other properties. 2224 and 2324 with lower Fe and Si contents reduced the number of constituent particles and extra thermomechanical treatment maintained the toughness at the increased strength level. Higher-strength version of 7075 led to slightly modified alloys 7050 and 7010. Reduced impurity levels and small amounts of Zr assured high toughness. Further developments to improve strength and corrosion resistance resulted in the newer variants 7150 and 7055, respectively.

The main driving force for improving the high-temperature capabilities of aluminum alloys is the replacement of much heavier Ti alloys or even steels. Today, the service temperature of conventional alloys like 2219 or 2618 is limited to about 150°C, but advanced dispersion-strengthened alloys such as 8009 or 8019 are aiming at temperatures as high as 450°C. These alloys contain transition elements like Fe, Mn, Cr, Ni, or Co.

Welding of Al alloys has become a central issue, and the establishment of friction stir welding has allowed a substantially increased number of Al alloys to be welded.

An all-welded supersonic aircraft would require specialized design and production procedures that ensure a significant improvement to aircraft performance under severe operating conditions, including high speeds and g-forces, and large temperature differentials.^[58] In order to

obtain homogeneous welds, the following steps need to be taken:

- Develop weld fillers and fluxes, as well as procedures, that result in homogenous welds.
- Develop methods of weld surface prep that prevent pitting and other structural-corrosion defects.
- Devise high-productivity welding procedures for gas-tungsten-arc, electron-beam, laser-beam, plasma, and other welding processes that minimize and balance heat input when welding parts of variable thickness and that minimize residual stresses and deformations.
- Establish robotic-welding work bays with simultaneous monitoring of weld quality and computer control of welding.

The first welded aluminum structures for aircraft in the world became possible with the advent of the weldable aluminum-lithium alloy 1420 and its variations. This alloy combines low density and high elastic modulus with high corrosion resistance and strength, characteristics that exceed those of the aluminum alloys widely used in aerospace. Elimination of rivets in welded Al-Li structures reduces the structure weight by up to 24%.

Due to the high reactivity of the ingots of Al-Li alloys, melting and casting require special methods of melt protection from oxygen, including the use of flux. Small flux inclusions may appear in the final ingot microstructure and shrinkage pores. During hot or cold plastic deformation of the ingots, these inclusions can become crack initiation sites.

The high reactivity and thermal conductivity of these alloys may yield nonhomogeneous microstructures. Defects such as flux inclusions, large intermetallic compounds, or zones of structural or chemical inhomogeneity result in reduced mechanical properties.

The transition to an all-welded aircraft requires procedures to fabricate reliable joints. Though material properties deteriorate slightly at welds on the fuselage and wings in the as-welded condition, proper welding design and procedures can ensure relatively uniform stress distribution and a higher degree of structural reliability compared to the use of rivets and bolts.

The aircraft airframe has been the most demanding application for aluminum alloys; to chronicle the development of the high-strength alloys is also to record the development of airframes. Duralumin, the first high-strength, heat-treatable aluminum alloy, was employed initially for the framework of rigid airships, by Germany and the Allies during World War I. Duralumin was an aluminum-copper-magnesium alloy; it was originated in Germany and developed in the United States as alloy 17S-T (2017-T4). It was utilized primarily as sheet and plate.

Alloy 7075-T6 (70,000-psi yield strength), an Al-Zn-Mg-Cu alloy, was introduced in 1943. Since then, most aircraft structures have been specified in the alloys of this

type. The first aircraft designed in 7075-T6 was the Navy's P2V patrol bomber. A higher-strength alloy in the same series, 7178-T6 (78,000-psi yield strength), was developed in 1951; it has not generally displaced 7075-T6, which has superior fracture toughness. Alloy 7178-T6 is used primarily in structural members where performance is critical under compressive loading. Alloy 7079-T6 was introduced in the United States in 1954. In forged sections over 3 in. thick, it provides higher strength and greater transverse ductility than 7075-T6. It now is available in sheet, plate, extrusions, and forgings.

Alloy X7080-T7, with higher resistance to stress corrosion than 7079-T6, is being developed for thick parts. Because it is relatively insensitive to quenching rate, good strengths with low quenching stresses can be produced in thick sections. Cladding of aluminum alloys was developed initially to increase the corrosion resistance of 2017-T4 sheet and thus to reduce the aluminum aircraft maintenance requirements. The coating on 2017 sheet—and later on 2024-T3—consisted of commercial purity aluminum metallurgically bonded to one or both surfaces of the sheet.

Electrolytic protection, present under wet or moist conditions, is based on the appreciably higher electrode potential of commercial purity aluminum compared to alloy 2017 or 2024 in the T3 or T4 temper. When 7075-T6 and other Al-Zn-Mg-Cu alloys appeared, an aluminum-zinc cladding alloy 7072 was developed to provide a relative electrode potential sufficient to protect the new strong alloys.

However, the high-performance aircraft designed since 1945 have made extensive use of skin structures machined from thick plate and extrusions, precluding the use of alclad exterior skins. Maintenance requirements increased as a result, and these stimulated research and development programs seeking higher-strength alloys with improved resistance to corrosion without cladding.

Aluminum alloy castings traditionally have been used in nonstructural airplane hardware, such as pulley brackets, quadrants, doublers, clips, ducts, and waveguides. They also have been employed extensively in complex valve bodies of hydraulic control systems. The philosophy of some aircraft manufacturers still is to specify castings only in places where failure of the part cannot cause loss of the airplane. Redundancy in cable and hydraulic control systems "permits" the use of castings.

Casting technology has made great advances in the last decade. Time-honored alloys such as 355 and 356 have been modified to produce higher levels of strength and ductility. New alloys such as 354, A356, A357, 359, and Tens 50 were developed for premium-strength castings. The high strength is accompanied by enhanced structural integrity and performance reliability.

Electric resistance spot and seam welding are used to join secondary structures, such as fairings, engine cowls, and doublers, to bulkheads and skins. Difficulties in

quality control have resulted in low utilization of electric resistance welding for primary structure.

Ultrasonic welding offers some economic and quality control advantages for production joining, particularly for thin sheet. However, the method has not yet been developed extensively in the aerospace industry.

Adhesive bonding is a common method of joining in both primary and secondary structures. Its selection is dependent on the design philosophy of the aircraft manufacturer. It has proven satisfactory in attaching stiffeners, such as hat sections to sheet and face sheets to honeycomb cores. Also, adhesive bonding has withstood adverse exposures such as seawater immersion and atmospheres.

Fusion welded aluminum primary structures in airplanes are virtually nonexistent because the high-strength alloys utilized have low weldability and low weld joint efficiencies. Some of the alloys, such as 2024-T4, also have their corrosion resistance lowered in the HAZ if left in the as-welded condition.

The improved welding processes and higher-strength weldable alloys developed during the past decade offer new possibilities for welded primary structures. For example, the weldability and strength of alloys 2219 and 7039, and the brazability and strength of X7005 open new avenues for design and manufacture of aircraft structures.

Automotive

The steadily growing interest in aluminum alloys in vehicles is connected with the unique set of their properties.^[59] The use of aluminum in the structure of automobiles is hindered by two factors, namely (1) the cost of aluminum alloys, which is twice higher than that of steel, and (2) the difficulties in manufacturing car bodies under the conditions of modern large-scale production.

Low weight is the golden goose of automotive technology. Everyone wants it because it brings about improvements in virtually all areas—performance, economy, handling—but engineering a car with lower weight than the one that preceded it is difficult to do.

However, the efficiency of a structure should not be evaluated only in terms of the cost of the material without taking into account other means that provide this efficiency, i.e., organizational, operational, manufacturing, and design ones. Allowance for this combination of properties has made one-piece aluminum structures for automotive competitive. According to the data, about 89% of the stock cars produced in Europe were made of aluminum, whereas 20 years ago this parameter was 2%. In 1998, the annual production of aluminum in the world was 23 million tons, of which 5.6 million tons were used in the conveyance industry.

The competitiveness of a modern automobile, like that of any marketable product, is determined by the proportion of market price, which primarily consists of the cost of its design and production, to the quality, which depends on

many parameters, i.e., the maintenance, cost (chiefly determined by the fuel efficiency), service life, safety, and level of comfort.

Automobiles are becoming heavier in order to satisfy requirements such as safety (collision safety and pedestrian protection), drivability, and larger interior space. Meanwhile, automobiles have to meet more stringent regulations against exhaust emission, including CO₂ and NO_x emission, to protect the environment. This cannot be done with the use of traditional materials, and aluminum moves forward as an alternative to steel. A decrease in the mass, which may attain about 120 kg per car due to the use of aluminum alloys instead of steel, will save 982 million liters fuel for 10 million cars with a mean annual haulage of 15,000 km, which will transform into a 2.3 million ton reduction in CO₂ emission into the atmosphere.

Aluminum has obvious advantages over steel, i.e., an almost three times lower density, a high corrosion resistance, and high degree of utilization reaching 85%–95%.

Japanese and European automotive and metallurgical companies have been working on the introduction of aluminum alloys into the structure of cars for over 100 years with support from their government. The International Association of Automakers (IAA) presented the result of this work at the Frankfurt Exhibition in 1981. A series of prototype haulers were exhibited by various companies (Unicar HAG Porsche 960, Porsche 928, VW, Audi, Daimler-Benz, Niesman Motor Homes, VAW Leichtmetall GmbH, Volvo, Motor Panels Coventry Ltd, Cleff, Alcoa, Magirus-Deutz, et.), which widely employed wrought aluminum alloys of the 5000, 6000, and 7000 series in car bodies (with standard doors), radiative coolers, and wheels and castable alloys of the Al-Si-Mg system in engines (including diesel ones), transmissions, suspension parts, and wheels.

In 1995, the consumption of aluminum in the automotive industry of Northern America amounted to 1.313 million tons, which exceeded the level of 1993 by 15%. Today, experts predict that automaker consumption amounts to 23 million tons, i.e., 65% rise by 2020. Aluminum has long been used in car doors and roofs, but unlike steel, it is difficult to weld, limiting its use in other automobile parts. Breakthrough in welding technology, though, helped Ford Motor Co. produce its top-selling vehicle, the F-150 pickup, with an aluminum body, and is opening up its use elsewhere. That is particularly important when the U.S. government target for fuel efficiency is set to rise to 54.5 mpg by 2025, almost double the figure for 2011. The lighter the car, the more fuel efficient it can be made.

Today the mass fraction of aluminum in a car is about 10%, and aluminum parts primarily replace steel parts in the motor compartment and wheels. However, the greatest gain in the weight (up to 45%) will be the use of sheet and pressed semi-products from aluminum alloy in car bodies.

The cost problems can be solved in favor of aluminum in the case of large-scale production. Recycling will yield a noticeable positive result upon close cooperation between

car producers and producers of car materials. The effect of repeated use of aluminum will be the highest if an “aluminum” car is designed with allowance for subsequent rapid disassembly for recycling. Automotive companies will turn to the module design principle, which has been employed quite successfully by the aircraft and spacecraft industries.

Car manufacturers have employed aluminum for more than a decade to take some of the heft out of engine blocks, wheels, car doors, and trunk lids. The current Audi R8 (Figs. 21 and 22) and TT are largely constructed from aluminum, and the A8 and old European market A2 sub-compact both use the substance. The Jaguar XJ is also aluminum-bodied, and the old Honda and Acura NSX and Honda Insight Mk1 were also constructed from aluminum.

Several other cars use aluminum chassis, the Chevrolet Corvette, and several Ferraris being prime examples.

Experience in the cooperation of Alcoa and Audi has shown that modular design of an aluminum car frame has many advantages over the traditional structure from sheet steel, i.e., an over 35% gain in the weight combined with opportunity of increasing the rigidity of the structure at lower capital and labor expenditure. Specifically, the use of a modular aluminum structure instead of the traditional welded steel variant reduces the number of parts by 25% and halves the number of body components.

The Nissan Company, which has been a pioneer in the field starting from the mid-1970s, has created an advanced FEV (Future Electric Vehicle) car. The body

Fig. 21 Aluminum alloys in Audi 8

Fig. 22 Light alloys in Audi 8

of this electro-mobile fabricated from an aluminum alloy instead of steel reduces the weight of a fully equipped and fueled car to 900kg including the 200kg rapidly charged nickel–cadmium battery. The use of aluminum parts for steel ones makes it possible to reduce the weight by 20%–25% and the payload and the haulage without recharging the batteries by 30%–35%.

The main aluminum alloy classes for automotive sheet application are the non-heat-treatable Al-Mg (EN 5xxx series) and the heat-treatable Al-Mg-Si (EN 6xxx series) alloy system, some especially tailored by variations in chemical composition and processing, e.g., Al-Mg alloys optimized for strength and corrosion resistance for use in chassis, or Al-Mg-Si alloys applied for auto-body sheets have been improved for formability, surface appearance, and age hardening response.^[60]

Non-heat-treatable Al-Mg-Mn alloys are applied in Europe for automobile parts in larger quantities as hot and cold rolled sheet and hydroformed tubes, due to their good formability which can always be regained during complex forming operations by inter-annealing where quenching is needed for age hardening. In chassis parts or wheel applications, the benefit is twofold since the weight reduction in the unsprung mass of moving parts additionally enhances driving comfort and reduces noise levels.

Several new product developments were introduced in the SLC (Super-Light-Car) project to meet specific demands of the BIW that cannot be met by the present aluminum alloys, e.g., a high Mg 5xxx alloy specially dedicated to warm forming.^[61] New 6xxx alloys and 7xxx alloys for structural applications were introduced,^[62] such as “Crash alloy” is used for the crash members in the front structure of the SLC model or a “Roof alloy” with special attention when placed on steel structure. Here, a 6xxx alloy (6013 type) has been introduced^[62] with fast paint bake response to withstand the thermally induced plastic deformation.

The SLC concept shows clearly that aluminum can be used for the car body structure and that there can be a weight advantage of at least 30% without losing performance. For most parts, the present grades used for exterior panels can be applied. In some cases where very high strengths are demanded, 7xxx series alloys can be used to maintain this significant weight advantage. For large volume, aluminum solutions are most cost effective. Castings will be applied for areas where strong part integration is feasible. Extrusions can be easily applied as straight profiles, but also forming of an extruded profile is a competitive process for high volumes, e.g., as bumper beams as used in the SLC prototype car.

Aluminum typically is more difficult to spot weld than steel, so Alcoa, among others, has been dedicating more research to discovering new methods of joining sheets of metal together. Research is also underway on better adhesives and coatings. Some of the new alloys may come from aerospace. Cars will not need the same level of

purity, so these alloys may be cheaper. While EVs (Electric Vehicle) and hybrids could benefit from less weight, aluminum bodies will likely appear first with heavier cars and trickle down.

Shipbuilding

Aluminum has proven itself as a lightweight, durable, and affordable material that allows naval ships to go faster speeds, carry bigger payloads, and travel longer ranges. New technologies and advancements are making aluminum an increasingly popular choice for civil and military ships of all sizes.

Their application to ship hull structures is increasing as the alloys make it possible to lower significantly mass of structures as compared with that of steel structures.^[63] By using Al alloys, lowering the mass by about 50% can be obtained, which makes it possible to increase ship buoyancy, or at maintained buoyancy to increase its load-carrying capacity or speed, as well as to improve its stability.^[64] For these reasons, Al alloys are used among others for construction of ship hull and superstructures. Among weldable Al alloys suitable to plastic working, the group of Al-Mg alloys (of 5xxx series) of good weldability and relatively good service conditions are still the most popular. Their relative insusceptibility to layer and stress corrosion is advantageous, and their disadvantage is low strength of welded joints of elements made of them, not exceeding 300 MPa.

Production of seagoing vessels using aluminum began in earnest after World War II with the introduction of GMAW welding technology and the invention of the 5000 alloy series. Arc welding swiftly established itself in the world of shipbuilding as the cheaper, quicker, and more effective method for joining panels and extrusions than riveting. Even above the waterline, where steel meets aluminum special measures are required to prevent corrosion, namely protective paint, insulation, and explosion-bonded aluminum–steel transition joints. The traditional and the most often used Al alloys in shipbuilding are 5083-type Al-Mg alloy for plates and 6082-type Al-Mg-Si alloy for extrusions. These alloys were found to be reliable in marine service as well as during manufacturing.

In order to more intensive craft of weight, Al-Zn-Mg alloys (7xxx series) became more interesting. They are characteristic of higher-strength properties as compared with those of Al-Mg alloys. Susceptibility to layer and stress corrosion is a disadvantage of Al-Zn-Mg alloys. Multiyear research has revealed that thermal working, chemical composition, and welding technology (welding method, kind of added materials, and type of joint) are responsible for stress corrosion susceptibility of the alloys.^[63–70] Practically all welded joints made of alloys of this group by means of traditional GMAW or GTAW methods do not show sufficient resistance to stress or layer corrosion, hence only Al-Mg alloys of 5xxx series are the

only materials applicable to hull structures of lightweight ships. However, the higher-strength alloys are used in ship design elements that have no direct contact with seawater, or are secured by suitable paint coatings.

Sheet alloys 7020, 5083, and 5059 (Table 18) with a thickness $w = 12$ mm were welded by the GMAW method. All welds were made in one of the companies producing marine structures of aluminum alloys—Wisla Aluminum International Ltd. shipyard in Gdansk (Poland).

The mechanical properties of weldments from alloys 7020, 5083, and 5059, and their connections presented in Table 19.^[67]

Table 18 Chemical composition of 7020, 5083, and 5059 aluminum alloys

Alloy	Alloying elements (%)								
	Si	Fe	Cu	Mn	Mg	Cr	Zn	Ti	Zr
7020	0.30	0.35	0.10	0.24	1.30	0.14	4.70	0.080	0.07
5083	0.195	0.18	0.09	0.66	4.75	0.11	0.04	0.025	0.037
5059	0.037	0.09	0.01	0.76	5.41	0.03	0.57	0.024	0.11

Table 19 Mechanical properties of alloys: 7020, 5083, 5059 and their joints welded by GMAW

Alloys	Welding process	UTS (MPa)	YS (MPa)	EL (%)
7020	Base material	373	317	14.2
	GMAW	315	283	8.2
5083	Base material	346	270	19.7
	GMAW	282	206	15.1
5059	Base material	401	280	16.2
	GMAW	296	192	7.6

Comparing the mechanical properties of the same alloys with each other can be seen that 7020 alloy has higher-strength properties of alloys 5083 and 5059. While the tensile strength of 7020 alloy is higher compared to alloy 5083 by 7.2% and less than the 5059 alloy by 7.5%, its yield stress, a parameter which is a ram into account by the designers, is much greater. This parameter is higher, respectively, by 14.8% compared to 5083 alloy and by 11.7% compared to the alloy 5059.

The minimum value of elongation must exceed 10%. The mechanical properties of the joint made by MIG and of the native material are the best for 7020 alloy. Both the tensile strength and yield stress achieve the highest values. Only the plastic properties of the alloy as compared to 5083 are nearly twice smaller and at the same level as the connector alloy 5059. Figure 23 presents those results.

Incat Tasmania Pty Ltd. (Shipbuilding) off the south-east coast of Australia, this manufacturer has over the years taken aluminum shipbuilding to exciting new levels. In 1977, they launched their first high-speed catamaran, and today they are manufacturing the new generation of 98-m (100 plus yards) wave-piercers that are being evaluated by the United States military (Fig. 24).

In modern commercial shipping, there are many examples showing that aluminum has recently proven its mettle. Aluminum profiles play a particularly crucial role in fast catamaran designs. The largest and arguably most impressive of these are Austal's Benchijigua Express that has been servicing the Canary Islands since 2005 and the 112 m long Natchan World, built by Incat and commissioned in 2008 to connect Japan and various Islands across the Tsugarua Strait. Both ships feature welded aluminum hulls. The former can carry over 134 cars and 1350 passengers. Four 8.2 MW engines enable the Benchijigua Express to reach top speeds of up to 75 km/h. Extra protection for the hull is provided by a vinyl film that covers the metal. The Natchan World, meanwhile, boasts a capacity to accommodate as

Fig. 23 Graphic interpretation of mechanical properties of compared alloys: 7020, 5083, 5059, and their joints welded by GMAW

Fig. 24 The Spearhead—new generation of 98-m wave-piercers^[71]

many as 350 cars and 700 passengers. These figures amply demonstrate that aluminum has come a long way from being primarily used as a construction material for smaller boats and luxury yachts. Another of the same type (MGC 66) was launched in February 2009.

But also high-speed monohull designs make use of the light metal. Until autumn 2008, several MDV1200 class ferries used to run between Finland and Estonia by sea before the operator was forced to declare bankruptcy. From 1996 to 1999, six of these ships were built at Genoa, Italy. Both its hull of 100m length, shaped as a deep V, and the superstructure are made of 400 tons of aluminum alloy. Most catamaran ferries in service around the world are smaller than these large ships. An altogether different kind of ships are liquefied natural gas carriers, a sizeable number of which have been built since the 1990s and which sport the so-called independent-type tank containment system. These large structures are made of aluminum alloy or 9% nickel steel.

With the increasing demand to create larger and faster ships, particularly for military service, and the development of new improved, high-performance aluminum base materials, it is apparent that aluminum welding has acquired an interesting and important place within the shipbuilding industry. Also, with the pending introduction of this unique technology into the United States, it is important that designers, manufacturers, and particularly welders and welding engineers are adequately trained and familiar with this new technology.

Railroad Transportation

Heavy operating conditions of railway cars (long life and ability to withstand shock loads) put forward specific requirements for its structural materials. The main construction material for the manufacture of bodies for railroad passenger cars in Russia, Europe, Japan, and the United States is mild steel. This is due to the low-cost steel semifinished products and good weldability with arc welding and contact welding.

At the same time, the connection between the aluminum industry and railroads goes back a long way, in fact almost to the inception of the aluminum industry itself in 1888. The first reported use of aluminum in this market was by the New York, New Haven, and Hartford Railroad in 1894 when it built a special lightweight car with aluminum seat frames. This was followed in 1931 by the development of the all-aluminum hopper cars for freight.^[1] At the World's Fair in Chicago in 1933, the first two mainline, all-aluminum, passenger railroad cars were exhibited.^[72] Experience with aluminum over the past several decades has resulted in numerous applications for the metal not only in freight cars, but also in light rail and inner city commuter trains, metros, and underground trains as well as in the express, intercity passenger trains. There is also considerable use of aluminum in the advanced high-speed trains such as the Acela, the TGV, Transrapid, Shinkansen, and Pendolino-type trains, and the futuristic magnetic levitation (Maglev) trains.

Aluminum alloys in railroad transport in the last decade have expanded the scope of aluminum alloys in railway cars. Replacement of steel structure railway wagon construction for aluminum alloys enables to reduce the mass of container of the car (up to 15%), increase the capacity and speed, reduce the wear of rails and electricity consumption or fuel pull trains (on average 10%), and reduce the cost of current and capital repairs of wagons (up to 18%).

One of the most significant applications of aluminum in rail has been in the development of freight cars for the transportation of a range of commodity materials, especially coal. Typically, railcars are designed for a 30-year life, and materials developments have tended to evolve gradually. However, much of the existing rail stock is now approaching the end of its original design life.^[73]

The use of aluminum in coal freight cars is only one of many freight applications. Aluminum cars are used to transport a variety of metal ores and minerals from mine to market. In all these applications, the high specific strength (strength to weight ratio) of aluminum enables the increased payload and fuel savings. Johnstown America offers an excellent overview of the large number of designs available in aluminum freight cars. Recently, FreightCar America has been able to redesign its Bethgon line of cars to further increase capacity through the use of alloy 6061 extrusions. In other products, aluminum sheet sidewalls offer improved aerodynamics and lower wind resistance and eliminate the need for paint, thereby lowering operating costs.

One of the most significant advantages of aluminum is the application of internally stiffened large hollow extrusions to fabricate moveable sidewalls for freight cars. As compared to conventional steel walls, this type of design enables the wall to be fabricated with many fewer parts, reducing the extent of welding required, and is significantly lighter, which has the further advantage that the wall can

be manipulated by a single worker, thereby saving labor. The 6xxx series alloys (aluminum–magnesium–silicon) normally used for this application offer excellent extrudability, as well as moderate strength and high corrosion resistance, and as a result the wall can be used unpainted and the cut ends of extrusions need not be sealed. The overall aluminum sidewall is virtually maintenance free (Fig. 25).^[74]

Another recent and popular product has been the automotive vehicle carrier. Here the car, enclosed with aluminum sheet, protects new vehicles in transit from the factory to the dealer. Extensive use of aluminum extrusions has enabled lightweight designs, with high carrying capacity for larger vans and Sport Utility Vehicles (SUVs), and especially large doors to facilitate the rapid loading and unloading operations.

The commuter and passenger rail category has an enormous variety of train designs and structures. These range from the light rail, commuter and metro trains, and trams to the more substantial inter-city and express trains. These railcars are made of longitudinal extrusions that run the total length of the car, and the individual extrusions are then welded together longitudinally. In the case of the Washington, DC metro system, these extrusions are 75 feet long. The overall structure is then stiffened by horizontal members that are attached around doors and windows. The floor structure is strengthened by the use of the hollow, integrally stiffened extrusions, and the area near the wheel bogie is strengthened by several transverse members. This design also minimizes the number of parts required, as compared to steel fabrication. This weight reduction is especially significant for commuter trains with frequent stops as it enables energy savings in service and reasonable acceleration between stops. The other advantages of aluminum in durability and corrosion resistance also provide low maintenance costs and long system life.

The Transrapid, which uses aluminum alloys 6061 and 6063, is designed for speeds in the range of 400–500 km/h, while the Japanese MLX01 version is planned to

operate at speed of 550 km/h (Fig. 26). Alloys chosen for railcars are selected based on ease of fabrication, mechanical strength, weldability, and corrosion resistance. As a result, the workhorse materials normally used are the aluminum–magnesium (5xxx) and aluminum–magnesium–silicon (6xxx) alloy series. The 5xxx alloys are not heat-treatable but can be strengthened by cold work and offer moderate strength and excellent corrosion resistance and weldability. The 6xxx alloys are heat treatable and can offer higher strength, good corrosion performance, and good weldability.

The railways of Switzerland are widely used new four-axle passenger cars of type Bt-4, whose body is made of aluminum alloys by welding. The most loaded parts and body parts are made of alloy A1-Mg-Si41. For flooring, corrugated sheet of alloy A1-Mg 1.2mm thick is used. The covering sidewalls made of sheets (thickness 2mm) of alloy A1-Mg3–18 and end walls lining from alloy sheets A1-Mg-Si61 with thickness 3mm. Roof structure consists of the Doug closed sections sheathed by sheet 1.5mm thick corrugated alloy A1-Mg3–18.

Switzerland has the great experience in manufacturing and operation of aluminum wagons. Over 3000 freight wagons with sliding side panels and aluminum bodies run on country roads. They covered with corrugated sheets. Switzerland made wagons for railroads in Morocco to transport phosphates. These cars use aluminum alloys in all constructive elements, except for the frame trucks and wheels. The weight of the car is 14.5 tons. To transport 3930 tons of phosphates, they need only 60 cars made of aluminum alloys instead of 66 made of steel.

The United States, Canada, and Australia widely use aluminum train cars to transport bulk cargo (coal, sulfur, potash, salt, quartz, sand, iron ore, cement, grain, etc.). Useful volume of these railway cars is more than 100m³ and load capacity is 100–200 tons. They are 5–10 tons lighter than railway cars made of steel. Canada use specialized wagons made of 5083 (Al-Mg-4.5 Mn) and 7004

Fig. 25 High-capacity railcar with sliding aluminum sidewall

Fig. 26 Shinkansen 300 (left) and 700 series at Tokyo station

(Al-Zn-Mg) for transporting grains. Thickness of sheet metal in the buffer zone of bars is 12.7 and 6.3 mm in other places. The weight of these cars is 80 tons and carrying capacity is 20 tons.

The AA manual on the repair of aluminum railcars indicates that the commonly used sheet or plate materials are alloys 5052, 5083, 5086, 5454, and 6061. The commonly used extrusion materials are 5083, 6061, and to a lesser degree, such as 7005. Newer alloys, such as 5059, 5383, and 6082, have also been used for railcar applications. A 5xxx filler alloy, such as 5356 or 5556, is generally recommended for the conventional fusion welding processes. The AA offers publications that provide much information on fabrication methods and weld repair procedures for all these materials.^[75,76]

In the past, the highest-strength 7xxx and 2xxx alloys were not widely used because of poorer weldability and corrosion performance.^[76,77]

It is interesting to note that the advanced trains are still using these similar materials. For example, the Japanese Shinkansen^[78] uses 5083 alloy, and also some 7075 material, which is more frequently used as an aerospace material, while the German Transrapid uses 5005 sheet for panels and 6061, 6063, and 6005 for extrusions.

Some recent research for improved rail materials has been evaluating newer aluminum alloys containing scandium additions.^[76] In the case of the 7xxx alloy, however, scandium additions did significantly improve mechanical properties, weldability, and corrosion resistance.

Because of higher mechanical properties, however, the extrusion rate of this alloy is somewhat slower, and hence production costs can be expected to be higher. So the trade-off is whether the improvements in mechanical properties, weldability, and corrosion resistance from the scandium addition to the 7xxx alloy are sufficient to overcome some increase in material cost. As the construction techniques of the advanced trains become more akin to aerospace technology, it could well be that the scandium-modified 7xxx alloy could provide some significant system advantage. For example, a higher-strength extrusion (due to the addition of a scandium-containing alloy) when used to build a total assembly might enable certain design improvements such as the need for less material resulting in a lighter, more fuel-efficient system.

While FSW is being developed for other metals as well, its application for aluminum has been most dominant. One reason for this is that tooling costs are relatively low for aluminum. The relatively low melting temperature of aluminum ($\sim 660^{\circ}\text{C}$) as compared to steel ($\sim 1,500^{\circ}\text{C}$), for example, ensures that the wear of the spinning tool and the forces required for the welding process are much reduced. For the fabrication of rail and passenger cars, FSW is an ideal process for the butt welding of the lengthy longitudinal extruded sections that comprise the roof and floor

sections of the cars. The fact that the technology enables the joining of some alloys that traditionally have been difficult to weld, e.g., most 2xxx and 7xxx alloys, provides a further competitive advantage.

In the United States, the development of passenger rail services has lagged behind the rapid growth of air traffic and air terminals and the continuing development of the interstate road system.

In Germany, France, and Japan, for example, the rail industry is driven by significant government investments. The national high-speed train systems are viewed with a certain amount of national pride and prestige and as an aid to tourism, and there is a continual interest in upgrading performance and establishing speed records between cities.

One major challenge for all countries in this new century surely will be the development of transportation systems that ensure sustainable mobility. With growing evidence of climate change and global warming, it will be increasingly difficult for the nations of the world to ignore these issues. Almost certainly, national transportation systems will strive to become as energy efficient and environmentally acceptable as possible. People around the world will also seek to travel more both for business and recreation and so the concept of enabling this increased mobility in a sustainable manner will become more important. Accordingly, the various attributes of aluminum and especially its lightweight, durability, and corrosion resistance will ensure that aluminum sheet and extrusions will have a strong future in the development of rail transportation systems around the world, and in striving to attain a situation of sustainable mobility for future generations.

Based on the latest achievements,^[79,80] a fundamentally new design—technological scheme has been developed in the manufacture of bodies for passenger cars made of weldable aluminum alloys. The entire body is welded from long hollow panels with only longitudinal seams without lateral seams and no additional longitudinal and transverse shear. The complexity of manufacturing the bodywork of such panels is two to three times lower than for traditional frame-panel manufacturing scheme (Fig. 27).

Table 20 summarizes the key attributes of aluminum and their impact on the various rail applications from freight to high-speed passenger systems.^[78]

Main Factors to Select Aluminum Alloys

Aluminum comes in many different shapes and grades. The type of aluminum grade to choose ultimately depends on how the company intends to use the metal. Table 21 shows the characteristics of each grade widely used aluminum alloys from most important to least important.

Fig. 27 The design of the welded body of the passenger train car (arrows show places of longitudinal welding)

Table 20 Aluminum attributes in rail applications

Attributes	Impacts
<i>Freight applications</i>	
Lightweight	Increase payload, fuel savings Higher initial cost repaid within 2 years
Durability	Lower maintenance, high salvage value
Corrosion resistance	Reduces or eliminates painting
Fabricability (including extrudability, formability, weldability, etc.)	Novel design Integrally stiffened sections with decreased weight Improved sidewall design, reduces labor Reduces number of components Reduces need for welding/machining
Recyclability	Retains high value at End-of-Life (EOL) Supports a sustainable industry
<i>Passenger Applications</i>	
Lightweight	Energy savings in service (commuter trains) High acceleration from propulsion designs
Stiff structures	High passenger safety More controlled tilting for Pendolino designs

(Continued)

Table 20 Aluminum attributes in rail applications (Continued)

Attributes	Impacts
Corrosion resistance	Low maintenance Unpainted structures or reduced need to paint Long service life
Recyclability	Retains high value at EOL Supports a sustainable industry
Advanced High-Speed Trains	
Lightweight	Enables double-decked designs on similar bogies Aluminum sheet sandwich panels employed
Aircraft construction techniques	Stiff, robust structures

Table 21 Types of widely used aluminum alloys and their applications

Alloy	Formability/ workability	Weldability	Machining	Corrosion resistance	Heat treating	Strength	End use applications
1100	Excellent	Excellent	Good	Excellent	Non-heat treatable	Not used for high-strength or high-pressure applications	Metal spinning and general fabrication
2011	Good	Poor	Excellent	Poor	Heat treatable	High strength	General machining
2024	Good	Poor	Fair— annealed	Poor	Heat treatable	High strength	Aerospace applications
3003	Excellent	Excellent	Good	Good	Non-heat treatable	Medium strength	Food and chemical equipment—general fabrication
5052	Good	Good	Fair—hard temper	Excellent	Non-heat treatable	Medium strength	Marine applications— general fabrication
6061	Good	Good	Good—T4 and T6 tempers	Excellent	Heat treatable	Medium to high strength	Structural applications—general fabrication
6063	Good	Good	Fair	Good	Heat treatable	Medium to high strength	Architectural applications
7075	Poor	Poor	Fair— Annealed	Average	Heat treatable	High strength	Aerospace applications

Welding Aluminium Die Castings

Toyosaku Gonda

Production Division, Toyohashi Works, Kyoto Die Casting Co Ltd, Japan

Aluminium die castings do not withstand high temperatures as well as the product of other casting methods. They are easily affected by heat treatments or baking finishes with temperatures over 400°C and to weld such components special measures are required. This article describes use of MIG welding to assemble aluminium die cast parts, covering a period from the initial research stage to the early stages of mass production.

WELDING OF DIE CASTINGS

Defects in die castings have traditionally been repaired by TIG welding. Examples of castings that have been welded are given below:

1955 *Steam iron boiler*. Watanabe Seisakujo Co (Yokkaichi City); ADC 1, gas welding, pressure resistance 3 kg/cm².

1977 *Intake-manifold*: Chrysler Co; A380 electron beam, He atmosphere, welding speed 740–1140 mm/sec.

1977 *Heat exchanger*. Japan Light-Metal Co; ADC12 (PFD) TIG.

FACTORS AFFECTING WELDABILITY

Among factors making the welding of die castings difficult, they contain gas pockets under high pressure and a high impurity content. Because most die castings are made of reclaimed materials, they contain more oxides and gases compared with other cast materials. The mould release agents and plunger lubricants cause hydrogen to be generated. The effect of these factors on weld quality was assessed. Since it is impossible to measure the gas content in a die casting, its effect was assessed by investigating the influence of pouring speed and the effect of vacuum die casting.

Die Casting Materials

Specimens cut from sheet as shown in Fig. 1 were die cast using five different alloys (Table 1). The castings were cut, edge prepared, and TIG welded. Cross sections of the weld samples were prepared and their microstructures were examined (Fig. 2).

ADC6 and Al-Mn alloys showed good results, while ADC12 contained many blowholes. This was attributed to the high gas content of the parent material.

Mould Release Agents and Plunger Lubricants

Specimens were made from mass produced die castings by varying the kinds and the application methods of mould release agents and plunger lubricants. Then, two die castings were TIG welded without filler metal. The welding was done without preparing the surfaces to be joined, which were the tips of the side walls put together at three places, *i.e.* sprue gate, sprue runner and overflow gate. After welding, the welds were fractured and blowholes on the fractured surfaces were examined and counted (Fig. 3 and Table 2).

As a mould release agent, a water soluble type is suitable, but it is inferior in releasing ability to a pigment release agent. Considering plunger lubricants, an oil type is not suitable for application to the inside of a sleeve. Lubricant diluted by ethanol is advantageous as it leaves less moisture.

The suitability of a mould release agent can be assessed from the appearance of the fused zone of a die casting melted by TIG. Figure 4 shows die castings which were made using the five different kinds of mould release agents listed in Table 2, and whose external surrounding edges were then melted by TIG. The appearance of the beads corresponds with the result of the previous test.

Pouring speed

Pouring speed and gas content of a die casting are considered to be related. Die casting was performed at the fixed pouring pressure of 8.14 N/mm² using three pouring speeds: 7, 35 and 91 m/sec. The same test as described above was implemented, but there was virtually no difference in results though the appearance of weld beads was neater when the pouring speed was higher.

Mould temperature

The same test was carried out using varying mould temperatures. The higher the mould temperature, the better the result (Fig. 5). The same trend was confirmed from the

Fig. 1 Die casting specimen and welding conditions

Fig. 2 Cross sections of weld zones of die casting materials

Fig. 3 The welded die casting: a) Assembly of die castings by TIG; b) Fractured surface

result of an investigation into TIG welding the continuous shots from the beginning of casting (Table 3).

Effect of the Vacuum Method

Reducing the gas in the mould by a vacuum method is effective in removing vapor and moisture. Figure 6 shows die castings made by the vacuum method welded by TIG. Figure 7 shows vacuum die castings after being heated to 500°C for 1hr. They have hardly any blowholes.

AUTOMATIC MIG WELDING FOR DIE CASTING

Heat exchangers with combustion chambers were mass produced by the welded assembly of die castings. Figure 8 shows the parts to be assembled and their cross sectional structures. They are made up of a blower casing, a burner proper and the heat exchanging system of a combustion chamber, which are all die castings. The blower and the burner were assembled with screws and the heat exchanger, composed of two die castings, welded together. Specifications are given in Fig. 9. Welding conditions are described below.

Depth of Penetration

Two each of the same die cast specimens as in Fig. 1 were welded longitudinally and then tensile test samples of 20mm width were taken from the center. The results of the tests are shown in Fig. 10. A trend is apparent in Fig. 10 though it is not comparing tensile strength as notches are

Table 2 Mould release agents, plunger lubricants, and weldability

Type		Amount used		Weldability			Remarks
		Solid type	Flux type	Sprue gate	Sprue runner	OF	
Mould release agent	1 ALD-TR	70cc	70cc	X	X	X	Parafin oil, 10 parts to 1 with aluminium powder
	2 AQD	60~80	80~90	X	X	X	Water, 20 parts to 1 part black lead
	3 PRD	130~150	180~200	X	X	X	Water, 20 parts to 1 part black lead
	4 PRD-E	130~140	180~200	⊙	○	○	Water 40%, ethanol 40%, PRD 10%, black lead
	5 ALD-OE	160~180	200~240	⊙	⊙	○	Water, 20 parts to 1 part wax
Plunger lubricant	1 PH	3cc sprayed on the inside of sleeves		X	X	X	As the original liquid, black lead (release agent 5)
	2 PH	3cc of liquid dropped on the outside of sleeves		⊙	⊙	○	As the original liquid, black lead (release agent 5)
	3 AC	10cc sprayed on the inside of sleeves		⊙	⊙	○	Water 30%, ethanol 40%, HC 40%, black lead (release agent 5)

Samples: ADC 12, weight 1420 g, average thickness 3.0 mm, number of samples three each, plunger lubricant was not used for mould release agent tests, mould temperature 180–260°C.

Welding conditions: TIG, 105A, without filler metal, speed 180 mm/sec.

Weld locations: Sprue gate side, sprue runner side, overflow gate, distance between each 60 mm.

Assessment method: Blowholes were examined in a 40 mm area at the centers of fracture surfaces.

⊙ The total of three samples is under 2.9 mm².

○ The total of three samples is 3.0–5.9 mm².

X The total of three samples is over 6.0 mm².

**Fig. 4** Test of effects of mould release agent on TIG welding

present and the heights of the beads differ: the deeper the fusion penetration, the smaller the strength per unit area becomes. Die castings contain more blowholes when the parent metal is melted.

Groove Shape

The height of the back bead varies to a large extent according to the shape and position of the die casting. This is

Sample no.	Temperature, °C		Weldability
	Sprue gate	Sprue runner

20	190	180	200	220	⊙	

**Fig. 6** Die castings by vacuum method

thought to cause a residue of combustion products, and hence a problem in corrosion resistance. To reduce the height of the back bead to under 1mm, a groove was made as shown in Fig. 11. The groove area was clad sufficiently to be thicker than the average thickness of the die casting, because the shape of a bead becomes unstable if the thickness of the surrounding area changes.

Filler Metal

Generally, A4043 is used for welding die castings. This produces a problem in wire feeding, but A5183 and A5356

Heating, 500°C for 1hr
 Top Vacuum method
 Bottom Vacuum method + O₂ blowing

Fig. 7 Heat resistance of vacuum die castings

with better feeding ability were not employed because of higher residual stress and more micro-fissures.

To improve the feeding ability of A4043-WY, it was decided to obtain wire with a higher Si content of 5.5–6.0%. A black lead insert was fixed at the end of the copper to reduce friction.

2.0	26	225

A4043 filler metal, 1.2mm diameter, Ar 24 litre/sec
Speed, 700 mm/sec

Fig. 10 Penetration depth and joint strength (dimensions mm)

Welding Speed and Number of Passes

When welding speed is reduced and the fusion penetration of the die casting becomes deeper, blowholes increase, and, as the bead runs on a curved surface, constant thickness cannot be ensured. Also, the shape of the surrounding area is easily affected.

The welding of a heat exchanger was performed under the conditions shown in Table 4.

Welding Defects

The following weld defects are found in die castings:

Fig. 11 Groove shape and bead

Table 4 Welding conditions for heat exchanger

	Voltage, V	Current, A	Speed, mm/sec	
			Straight weld line	Curved regions
Start (1.5sec)	22	160	1500	1.25 0
Pass 1	23~24	170~180		
Pass 2	24~25	210~220	1250	1.25 0

A4043 wire, 1.6 mm diameter, pass 2 was continued from pass1 by reversing rotation Welding time 80 sec/piece.

Blowholes

These are generated if traces of mould release agents and lubricants are left in die castings. They are also easily generated in a curved weld area as it is not shielded well by Ar gas. Therefore, it is necessary to ensure a sufficiently large value for the component radius.

Bead Irregularities

These are generated in the curved areas and inflection points, and become larger unless the position of the work-piece and the angle of the torch are altered smoothly. It is preferable to use lower current and voltage. Also, it is effective to increase the thickness of such areas so that heat capacity can be larger.

Cracking

There are rare cases in which cracking occurs at right-angles to the bead. When the composition of such an area

is analyzed, copper is found in unusual quantities. When a copper tip is burnt back, it penetrates deeply and causes high temperature cracking.

SUMMARY

Die casting is an efficient process for mass production. Assembly by welding is competitive in cost with screw assembly and one-piece moulding by soluble cores.

Die castings are inferior in heat resistance, but improvements are being made. Ease in producing a wide range of shapes can make up for this disadvantage. Joint shapes which are good in sealing ability and stress resistance can be produced.

Welding Parameters for Aluminum Alloys

Meysam Haghshenas

Department of Mechanical Engineering, University of North Dakota, Grand Forks,
ND 58202, United States

Abstract

With increasing application of aluminum and aluminum alloys, as the most commonly used non-ferrous metallic alloys in industrial scales, joining and in particular welding of these alloys remains an important area for mechanical and welding engineers as well as manufacturers to gain broad and comprehensive knowledge of welding parameters of aluminum. This article presents a discussion about weldability and properties of different aluminum alloys before and after welding. To this end, welding of cast and wrought, and heat treatable and non-heat treatable aluminum alloys are assessed in detail in this article. Also, the challenges encountered with aluminum welding, different aluminum welding processes including conventional and solid-state welding techniques are discussed.

Keywords: Aluminum; Cast alloys; Heat treatment; Weldability; Welding; Wrought alloys.

INTRODUCTION

Welding is the secondary step in manufacturing of aluminum-made components in aerospace, automotive, and structural applications. It is reported that the manufacturing of an aluminum-welded product is faster (and therefore more cost saving) than the equivalent steel fabrication. It is also reported that 10% reduction of the total mass of vehicle involves saving 6%–8% of gasoline. Decreasing the total weight of each 45 kg causes savings of 3.4–5.3 l fuel per 1600 km.^[1]

Welding of aluminum as a nonferrous metallic material is completely different from ferrous metallic materials, like steel and cast iron, and therefore requires specific consideration/characteristics that need to be understood and proper procedures must be employed. The main characteristics of aluminum as compared with steels are listed here:

- Coefficient of thermal expansion of aluminum is twice that of steel; therefore, it is prone to more distortion and stress inducement as compared with steel.
- Aluminum, unlike steel, does not change color when heated (welded).
- As a reactive material, aluminum contains a tenacious and refractory surface oxide film (i.e., Al_2O_3) creating some challenges during welding, i.e., lack of fusion or porosity.
- Unlike steel, a reduction of strength in the aluminum weld area is observed, which creates local softening.
- Thermal conductivity of aluminum is three to five times that of steel, which means heat is easily conducted away from the welding area creating some challenges in the welding adjustments.

- Aluminum is very prone to contaminations, and therefore very clean working practice is required when considering aluminum welding.
- The high solubility of hydrogen in liquid aluminum, which is compared with its solubility in solid aluminum, can lead to porosity in weld metal.

Considering abovementioned challenges, this chapter is aimed at providing detailed information about welding of wrought and cast aluminum alloys, different aluminum welding techniques, and possible welding challenges in aluminum and its alloys.

To obtain a material with good combinations of properties (i.e., physical and mechanical), aluminum is nearly always alloyed with other metals. Main alloying elements, added to aluminum, are silicon (Si), magnesium (Mg), manganese (Mn), copper (Cu), and zinc (Zn). Aluminum alloys are divided into two groups: wrought alloys and cast alloys, Table 1. In Tables 2 and 3, the most commonly used cast and wrought aluminum alloys are listed. The wrought alloys are mainly used for profiles and sheeting, and are most commonly used in welded constructions. The wrought alloys are themselves divided into “non-heat-treatable” and “heat-treatable” alloys, Fig. 1 and Table 2. Heat-treatable alloys are based on aluminum-copper (i.e., Al2024 and Al2014), aluminum-magnesium-silicon (i.e., Al6051 and Al6070), aluminum-zinc (i.e., Al7075 and Al7079), and aluminum-lithium (i.e., Al8090 and Al8011) alloy systems. They can develop high strength by solution treatment followed by age hardening at elevated temperature (precipitation strengthening). Non-heat-treatable alloys include pure aluminum, and those alloys based on aluminum-manganese (i.e., Al3003

and Al3004), aluminum-silicon (i.e., Al4041), and aluminum-magnesium (i.e., Al5052 and Al5083). These alloys can be strengthened mainly through cold working (strain hardening).

WELDABILITY OF ALUMINUM AND ITS ALLOYS

The term “weldability” refers to the material’s ability to be welded. A material’s weldability is used to determine the welding process and to compare the final weld quality with other materials. Many elements will alloy with aluminum but only a relatively small number of these gives an improvement in strength or weldability.

The weldability of aluminum alloys varies significantly depending on the following:^[4]

- Chemical, metallurgical, and physical properties of the alloy.
- Design, service, and loading conditions.
- Welding conditions including preparation for welding, welding operations, and post-welding operations.

Alloy composition and solidification process play important roles in the weldability of aluminum and aluminum alloys; therefore, to better understand the concept of weldability in aluminum alloys, solidification behavior of aluminum welds is discussed here.

Three solidification mechanisms are known:

- Pure metals where solidification occurs at a constant temperature equal to freezing (melting) temperature.
- Eutectic alloys with little eutectic at the grain boundaries.
- Hyper- and hypoeutectic alloys with sufficient eutectic at the grain boundaries, no critical temperature.

Those aluminum alloys with large solidification range are susceptible to hot cracking (this concept will be addressed more in detail in the next sections). To prevent the problem, the welding speed has to be increased to lower the heat input. Preheating, also, reduces the temperature gradient across the weld zone and therefore helps reduce hot cracking; it, however, can reduce the mechanical properties of the base material and should not be used when the base material is restrained. The design of the joint can be changed as well to avoid hot cracking (i.e., a V-groove with width-to-depth ratio <1). A more compatible filler alloy can be selected to decrease the likelihood of hot cracking as well. In fusion welding processes, due to the rapid cooling of the molten weld pool, the filler metal must be able to guarantee the strength and formability as well as to be able to counteract the risk of cracking due to shrinkage. Also, the filler metal must be chosen to ensure a sufficiently large amount of eutectic. Grain boundary sliding leads to deformation and material separation. If enough eutectic is available, this can flow in and counteract solidification defects. Therefore, Al-Si filler materials have a lower risk of cracking than the Al-Mg-Mn fillers, but with reduced strength. Aluminum alloys should also be cleaned prior to

welding, with the goal of removing all oxides, oils, and loose particles from the surface to be welded. This is especially important because aluminum welds are susceptible to porosity due to hydrogen and dross due to oxygen.

WELDING OF CASTING ALUMINUM ALLOYS

Copper, silicon, magnesium, zinc, iron, manganese, and nickel are the main alloying elements frequently used in aluminum castings. Many aluminum cast alloys are based on the Al-Si or Al-Cu systems. Silicon provides good fluidity for casting of intricately shaped sections. Beside this, Si reduces hot shortness and the tendency for castings to crack on solidification.

Aluminum castings possess limited applications in welded constructions, mainly due to their low ductility

and high porosity content. However, repair of castings by welding is often required. Many casting alloys, specifically those containing copper, are not recommended for welding because they are very sensitive to crack propagation. Pure aluminum, Al-Si, and Al-Mg based alloys may be welded with appropriate filler metals.

WELDING OF WROUGHT ALUMINUM ALLOYS

Non-heat Treatable Alloys

Pure Aluminum (1XXX Series)

Series 1XXX contains no alloying elements, and therefore it is not heat-treatable. It is used primarily in decoration applications, electrical bus conductors (due to its excellent

7XX.O (Zn)		
710.0	X	Good brazing characteristics
712.0	X	General purpose, corrosion-resistant applications

electrical conductivity), as well as chemical tanks and pipe services (thanks to its superior corrosion resistance). This series can be joined using conventional welding techniques [i.e., gas metal arc welding (GMAW) and gas tungsten arc welding] as well as resistance and friction (stir) welding methods. The 1XXX series are readily welded using filler metals of matching composition. It is also possible to use Al-Si or Al-Mg filler metals for some applications.

Aluminum-Manganese Alloys (3XXX Series)

Moderate in strength, the 3XXX series is used for forming applications including utility and sheets. 3XXX series are non-heat treatable and their mechanical properties are improved through strain hardening. The 3XXX series

alloys are weldable alloys, welded typically with 4043 or 5356 filler wire; this series is excellent for welding and not prone to hot cracking. However, those alloys containing copper (i.e., Al3003) or magnesium (i.e., Al3004, Al3005, and Al3105) are more sensitive to hot cracking.

Aluminum-Silicon Alloys (4XXX Series)

Silicon mainly improves fluidity (castability) of aluminum alloys. In particular, 4047 alloy is used in the automotive industry thanks to its good response to brazing and welding. Using Al-Si filler metal, these alloys are welded by different welding processes. However, these alloys are majorly used for welding purposes, i.e., Al4043 and Al4047 for their high fluidity and low sensitivity to hot shortness.

Aluminum-Magnesium Alloys (5XXX Series)

The 5XXX series possess the highest strength of the non-heat treatable aluminum alloys. It is used for chemical storage tanks and pressure vessels as well as structural applications (i.e., bridges), and automotive and railway industries. If the magnesium content in the alloy is less than about 3% (i.e., Al5251 and Al5454), the welding is challenging as it is susceptible to cracking. Therefore, use of higher magnesium fillers is recommended to overcome cracking tendency. Alloys with more than 4.5% Mg can be readily welded. GMAW and gas tungsten arc welding are the most frequently used welding processes for these alloys. The strength of 5XXX aluminum weld metal is generally close to that of the annealed wrought parent metal of the same composition and therefore joint strengths, at least, equal to the annealed condition are quite achievable.

Heat-treatable Alloys

Aluminum-Copper Alloys (2XXX Series)

The 2XXX aluminum series is mainly used in aircraft parts, rivets, and screw products. The strength in this series can be achieved through precipitation hardening with hardening phase of copper aluminide, CuAl_2 . Precipitation hardening, also called age hardening as it involves the hardening of the material over a prolonged time, is a strengthening method based on heat treatment in metals and alloys including aluminum (i.e., Al2024 and Al6061), magnesium (i.e., AZ91), nickel-based super alloys (i.e., Alloy 718), titanium (i.e., Ti-6Al-6V-2Sn and Ti-6Al-4V), and some stainless steels (i.e., A286 and 17-4 PH). Precipitation hardening is achieved by the following:

1. Solution heat treatment where all the solute atoms are dissolved to form a single-phase solution.
2. Rapid cooling across solvus line to exceed the solubility limit. This leads to a supersaturated solid solution that remains stable (metastable) due to the low temperatures, which prevent diffusion.
3. Precipitation heat treatment where the supersaturated solution is heated to an intermediate temperature to induce precipitation and kept there for some time (aging).

Strengthening involves the formation of a large number of microscopic nuclei called as zones. It is accelerated at high temperatures. Hardening occurs because the deformation of the lattice around the precipitates hinders slip. Aging that occurs at room temperature is called natural aging, to distinguish from the artificial aging caused by premeditated heating.

The 2XXX aluminum series tend to crack (hot cracking) if attempts are made to weld them through fusion welding processes; the use of Al4047 filler may sometimes give

reasonable results though. Most 2XXX series alloys are considered poor for arc welding because of their sensitivity to hot cracking. Within this series, three alloys that are widely used in welding fabrication include Al2014, Al2219, and Al2519 being easily welded with Al4043 or Al2319 filler wire. Solid-state techniques can give some success in joining similar and dissimilar 2XXX aluminum series. Solid-state welding is a group of welding processes, such as friction welding (FRW) and friction stir welding (FSW), which produces coalescence at temperatures essentially below the melting point of the base materials being joined, without the addition of brazing filler metal. Solid-state welding techniques and their parameters in aluminum will be discussed later in this chapter.

Aluminum-Magnesium-Silicon Alloys (6XXX Series)

The 6XXX aluminum series is the most commonly used aluminum alloys in automotive, pipe, railings, and structural applications. This series can be strengthened through age hardening and its hardening constituent is magnesium silicide, Mg_2Si . If high heat inputs are used, those alloys with less than 1% Si and 1% Mg are prone to hot cracking; however, this problem can be overcome by the correct choice of filler metal, i.e., filler containing 5% Mg or 5% Si. Al4043 filler wire is most commonly used with this series. A weld metal with a composition close to that of the parent metal may age harden naturally (or artificially) to achieve a strength approaching that of the aged parent metal.

Aluminum-Zinc-Magnesium Alloys (7XXX Series)

The 7XXX is the strongest heat-treatable aluminum wrought alloy. It is mainly used in aerospace and aircraft applications. Precipitates of composition MgZn_2 and CuAl_2 and intermetallic of the copper-zinc system are the main strengthening elements in this aluminum series. Both weldable and un-weldable grades exist in this series although even the weldable alloys are susceptible to HAZ hot cracking due to wide melting ranges and low solidus melting temperatures. The Al7005 and Al7039 alloys are weldable with 5XXX filler wires widely used for bicycle frames and other extruded applications. GMAW and gas tungsten arc welding are the main processes used to weld these alloys. However, one peculiar problem in the fusion welding of 7XXX series is rapid formation of zinc oxides during welding, affecting the surface tension of the weld pool and therefore increasing the risk of lack of fusion defects. To prevent this problem, a welding current of 10%–15% higher than that of 5XXX alloy and shorter arc length are recommended.

Other Alloys (8XXX Series)

Included in the 8XXX series are the Al-Li alloys that give substantial weight savings of up to 15% and a higher Young's modulus compared with some of the other

high-strength alloys. Al-Li alloys generally contain some 2%–3% of lithium and small amounts of copper and magnesium. They are fully heat treatable, with a number of different precipitates, the principal one being Al_3Li . Strength loss in the HAZ and lithium’s great affinity for oxygen are two main challenges when considering welding of 8XXX series. However, a post-weld artificial aging treatment can restore a large proportion of the strength. Al-Cu filler metals, i.e., Al4043 and Al4047, can be used in welding of these alloys.

THE CHALLENGES OF ALUMINUM WELDING

Porosity

Porosity arises from gas dissolved and trapped in the molten weld metal as it solidifies, thus forming bubbles in the solidified weld. The porosity problem in the case of aluminum welding arises from high solubility of hydrogen in molten aluminum but very low solubility in the solid (Fig. 2). A decrease of solubility to the order of 20 times is observed as solidification takes place. This drop in solubility is so pronounced that it is extremely difficult to produce a porosity-free weld in aluminum.

The sources of hydrogen that create porosity are as follows:

- Hydrocarbons in the form of paint, oil, grease, other lubricants, and contaminants.
- Hydrated aluminum oxide: aluminum oxide can absorb moisture and become hydrated. The hydrated oxide will release hydrogen when subjected to heat during welding.

- Moisture (H_2O); moisture within the atmosphere can be a serious cause of porosity under certain circumstances. Moisture from other external sources such as compressed air, contaminated shielding gas, or pre-cleaning operations must also be considered.

Remedial actions to prevent porosity problem include the following:

- Ensure base metal and filler wire free from moisture, oil, lubricants, paint, or grease.
- Use low dew point shielding gases (Argon or Argon/Helium mixtures). Helium mixtures reduce porosity.
- Clean joints with special solvents, i.e., acetone, methyl ethyl ketone, lacquer thinner, toluene, and dedicated steel brushes.
- Cover welding wire at all times.
- Store metals vertically to lower condensation and water accumulation.
- Introduce filler and base material in the welding area 24 hours before welding so as to familiarize them to workshop conditions.
- Monitor torch angle to ensure air is not being aspirated into the protective inert gas shield. The standard fore-hand angle is 10° – 15° from perpendicular.
- Avoid excessive spatter buildup inside gas nozzle.
- Use the correct contact tip to work distance.
- Avoid exhaust contamination from compressed air tools.
- Check for inadequately pure shielding gas (as supplied). Argon should be 99.997% pure. Helium should be 99.995% pure.

Table 4 summarizes the causes and prevention of porosity in the welding of aluminum.

Fig. 2 Solubility of hydrogen in aluminum^[5]

Table 4 Summary of causes and prevention of porosity^[4]

Mechanism of porosity formation	Potential causes	Remedial measures
Hydrogen entrapment	Oxide film, grease, drawing soap on filler wire; oxides, grease, dirt on parent plate; dirt/grease in liner; contaminated shield gas; water leaks in torch; spatter on weld face.	Clean wire, use high-quality gas, change liner, protect wire from contamination, change torch, clean plate, minimize spatter.
Gas/air entrapment	(a) Weld pool turbulence due to high current. (b) Gas expanding from root of partial penetration/fillet welds.	(a) Use lower current, reduce travel speed, change gun angle. (b) Use full pen weld, allow gap in fillet weld root, use high heat input.
Rapid freezing trapping gas	Heat input too low, rapid heat loss, viscous weld pool, cold backing bar.	Increase current, slow travel speed, consider preheat, heat backing bar, replace argon shield gas with helium.
Erratic wire feed	Kinked, blocked, or wrong size liner; incorrect or badly adjusted drive rolls; damaged contact tip; unstable power supply.	Straighten wire conduit, replace contact tip, adjust drive roll pressure, fit correct liner, fit grooved rolls.

Oxide Film

The high affinity of aluminum for oxygen, which causes metallic blank aluminum to be covered at once with a thin, dense, and tightly adhering oxide film, has a major effect on the suitability of aluminum for spot welding. Aluminum oxide (Al_2O_3) is a very tenacious and rapid-forming oxide that provides excellent corrosion resistance in aluminum alloys. The melting temperature of Al_2O_3 is slightly above 2060°C compared with the aluminum base metal with the melting temperature of 660°C . Therefore, heating aluminum to its melting point without dispersing the oxide film will result in a molten pool of aluminum entrapped in a skin of oxide. For a successful welding operation, this skin has to be removed by some suitable means.

The structure of the oxide film consists of an almost pore-free barrier layer and a covering porous oxide layer. The typical thicknesses lie between 0.005 and $0.01\ \mu\text{m}$ (Fig. 3). In resistance spot welding (RSW), for example, the high electrode contact pressure causes the sheet surfaces to be deformed locally breaking the brittle oxide film and causing the welding current to flow through the fine contact bridges; due to the heat developed and the continuing deformation, the contact bridges are enlarged, causing the contact resistance to fall rapidly.

Remedial Actions

In gas shield arc welding, during the positive polarity at electrode, the cathodic cleaning of oxides occurs. Once the electrode is connected to the positive pole of the power source and direct current (DC) is passed, electrons flow

from the work piece to the electrode with ions traveling in the opposite direction and bombarding the work piece surface (Fig. 4). This action breaks up and disperses the oxide film and permits the weld metal to flow and fuse with the parent metal. In MIG welding process, only DC electrode positive (DCEP) current is used and using DC electrode negative (DCEN) results in an unstable and erratic arc. In tungsten inert gas welding (TIG) welding, DCEN results in poor quality weld as well. On the other hand, DCEP with TIG results in the tungsten electrode overheating as $60\%–70\%$ of the heat generated in a TIG welding arc may be produced at the positive pole. To remove the oxides during melting of aluminum alloys by GTAW, alternative current (AC)/DCEP can be used.

**Fig. 3** The structure of oxide film on the aluminum surface^[6]

Fig. 4 Effect of polarity on cathodic cleaning and heat balance^[4]

Hot Cracking

Hot cracking, as the name suggests, is a high-temperature cracking mechanism being known, because of its prevalence, by a number of different names, i.e., hot fissuring, hot shortness, liquation cracking, centerline cracking, or solidification cracking.

Three areas can significantly influence the probability for hot cracking in an aluminum-welded structure:

1. Susceptible base material chemistry that effects the probability of cracking.
2. Selection and use of the most appropriate filler metal to help prevent the formation of a crack-sensitive chemistry.
3. Choosing the most appropriate joint design that will provide the required dilution of filler metal and base metal in order to avoid a crack-sensitive chemistry in the weld.

The risk of hot cracking is a function of how metal alloy systems solidify (see Fig. 5). The cracking susceptibility increases with increasing solidification range. Pure metal has no such solidification range and has, therefore, almost

no hot crack sensitivity. The addition of alloying elements to a pure metal will cause a change in the freezing temperature of the alloy from that of the pure metal and may result in a number of different phase, i.e., solid solution, eutectic, and intermetallic compound. *Eutectic* composition, the lowest melting point composition of the alloy, freezes at one specific temperature while the other non-eutectic compositions freeze over a range. Therefore, the first metal to solidify will be the highest melting/freezing point alloy and the last to be the lowest melting point composition, always eutectic if one has formed. The end result of such a solidification pattern is that the lowest melting point alloy composition is pushed ahead of the solidifying dendrite until it becomes trapped between the adjacent dendrites, i.e., along the grain boundaries.

Aluminum crack-sensitive curve diagrams are a very helpful tool for understanding why aluminum welds crack and how the choice of filler alloy and joint design can influence crack sensitivity. The diagram (Fig. 6) shows the effects of four different alloy additions—silicon (Si), copper (Cu), magnesium (Mg), and magnesium silicide (Mg_2Si)—on the crack sensitivity of aluminum. The crack -sensitive curves reveal that with the addition of small amounts of alloying elements, the crack sensitivity

Fig. 5 Different types of solidification in aluminum weld^[7] from left to right: unalloyed structure (susceptible to pores), the structure with low content of alloying elements (susceptible to cracks), and sufficient grain boundary eutectic (susceptible to cavities)

Fig. 6 Effect of solute concentration on crack sensitivity^[4]

becomes more severe, reaches a maximum, and then falls off to relatively low levels. After studying the crack-sensitive curves, it is easy to recognize that most of the aluminum base alloys considered un-weldable autogenously (without filler alloy addition) have chemistries at or near the peaks of crack sensitivity. Additionally, the chart shows that alloys that display low cracking characteristics have chemistries well away from the crack-sensitive peaks.

Based on this information, it is clear that crack sensitivity of an aluminum base alloy is primarily dependent on its chemistry. Utilizing these same principals, it can be concluded that the crack sensitivity of an aluminum weld, which is generally comprised of both base alloy and filler alloy, is also dependent on its chemistry. With the knowledge of the importance of chemistry on crack sensitivity of an aluminum weld, two fundamental principles apply that can reduce the incidence for hot cracking. First, welding base alloys that have low crack sensitivity always use a filler alloy of similar chemistry. Second, welding base alloys that have high crack sensitivity use a filler alloy with a different chemistry than that of the base alloy to create a weld metal chemistry that has low crack sensitivity. When considering the welding of the more commonly used 5XXX series (Al-Mg) and the 6XXX series (Al-Mg-Si) aluminum base alloys, these principals are clearly illustrated.

The Si and Mg contents have a very pronounced effect on the weld cracking sensitivity. The heat-treatable alloys, in particular, have compositions that lie in the critical region. Consequently, these alloys are welded using non-heat-treatable filler metal alloys even though this tends to

reduce the strength at the joint. The use of heat-treatable filler metal alloys has proved to be unsatisfactory. Aluminum alloys containing copper have solidification intervals of greater than 100°C and are thus highly sensitive to cracking.

The 6XXX alloys show a strong tendency to hot cracking during welding (Fig. 7). The Al-Mg-Si alloys are of a chemistry that makes them crack sensitive because the majority of these alloys contain approximately 1.0% magnesium silicide (Mg_2Si), which falls close to the peak of the solidification crack sensitive curve. The Mg_2Si content of these materials is the primary reason behind no 6XXX series filler alloys. Using a 6XXX series filler alloy or autogenously welding would invariably produce cracking problems in the weld. During arc welding, the cracking tendency of these alloys is adjusted to acceptable levels by the dilution of the base material with excess magnesium (by use of the 5XXX series Al-Mg filler alloys) or excess silicon (by use of the 4XXX series Al-Si filler alloys). In TIG welding of thin sections, utmost protection must be employed. It is often possible to produce a weld, particularly on outside corner joints, without adding filler material by melting both edges of the base material together. These types of techniques should be avoided as the absence of filler metal will produce welds that are extremely susceptible to cracking.

The 5XXX alloys such as the Al5754 and Al5182 show less susceptibility to hot cracking.^[9] The majority of the 5XXX base metals that contain around 5% Mg (Al5086 and Al5083) show low crack sensitivity. These base metals are

Fig. 7 A typical hot cracking phenomenon in the weld material, partial penetration weld of Al6061: (a) cross section of weld macrograph; (b) solidification cracking, it is dendritic fracture surface; (c) liquation cracking, it shows smooth fracture surface^[8]

easy to weld with a filler metal that has Mg content similar to the base metal. This will usually provide a weld with excellent crack resistance. These alloys should not be welded with a 4XXX series filler alloy as excessive amounts of magnesium silicide can form in the weld and produce a joint with undesirable mechanical properties. There are base alloys within the 5XXX group, such as Al5052, that have a Mg content that falls very close to the crack sensitive peak. In case of these alloys, definitely avoid welding autogenously. The Mg base alloys like Al5052 with Mg contents below 2.5% can be welded with the 4XXX filler alloys such as Al4043 or Al4047 and the 5XXX filler alloys such as Al5356.

A number of methods can be employed to reduce the crack sensitivity in aluminum welds including

- Preheating the parts (recommended for thick sheets).
- Applying low heat input (welding processes with higher welding rates and lower energy per unit length of weld).
- Having a small grain size: it has been found that small additions of elements such as titanium, zirconium, or scandium will act as nuclei for the formation of a very fine grain during solidification. Filler metals can be purchased that are alloyed with titanium and/or zirconium.
- Controlling the composition of the weld pool by adding filler metal to produce an alloy that is not in the hot short range.
- Using an edge preparation and joint spacing to permit sufficient filler metal to be added to achieve a weld metal composition outside the hot short range.
- Using the highest welding speed: High speeds reduce the length of time the weld is within the hot short temperature range.
- Using high-speed, small-volume multi-run procedures instead of large volume, single run deposits.
- Selecting welding and assembly sequences that minimize restraint and residual stresses.
- Applying an external force to maintain the weld in compression while it is in the hot short range.
- Selecting a filler metal with a melting point close to that of the parent metal.

ALUMINUM WELDING TECHNIQUES

A variety of welding processes can be used to join aluminum including fusion welding methods (i.e., GMAW, gas tungsten arc welding, and laser welding), and resistance and solid-state (i.e., friction Stir) welding techniques to join similar and dissimilar aluminum alloys. Choice of process is based on technical and/or economic reasons. For most structural, economical, and quality welds, GMAW and gas tungsten arc welding are recommended for aluminum.

Gas Metal Arc Welding (GMAW)

GMAW uses a continuously fed wire as electrode and as filler metal; in this technique, the arc and the weld pool are protected by an inert gas shield. Fig. 8 shows a schematic illustration of GMAW. The GMAW of aluminum is always carried out with a completely inert gas shield, traditionally argon but now increasingly helium-argon mixtures, which help to increase penetration and to reduce the incidence of porosity. It must be remembered that aluminum and its alloys must not be welded through GMAW using active gases such as carbon dioxide or Ar/CO₂ mixtures, since these will lead to severe oxidation and failure to produce a weld.

The main advantages of GMAW in welding of aluminum include the following:

- High welding speeds.
- No need for flux.
- Excellent oxide film removal during welding.
- All positional welding capability.

For these reasons, GMAW is the most widely used arc welding process for the joining of aluminum. The thermal conductivity of the aluminum base material is higher than it is for carbon steel; therefore, lower energy modes of metal transfer (i.e., short circuit transfer) are unable to provide sufficient melting of the base material to ensure good fusion. Axial spray (Fig. 9a) and pulsed spray metal transfer (Fig. 9b) are the preferred metal transfer modes

Fig. 8 Schematic illustration of GMAW

Fig. 9 Schematic illustration of axial and pulsed spray metal transfer in GMAW^[7]

for aluminum, each of these are capable of providing the required energy levels for base metal melting to assure good fusion. Spray transfer is named for the spray of tiny molten droplets across the arc, and it is usually smaller than the diameter of the wire and uses relatively high voltage and wire feed speeds or amperage. Unlike short-circuit transfer, once the arc is established, it is on at all times. This method produces very little spatter and is most often used on thick metals in the flat and horizontal positions. In the pulse-spray transfer mode, the power supply cycles between a high spray transfer current and a low background current. This allows for supercooling of the weld pool during the background cycle, making it slightly different from a true spray transfer. Ideally, in each cycle, one droplet transfers from the electrode to the weld pool. Because of the low background current, this mode of transfer can be used to weld out of position on thick sections with higher energy than the short-circuit transfer, thus producing a higher average current and improved sidewall fusion. Additionally, it can be used to lower heat input and reduce distortion when high travel speeds are not needed or cannot be achieved because of equipment or throughput limitations.^[8,11]

For parts less than or equal to 3 mm, pulsed spray transfer is the preferred choice due to the fact that the average current is lower in magnitude for GMAW-pulsed than axial spray transfer welding current. GMAW-pulsed has the following advantages when used for welding aluminum:

- Lower heat input—less distortion.
- Ability to handle poor fit-up.
- Ability to handle thinner materials.
- The lower heat input of GMAW-pulsed reduces the size of the heat affected zone.
- Out-of-position welding is greatly enhanced.

FILLER ALLOYS FOR ALUMINUM GMAW

1XXX alloys: These base materials are usually used for their electrical conductivity and/or corrosion resistance. Their tendency to hot cracking is very low. They are usually welded using Al1100 or Al1188 fillers, but matching filler metals are also available for specialized alloys such as Al1350. If electrical conductivity of the finished weld joint is not of primary importance, then Al4043 may be used.

2XXX alloys: Many base materials in this series are not recommended for arc welding. Those that are weldable include Al2219, Al2014, Al2519, Al2008, and Al2036. Alloy Al2319 is a matching filler alloy for Al2219 and Al2519 and can also be used on other weldable alloys. Alloys Al4043 and Al4145, which contain copper, can also be used. **5XXX fillers,** such as Al5556 and Al5183, should not be used to weld 2XXX parent materials, otherwise weld cracking will result.

3XXX alloys: These moderate strength aluminum-manganese base materials are relatively crack resistant and can be welded easily using either Al4043 or Al5356 filler alloys.

4XXX alloys: These base materials are usually found as welding or brazing fillers. In the rare event, they are encountered as parent materials; Al4047 is usually the best choice as a filler metal.

5XXX alloys: These higher strength aluminum-magnesium base materials are the most commonly found structural aluminum sheet and plate alloys. The general rule, except for Al5052, is to choose a 5XXX filler metal with slightly higher magnesium content than the parent material being welded. For all alloys except Al5052, 5XXX alloys should not be welded using 4XXX filler alloys. The high Mg content of the parent material when combined with the high silicon content of the 4XXX fillers will result in a high level of Mg_2Si , a brittle intermetallic compound that will cause the weld to have poor ductility and toughness.

6XXX alloys: These Al-Mg-Si alloys are primarily used for extrusion alloys, although they can also often be found as sheet and plate. The chemical composition of these alloys makes them very sensitive to hot cracking. Autogenous welds (i.e., welds made without adding filler metal) are susceptible to cracking. But these alloys are readily weldable using either Al4043 or Al5356 filler metal. Al4043, aluminum with 5% silicon, or Al5356, aluminum with 5% magnesium, when combined with Al6061 provides a crack-resistant composition.

7XXX alloys: As mentioned previously, most of these alloys are not arc weldable. However, Al7005, Al7003, and Al7039 are weldable, and they should be welded using a Al5356 filler alloy.

8XXX alloys: Other elements that are alloyed with aluminum (i.e., lithium) fall under this series (i.e., Al8090). Most of these alloys are not commonly welded, though they offer very good rigidity and are principally used in the aerospace industry. Filler wire selection for these heat-treatable alloys include the 4XXX series.

GAS TUNGSTEN ARC WELDING (GTAW)

GTAW is an arc welding process that uses a nonconsumable tungsten electrode and an inert gas shield to protect the electrode arc column and weld pool. Fig. 10 schematically shows the GTAW process. GTAW must also be carried out using inert gas shield, argon, or argon-helium mixtures, not only to prevent oxidation of the weld but also to prevent the tungsten electrode being consumed. The rate of metal deposition is quite slow in GTAW, limiting the range of application for thicknesses (i.e., in welding of aluminum alloys, GTAW shall be used in thicknesses <6 mm).

GTAW process conventionally uses DC with the electrode connected to the negative pole of the power source and DCEN for welding of most materials. The GTAW with the electrode connected to the positive pole, DCEP, results in overheating and melting of the electrode. Therefore, GTAW welding of aluminum is normally performed using

Fig. 10 Schematic illustration of GTAW

AC, where oxide film removal takes place on the electrode positive half cycle and electrode cooling and weld bead penetration on the electrode negative half cycle of the AC sine wave.

In GTAW of aluminum, the preferred shielding gases are argon, helium, and argon-helium mixtures. Argon is the most commonly used one due to easy arc ignition and arc stability; therefore, a bright and silvery weld bead is achieved using Argon gas.

Friction Welding

FRW is a solid-state welding process in which coalescence is achieved by frictional heat and pressure (Fig. 11). Mechanical rubbing between the two surfaces creates heat, usually by rotation of one part relative to the other. This raises the temperature at the joint interface to the hot working range for the metals involved. Then the parts are driven toward each other with sufficient force to form a metallurgical bond.

An important characteristic of FRW of aluminum alloys is the ability of this technique to weld so-called unweldable alloys. It is possible to make dissimilar joints (i.e., steel and copper to aluminum) and to successfully weld alloys such as Al 2618 and Al 7075 without hot cracking. There is no melting involved in this technique, thus no brittle intermetallic phases are formed.

FSW of Aluminum

In FSW, a cylindrical, nonconsumable tool with a profiled probe is rotated and plunged into the joint line between two pieces of sheet or plate material, which are butted or overlapped together. Due to the interaction between tool and material of the work pieces, frictional and deformational heat is generated. The heat causes the materials to soften, without reaching melting point (typically in the range of 70%–85% of the melting temperature), and allows the pin to traverse along the joint. As the tool moves along, the material is plasticized by the frictional heat at the front of

Fig. 11 (1) Rotating part, no contact; (2) parts brought into contact to generate friction heat; (3) rotation stopped and axial pressure applied; (4) weld created^[12]

the rotating pin and transported to the back. Fig. 12, schematically, shows FSW process and main microstructural zones associated with the FSW joint.

There is no melting involved in FSW, therefore, some important metallurgical advantages compared with fusion welding can be achieved:

- Solidification and liquation cracking are eliminated.
- Dissimilar alloys can be successfully joined.
- The stirring and forcing action produces a fine-grain structure.
- Less alloying loss in the welded structure is achieved.
- Less residual stress, and therefore distortion, is observed in FSW as compared with fusion welding.

The main parameters in FSW of aluminum are tool rotational speed, ω , in rpm, tool rotational direction, and the tool traverse speed, v , in mm/min, along the line of joint as well as the angle of spindle (tool tilt) and pressure. Tool rotation results in mixing and stirring of materials from both parameters and tool travel moves the stirred material from the front to the back of the tool. A suitable tilt of the spindle toward trailing direction ensures that the shoulder of the tool holds the stirred material by threaded pin and move material efficiently from the front to the back of the pin. The heat generation rate, temperature field, cooling rate, torque, and power are totally depended upon the welding speed, the tool rotation speed, and the vertical pressure on the tool. Fig. 13 shows a relationship between rotational speed and peak temperature in FSW of a 6063 aluminum alloy.^[15]

FSW can be readily used to weld similar and dissimilar grades of aluminum including Al5083, Al5454, Al6061, Al6082, Al2014, Al2219, and Al7075.^[16] Beside these alloys, FSW can be used to join aluminum to other alloys, i.e., steel, Ni and Ni alloys, Cu and Cu alloys, Mg and Mg alloys, etc.

FSW is commercially used in ship building, high-speed train manufacturing, and aviation industries.^[17–19] FSW was first commercially used in joining of 6XXX series alloy extrusions for use in fish freezing plants for fishing vessels.^[20] The 6XXX aluminum extrusions have been joined through FSW for incorporation in bulkheads and decks in various high-speed aluminum vessels, and in large steel cruise ships which have lightweight aluminum superstructures.^[21] Furthermore, FSW is successfully used in welding of fuel tanks of Al-Li and Al2195 alloy space shuttles.^[19] FSW has a great potential for lightweight Al structures such as some parts in passenger aeroplanes and further research is conducted in this field.^[17,22] This welding technique is used in carriage manufacturing of high-speed trains in Japan and in the production of honeycomb structures from Al extrusions (Fig. 14).^[17]

In automotive applications, as there are few long straight welds in vehicles, adoption of FSW primarily has been used for components such as suspension parts, wheels, seat components, crash boxes, etc. The mass production in the automotive sector has driven the development of robotic FSW to cope with the complex shapes and high-volume/low-cost culture of this market.

Jannet et al.^[23] performed a comparative investigation of FSW and fusion welding of Al6061 (T₆)-Al5083 (O) aluminum alloy based on mechanical properties and microstructure. The welding conditions and optimized process parameters, presented in Table 5, were used to fabricate the joints in their study.

They showed that FSW joints exhibit better tensile properties as compared to GMAW and GTAW joints. The reasons for the better tensile performance of the FSW joints can be attributed to the grain refinement and therefore superior mechanical properties in the weld region. However, some decrease in elongation, in the friction stir welded samples, was reported as compared with fusion welding techniques (Fig. 15).

Fig. 12 Schematic illustrations of (a) FSW process, (b) the main microstructural zones associated with the FSW joint,^[13] and (c) macrostructure analysis on AA 5083-H111 (welding speed 400 mm/min and rotational speed 800 rpm)^[14]

Explosive Welding of Aluminum

Explosive welding (Fig. 16) is a solid-state welding process, which uses a controlled explosive detonation to force two metals together at high pressure (i.e., shock wave of 3000–9000 m/s can produce pressures of up to 6×10^6 N/cm²). The resultant composite system is joined with a durable, metallurgical bond.

Explosive welding can effectively be used to join similar and dissimilar aluminum grades as well as aluminum/steel and aluminum/copper giving composite joints. “Multiple explosive welding” can be used to join a number of materials of different thicknesses (Fig. 17). Using explosive welding, it is possible to join materials that cannot be joined by other processes.

Ultrasonic Welding of Aluminum

In ultrasonic welding technique, ultrasonic waves produce frictional heat and then external force is used for the joining process. Ultrasonic waves (i.e., between 15 and 60 kHz) are transferred to the material under pressure, up to 7 bar, with a sonometer within less than 3 s. The welding can proceed with or without the application of external heat (Fig. 18).

Ultrasonic welding is particularly suitable for joining aluminum and its alloys with each other as well as for producing dissimilar joints with other materials including ferrous metals (i.e., steel) and nonferrous metals (i.e., copper, magnesium, nickel, titanium, etc.). In particular, the joining of aluminum to copper is quite interesting because of similarity between their thermal and electrical conductivities. In dissimilar

Table 5 Process parameters used by Jetta et al.^[23] to compare GMAW, GTAW, and FSW

Process	GMAW	GTAW	FSW
Welding machine	Lincoln Electric, ^a USA	Lincoln Electric, ^a USA	RV Machine Tools, ^b India
Tungsten electrode diameter	1.6	3	
Filler rod/wire diameter	1.6	3

Tool pin profile			Cylindrical threaded
Pin diameter (mm)			6
Pin length (mm)			5.8

^aLincoln Electric welders for GTAW offer AC and DC welding on aluminum and other metals. Inverters are portable and ideal for critical applications including maintenance, fabrication, motorsports, automotive, piping, and shipbuilding. ^bRV Machine Tools, established in 1992 in India, is a precision machine tools manufacturer. Metal cutting equipment like turning, milling, drilling, and tapping as well as arc welding machineries are the main products of RV Machine Tools.

hybrid structures, for lightweight vehicles, this is useful. Indeed, aluminum is lighter than copper with slightly less, though still comparable, electrical conductivity. However, joining aluminum to copper using conventional techniques is quite challenging due to the formation of Al/Cu intermetallic compounds at the interface of the welded materials. Therefore, ultrasonic welding is a preferred method for joining these materials together due to its ability to easily join dissimilar metals, as well as not requiring flux for the bonding.

Fig. 19 shows an actual joint in aluminum through ultrasonic weld. In electrical and electronic applications, the frictional energy creates clean welding zones with low contact resistances. Hardness influences the weldability of composite joints with steel. Hard alloys are less suitable for ultrasonic welding, since the plastic formability required for the joining is not sufficient. Very often an intermediate layer is used to overcome this deficiency.

The main advantages of ultrasonic welding include the following:

- Low heat distortion.
- Low heat-affected zone.
- Surface preparation is not critical.
- Excellent electrical joint properties.
- Low energy joining process.
- No arcs and fume emissions.
- Short second cycle times.
- Bimetallic.
- No water cooling or filler materials.

However, there are some limitations associated with ultrasonic welding:

- Thickness limited to approximately <3mm.
- Difficult for deep parts (throat depth).
- Requires good workpiece alignment.

**Fig. 13** Relationship between rotational speed and peak temperature in FSW of AA6063^[15]

Fig. 14 (a) Train sets with FSW floor panels of Sumitomo Light Metal operate on the Shinkansen in Japan, and (b) friction stir welded floor panel produced by Sumitomo Light Metal for Shinkansen trains^[17,18]

Fig. 15 Mechanical properties in FSW and GMAW as compared with base metal^[23]

Fig. 16 Schematic illustration of explosive welding

The main application of ultrasonic welding for aluminum alloys includes the following:

- Electrical wiring.
- Light gauge sheet joining.
- Sheet-to-wire joints.
- Bimetallic, multi-material joining.
- Products in consumer, industrial, auto, defense, and aerospace fields.

Resistance Welding of Aluminum

In resistance welding, heat and pressure are simultaneously applied to achieve a sound joint. The simplest form of the process is RSW where the required pressure is supplied through clamping of stacks of sheets between two electrodes; then welding current is passed between electrodes through the sheets creating heat at the interface of sheets by resistance to the flow of the current. Generated heat is high enough to locally melt the materials and create a weld nugget between the plates.

Fig. 17 Macrostructure of explosive welded joints^[24]

Fig. 18 Ultrasonic welding; general setup for a lap joint and close-up of weld area^[12]

Fig. 19 Cross sections through Al-Al welds after various times^[25]

There are a number of variants of the resistance welding process including spot, seam, projection, and butt welding. RSW is the most popular method of joining parts in automotive industry thanks to its low cost, rapidity, and simplicity (Fig. 20). Over 90% of spot welds from all over the world are performed by automotive industry.^[1] The RSW of aluminum and its alloys requires high power welding guns as the welding current must be two to three times higher than that of steel but the welding time is one-third of steel. Thermal and electrical conductivities of aluminum are three times than steel meaning that current and voltage must be controlled more precisely in narrower window of time.^[1] Table 6 summarizes a comparison between aluminum and steel in RSW.

Seam welding is used in the production of thin sheet, leak-tight containers like fuel tanks. Projection welding is generally used for welding items such as captive nuts onto plate. Flash welding, unlike spot and seam welding that require a lap joint, is capable of making butt welds. This is achieved by resistance heating the abutting faces and then forging them together.

Resistance welding of aluminum is not a friendly process as compared with steel due to specific characteristics of aluminum including (i) its high electrical conductivity, requiring high welding currents and large capacity equipment, and (ii) the risk of alloying between the resistance welding electrodes (made from copper) and aluminum, resulting in rapid wear and a short electrode life.

- High electrode force (4–8 kN).
- High welding current (20–45 kA).

Table 6 Different parameters used in RSW of aluminum and steel

Material	Welding current (kA)	Welding time (periods for 50 Hz)	Welding force (kN)
Mild steel	11	8	2.7
Al alloys (5XXX and 6XXX series)	25	4	2.5

Fig. 20 (a) Schematic, (b) actual illustration of RSW, and (c) ideal resistance spot weld between two aluminum sheets

- Minimal deflection in gun arms (<1 mm).
- Efficient water cooling of electrodes, gun arms, and all current-carrying components.
- Low-friction force actuator, to maintain weld force as electrodes, move during weld formation.

The main properties of ideal electrodes for RSW of aluminum alloys include the following:

- Maximum electrical and thermal conductivities.
- Maximum hardness or resistance to deformation.
- Tip design that reduces wear.
- Minimum tendency to alloy with the material being welded.

Laser Welding of Aluminum

The application of laser welding of aluminum alloys is increasing in automotive industries for body and exterior paneling. Many advantages are involved with laser welding of aluminum alloys; i.e., precise heat input, narrow weld

bead, narrow heat-affected zone, minimal thermal distortion, as well as elevated welding speeds on thin sections and deep penetration on thick sections.

Although aluminum is one of the easiest metals to penetrate with an electron beam, it is one of the most difficult to melt with a laser. Aluminum is one of the best reflectors of light; therefore, the incident beam reflection due to poor coupling between aluminum alloys and the laser beam is a major concern in laser welding of aluminum. In addition, many aluminum alloys contain magnesium or zinc; these elements are easily vaporized during welding forming plasma that blocks the incident beam. Porosity and solidification cracking are also among common problems encountered in the laser welding of aluminum alloys.

Most strain-hardenable aluminum alloys (i.e., Al5182 and Al5754) can be laser welded autogenously. In laser welding of aluminum, filler metal can be introduced to add reinforcement or to improve the strength and ductility of the joint. Many heat-treatable alloys (i.e., Al6061) are susceptible to hot cracking during welding; this is due to their

chemical compositions and the thermal strains induced in the metal during welding. To avoid hot cracking, a filler metal is used to adjust the weld bead composition beyond the crack-sensitive range.

Aluminum alloys absorb the laser more efficiently as the laser wavelength decreases and the temperature increases. It has been reported that the Nd:YAG laser with a characteristic wavelength of $1.06\text{ }\mu\text{m}$ provided better coupling with aluminum than the CO_2 laser, which has a characteristic wavelength of $10.6\text{ }\mu\text{m}$.^[26] Furthermore, the absorption of the laser beam increases drastically when a keyhole is formed due to multiple reflections of the beam in the keyhole.^[27] Therefore, the Nd:YAG laser seems to be better choice for welding of aluminum alloys.

It is pointed out that improvements in the laser weldability of a range of aluminum alloys are possible by increasing the power density of the focused spot, and this can be achieved through higher average powers, improved beam focusing system, and decreasing beam reflectivity on work piece surface. The solidification cracking problem of laser-welded aluminum alloys can be solved mainly through the addition of filler metals.

The main advantages of laser welding for aluminum include the following:

- Higher welding travel speeds on thin sections.
- High penetration/width ratio of welds.
- Strong welds with ultimate tensile strength joint efficiency of $>90\%$ in some alloys.
- Precise heat input that leads to narrower weld beads, heat-affected zones, and distortion.
- Readily automated using robot or gantry systems.
- Ready beam-sharing between different stations and/or use with hybrid welding processes (i.e., GMA/laser) of 6XXX.

The main disadvantages of laser welding include the following:

- Certain alloys will require a filler alloy.
- Joint fit-up and precision.
- Capital costs.

ELECTRON BEAM WELDING

In electron beam welding process (Fig. 21), a vacuum chamber is used to generate a high-energy density beam of electrons of the order of $0.25\text{--}2.5\text{ mm}$ in diameter. The workpiece is bombarded with a focused stream of electrons traveling at high speeds. The kinetic energy of the electrons is converted to heat energy, which is the driving force for fusion. The process may be used for the welding of material as thin as foil and up to 400 mm thick in a single pass.^[14] The main electron beam welding parameters are as follows:

Fig. 21 Principles of electron beam welding^[28]

1. The accelerating voltage, a 150 kV unit being capable of penetrating 400 mm of aluminum.
2. The current applied to the electron gun filament, generally measured in milliamperes.
3. The travel speed.

The main advantages of electron beam welding include the following:

- Welding in a vacuum ensures no contamination.
- Deeper penetration with high aspect ratios.
- Energy absorption independent of material or surface conditions.
- Similar heat-affected zone to that of laser beam welding.
- Permits welding of refractory and dissimilar metals not weldable using conventional welding process.
- Proven track record (widely accepted).
- Included in many welding specifications.
- No added filler material is required and distortion is minimal.
- A vacuum environment ensures a contaminant-free weldment.

One specific problem in using electron beam welding (EBW) in aluminum and aluminum alloys is the formation of cavities in the weld. During the welding process, metal vapors from the weld pool result in arcing phenomenon inside the electron beam gun. Arcing inside the gun interrupts the beam and causes cavities and porosities to be formed in the weld. This problem becomes worse with those alloys that contain low boiling point elements such as magnesium and zinc. The remedy is to trap the vapors by changing the beam path with a magnetic field or by shutting off the beam once arcing is detected and reestablishing the beam. Therefore, careful control of the travel speed and beam fade-out is necessary to get a defect-free weld in aluminum alloys.

The non-heat-treatable aluminum alloys can be electron welded without the addition of filler wire; however, the hot cracking tendency increases with increasing magnesium content.

The heat-treatable alloys have only a limited suitability for EBW. The high vapor pressure of zinc leads to weld porosity. The weldability of copper-containing aluminum alloys with other welding processes is poor; however, these alloys can be easily electron beam welded due to the reduced heat input. Alloys that can be aged exhibit an increase in hardness after welding, without, however, attaining the original hardness fully.

COMPARISON BETWEEN ELECTRON BEAM WELDING AND LASER WELDING

One of the main advantages of laser welding over electron beam welding is that the handling of the former is technologically simpler and the welding process can be conducted under atmosphere conditions. The laser welding equipment has a relatively simple mechanical construction and a higher welding accessibility, making it highly flexible. In this respect, the vacuum chamber required for electron beam welding poses strong limitations on the process.

On the other hand, the vacuum conditions existing in the electron beam welding process inhibit the formation of plasma streams which tend to reduce the welding performance. Thus, much higher weld penetrations can be attained than with laser welding. Multi-station welding machines can be used for laser welding, thereby increasing productivity and decreasing cost per piece.

Diffusion Welding of Aluminum

Diffusion welding is a solid-state welding process that produces a weld by the application of pressure at elevated temperature with no macroscopic deformation or relative motion of the pieces. Diffusion welding is usually used for dissimilar joining between aluminum and other alloys (i.e., copper, titanium, steel, etc.), where fusion welding cannot be applied due to large physical and mechanical dissimilarities between the partners. Diffusion welding occurs in three stages (Fig. 22):

- Stage I: deformation forming interfacial boundary.
- Stage II: grain boundary migration and pore elimination.
- Stage III: volume diffusion and pore elimination.

The primary variables controlling diffusion welding are pressure, temperature, surface finish, and surface cleanliness. Typical contact pressures are 3.5–35 MPa at temperatures of 0.6 or more of the absolute melting temperature of the metal.

Fig. 22 Three-stage mechanistic model of diffusion welding: (a) Initial asperity contact, (b) first-stage deformation and interfacial boundary formation, (c) second-stage grain boundary migration and pore elimination, and (d) third-stage volume diffusion and pore elimination^[29]

Fig. 23 Titanium (Ti-6Al-4V)-aluminium (Al-6082) bonds after being subjected to bending and torsion loads^[30]

Fig. 23 shows a diffusion welded joint between Ti-6Al-4V and Al-6082 alloys after being subjected to bending and torsion loads.

Those metals that contain surface oxide films that are not stable at high temperatures, i.e., silver, are very easy to bond by diffusion. Iron, titanium, and copper, although capable of forming stable oxides, are also easily bonded because the oxide will diffuse into the base metal at the elevated bonding temperatures. Aluminum and magnesium are difficult to bond by this method because their oxides are stable and are not readily soluble in the bulk metal.

CONCLUSION

In this article, first, the application of welding for casting and wrought aluminum alloys was presented. Within wrought alloys, the weldability of heat-treatable and non-heat treatable aluminum alloys was discussed and classified for each series of alloys. Also, the main challenges involved with welding of aluminum, as compared with steel, were addressed in detail. Moreover, the fundamental characteristics of the most commonly used welding processes of aluminum and aluminum alloys including fusion based, i.e., GMAW, GTWA, and laser welding, and

solid-state based, i.e., FSW, diffusion welding, explosive welding, and resistance welding, techniques were discussed in terms of advantages, disadvantages, and application of each process.

Welding Technology: Gas Chromatography in

R. Probst and K. Splitt

Abstract

It is important to understand the effect of the protective gas atmosphere on the welding process to relate qualitatively the chemical composition of the welding atmosphere to the quality of the weld produced. Of particular interest are the reactions occurring within the gas phase of the arc welding process. This article presents the results conducted on the gaseous atmosphere with the aid of gas chromatography. The objective of this work was to obtain an overall understanding of the quantitative interaction of the welding atmosphere and liquid metal, and to improve the quality of the weld metal produced by specific metallurgical and technological means.

Keywords: Arc welding; Gas chromatography; Hydrogen; Porosity; Welding current; Welding speed.

INTRODUCTION

The effect which the protective gas atmosphere has on the welding process has been the subject of numerous investigations, the purpose of which has been to relate qualitatively the chemical composition of the welding atmosphere to the quality of the weld produced.

In attempting to understand of the overall process, there is often a lack of experimentally substantiated data available to permit the interaction of these parameters to be investigated in detail.

Of particular interest are the reactions taking place within the gas phase of the arc welding process. A gas phase is formed in every fusion welding process, which reacts with the droplets of molten metal during their transfer to the weld pool in the parent metal. As a result of external influences, e.g. the action of gases, undesirable effects may occur leading to defects in the weld or heat affected zone. The factors affecting the composition and chemical action of the gas phase in gas shielded welding processes are shown in Fig. 1.^[1,2]

The following article presents the results of a series of investigations carried out on the gaseous atmosphere with the aid of gas chromatography. The investigation aimed to promote an overall understanding of the quantitative interaction of the welding atmosphere and liquid metal, and to improve the quality of the weld metal produced by specific metallurgical and technological means.

USE OF GAS CHROMATOGRAPHY IN WELDING TECHNOLOGY

From the literature, methods are available to calculate the reactions taking place both in the gas phase and in the arc itself.^[3-5]

A direct method of determining the amount of hydrogen in the welding arc has been described.⁶ The measurements were made spectroscopically in the arc, and a relationship was established between the diffusible hydrogen content in the weld metal and the hydrogen content of the arc atmosphere. One suitable method of determining both the quantitative and qualitative composition of gaseous media is by gas chromatography. The direct use of gas chromatography in welding technology is, limited to only a few examples, however. Its use has been mainly in determination of gases causing porosity,^[7-9] in investigation of welding gases in occupational medicine and in determination of diffusible hydrogen in weld metal deposited using various different electrodes.

Gas Chromatography as a Method of Measurement

Gaseous materials and un-dissociated vapors can both be investigated using gas chromatography. The advantages are a very short analysis time (only a few minutes), automatic evaluation of the analytical results obtained and the possibility of analyzing very small specimen quantities. Using very efficient detectors, only 10^{-14} g/s are required to obtain an analysis.^[10] High temperature gas chromatography works at a maximum temperature of 400°C. In analysis of welding gases this represents a definite disadvantage in that the investigations cannot be carried out at the actual temperature of the welding atmosphere. It is thus necessary to calculate the actual percentages of the various component gases using known data on the dissociation of each of the gases present.

Fig. 1 Factors influencing the gas phase in gas shielded welding^[1,2]

Construction and Principle of Measurement

Figure 2 shows a gas chromatography measuring apparatus. A carrier gas (1) (e.g. He, Ar, Ne, N₂) flows through the apparatus. At the specimen entry point (2) the specimen is introduced into the gas chromatograph (3) and is transported through the stripping column by the carrier gas. The stripping column contains a stripping medium which breaks down the gas mixture into its individual components. As the individual components appear in the detector (4), an electrical signal is produced which, after amplification, is recorded on a plotter and manually evaluated. To enable the evaluation to be carried out more rapidly and accurately, an evaluation integrator 'Ursalyt AG 4000' (6) is employed.

Fig. 2 Gas chromatography apparatus

Use of Gas Chromatography for Investigation of Welding Atmospheres in MIG/MAG Welding

In the department of construction and welding at the University of Magdeburg the method shown in Fig. 3 was developed to investigate the welding atmosphere during welding with gas shielding. The aim was to investigate quantitatively the composition of the welding atmosphere. The

Fig. 3 Principle of sampling and detection of the gases in the gas phase during MIG/MAG-welding. 1. Point of welding (Hood with probe); 2. Gas tube; 3. Gas storage cartridge; 4. Type 2DS2 vacuum pump; 5. Carrier gas supply; 6. Specimen entry point; 7. Gas flow regulator; 8. Manometer; 9. Gas entry point; 10. Column furnace with stripping column; 11. Detector; 12. Amplifier; 13. Plotter; 14. 'Ursalyt AG 4000' data evaluation unit

central need in the investigation was to ensure reproducible collection of the gas samples. The samples were taken using a probe made of a temperature resistant ceramic material. With the aid of a type 2 DS 2 vacuum pump, the gases were drawn from the point of sampling, stored in gas sampling cartridges, and analyzed by gas chromatography.

The point of welding itself was screened by a protective hood on which the movable probe was mounted. To achieve exact positioning of the probe in regions close to the arc, and to ascertain the effect of the probe on the flow of the shielding gas, optical interference methods were used.

TEST CONDITIONS AND RESULTS

The gas chromatographic investigations were carried out on TIG, MIG, MAGM, and MAGC welding processes. In the following paragraphs, the investigations carried out using mixed gas - and plain CO₂ - welding are described. The most important test data were as follows:

- shielding gas 1: 80% argon + 20% CO₂
- shielding gas 2: 60% argon + 40% CO₂
- shielding gas 3: 100% CO₂
- amount of shielding gas: 5; 10; 15 and 20 l/min
- velocity of shielding gas: 0.3; 0.4 and 0.5 m/min
- welding current: 200; 250 and 300 A
- parent metal: St 38 b2; plate thickness: 8 mm
- welding wire: 10 MnSi 6; wire diameter: 1.6 mm

The initial results of the gas chromatographic investigations are shown in Figs. 4–7. The results of the analyses, with the exception of oxygen, are reported in area percent.

The aim of the investigation was to determine the gases H₂, O₂ and CO as a function of the welding current, the welding speed and the composition and amount of the shielding gas used.

The temperatures at the point of sampling can be determined by comparing the measured proportions of oxygen in

Fig. 4 CO content as a function of welding speed

Fig. 5 Amount of CO in the welding atmosphere as a function of the welding current

Fig. 6 Oxygen content of the MAGC-welding atmosphere as a function of the welding current

Fig. 7 Amount of hydrogen in the welding atmosphere as a function of the welding current

the welding atmospheres with those calculated.^[11] Depending on the current and welding speed, these are calculated to be from 2100–2650,^[12] the temperature increasing almost linearly with the welding current.

Although all of the tests were carried out in a closed room, it was found that both the weather and the ambient conditions had an effect on the hydrogen contents measured. In several of the tests methane was also found in the welding atmosphere.

SUMMARY

The aim of the gas chromatographic investigations carried out was to determine the nature of the gaseous atmosphere in the region of the welding arc, and from these initial investigations to obtain information regarding future work required. The significance of the first measurements can only be judged taking into account the test conditions and the results of continuing work. However, a reduction in the CO content with increasing quantities of shielding gas or at higher welding speeds, an increase in the oxygen content of the gas atmosphere with increasing welding speeds and a decrease in the H₂ concentration with increasing welding current were all observed. Future work will need to include a number of supplementary investigations, for example it will be necessary to sample the easily and less readily diffusible hydrogen in the welding process, and to restrict the test conditions to only a few variable parameters.

Overall, using gas chromatography to investigate welding atmospheres, new and interesting information can be expected which will aid in a better understanding of the chemical metallurgical and technological interactions taking place between the gas phase and the metal during fusion welding.

Welding: Particulate and Gaseous Emissions

Abstract

Fabrication and repair of aluminum components and structures commonly involves the use of electric arc welding. The interaction of the arc and the metal being welded generates ultraviolet radiation, metallic oxides, fumes, and gases. Aluminum is seldom used as the pure metal but is often alloyed with other metals to improve strength and other physical properties. Therefore, the exact composition of any emissions will depend on the welding process and the particular aluminum alloy being welded. To quantify such emissions, The Aluminum Association sponsored several studies to characterize arc welding emissions by the gas metal arc welding (GMAW) and gas tungsten arc welding (GTAW) processes for various combinations of base and filler alloys. In all cases, the tests were conducted under conditions that could be found in a production weld shop without forced ventilation. The concentrations of each analyte that a welder could be exposed to were greatly affected by the welding process, the composition of the base and filler alloys, the position of the welder, and the welding helmet. The results obtained can be used by employers to identify and control potential hazards associated with the welding of aluminum alloys and can provide the basis for hazard communication to employees involved in the welding of these alloys.

Keywords: Aluminum; GMAW; GTAW; Welding.

INTRODUCTION

Aluminum alloys are joined by electric arc welding usually by either the gas metal arc welding (GMAW) or the gas tungsten arc welding process. In the GMAW process (also known as metal inert gas welding, or MIG), a direct current electric arc is established between a consumable aluminum electrode and the work piece (Fig. 1).^[1] The consumable electrode, an aluminum alloy wire when welding aluminum alloys, is automatically fed from a spool in the welding machine through the welding gun into the arc. A shield gas that protects the weld point from oxidation is also fed through the welding gun directly over the arc. With large spools of wire there is no need to stop welding to change consumed electrodes. Therefore, productivity with GMAW (e.g., length of weld, amount of filler metal transferred to welded product, linear speed of the weld) can be much higher than with other welding methods. A large variety of alloys and thicknesses of metal can be welded by varying the voltage, current, and thickness of the wire.

Metals can be welded by GMAW using several transfer mechanisms that are dependent on the welding current: short-circuit, globular, spray, and pulsed-spray. In short-circuit transfer, which occurs at the lowest current

ranges, metal transfer occurs only when the filler wire is in direct contact with the work piece. Globular transfer, the transition between short-circuit and spray transfer, occurs when small globules of metal are sprayed between the electrode and the work piece. Spray transfer occurs above the *transition current* when a discrete stream of metal droplets are accelerated by electrical forces from the electrode to the work piece. Pulse-spray transfer is identical to spray transfer except that the current is pulsed above and below the transition current. This pulse allows the weld pool to cool between metal transfers. Of the four mechanisms, spray transfer would be expected to produce the most welding fumes.

In the gas tungsten arc welding (GTAW) process (also known as tungsten inert gas welding, or TIG), the electric arc is established between a nonconsumable tungsten electrode and the work piece (Fig. 2).^[1] The arc melts the surface of the work piece, creating the weld pool. The appropriate filler metal is held at the weld point and allowed to melt into the weld pool. As with GMAW, a shield gas is fed through the welding gun; however, unlike GMAW, the filler wire is introduced to the weld pool separately from the welding gun. The filler metal can be handled manually by the welder or can be fed automatically. There is no

Fig. 1 Gas metal arc welding

Fig. 2 Gas tungsten arc welding

transfer of filler metal across the arc. GTAW, due to the less turbulent transfer mechanism and slower weld speed, should generate fewer welding fumes than GMAW.

Electric arc welding of aluminum produces chemical and physical emissions that include aluminum fumes, aluminum oxide, ozone, nitrogen oxides, and ultraviolet radiation. Additional metallic fumes and oxides can be generated depending on the constituents of the alloys being welded. These emissions create the possibility for occupational exposures for welders and others involved in welding processes. Employers must understand these potential exposures to exercise their responsibilities under the Occupational Safety and Health Administration (OSHA) Hazard Communication Standard.^[2] Welders must understand the potential hazards so that proper precautions can be taken.

Little definitive data have been published regarding the emissions from welding aluminum alloys. One study reported that the evolution of ozone when welding aluminum was an order of magnitude greater than when welding steel.^[3] Another study observed the effects of welding parameters (e.g., current, welding speed, shield gas) on the evolution of ozone, nitrogen oxides, and welding fume.^[4] However, only a limited number of base and filler alloy combinations were considered, and only minimal attempts were made to relate the components present in the welding fumes to alloy compositions.

To provide such information, The Aluminum Association sponsored a series of laboratory studies to characterize the emissions generated when electric arc welding a variety of base and filler alloy combinations.^[5] Laboratory conditions were designed to represent those expected in a production welding facility with natural ventilation. The results from the first of these studies,^[6] including both particulate and gaseous emissions, are summarized here.

MATERIALS AND METHODS

Welding Facility

Experiments were conducted in a high bay, production welding facility. Welding areas of approximately 3.1×3.7 m were enclosed using flexible welding curtains (Fig. 3). The curtains were suspended 0.30 m above the floor and extended up to approximately 2.4 m above the floor. The enclosure was designed to allow air movement under the curtains and updraft convection currents while minimizing cross drafts. Cross drafts could change the direction of the plume causing variability in the results. In addition, cross drafts could affect the welding conditions by sweeping the shield gas away from the weld, thereby changing the emissions. The GMAW area and the GTAW area differed slightly in size and in that two sides of the GTAW area were solid walls rather than curtains. However, these differences were considered insignificant, since the large open spaces above the curtains would prevent any buildup of emissions.

Welding Parameters

The welding parameters used in this study are shown in Table 1. Voltage, current, and welding speed were selected as appropriate for each alloy and the thickness of the metal plates. For GMAW, welding was conducted using spray transfer of metal to the weld. The filler wire was fed automatically by the welding machine. For GTAW, the filler wire was fed manually by a certified welder.

Base and Filler Alloys

The alloys and their compositions are listed in Table 2. The alloys selected for these studies were commercially available, were routinely welded using GMAW and GTAW processes, and contained relatively high concentrations of the elements of interest. All alloys, base and filler, were analyzed by quantometer prior to testing and were within the specifications established by The Aluminum Association.^[7] However, only the concentrations of the metals of interest in this study were reported; therefore, the values provided in Table 2 are a combination of actual and specification concentrations. Any additional metals that might have been present, either as contaminants in the alloying metals or in recycled scrap, were limited by the

Fig. 3 Welding areas

specifications to maximum concentrations of 0.05% each and 0.15% for their combined total. The plates of base alloy were 15 × 90 cm pieces sawn from 0.95 cm thick stock. The combinations of base and filler alloys tested and the shield gases used are shown in Table 3.

Welding Mannequin

To simulate manual welding in a reproducible and realistic manner, a mannequin was constructed to represent the welder. The mannequin was fitted with a standard, curved-chin, welding helmet modified for sample collection. Initially, the mannequin was placed directly over the welding arc, with the center of the welding helmet located 10 cm back from the line of the weld and 36 cm from the arc. This position was used for the initial GMAW tests.

Subsequently, the alignment between the mannequin and the workpiece was slightly modified. The mannequin was moved 8 cm ahead of the welding arc, with the welding

helmet tilted as looking back toward the arc. This position better represented the stance that a welder would assume, tilting slightly off center to view the weld. As before, the center of the welding helmet was located 10 cm offset from the line of the weld and 36 cm from the arc. This final position was used for the remaining GMAW and all of the GTAW tests.

Figure 4 shows the experimental setup with the mannequin in the final position and the welding torch over the work piece. The mannequin and welding torch were attached to the welding table. The work piece was clamped to the carriage of a geared track that was fixed to the top of the welding table. The speed of the carriage was adjusted to match the weld speed appropriate for the work piece and welding process. During all tests, the mannequin and arc remained stationary while the work piece moved under the arc at speeds of approximately 30 cm/min for GMAW and 13 cm/min for GTAW. Each test involved 100 min of arc time. This time period was selected because it would

provide sufficient sensitivity for the analytes of interest and was estimated by the welding staff to be the average arc time struck by a welder at this particular facility during a typical 8-hr shift.

Figures 5 and 6 show the welding helmet with the external and internal sample media, respectively. Samples of particulate matter, metal fumes, NO, NO₂, and ozone were collected simultaneously both outside and inside the helmet. Sampling occurred only during active welding. Analyses were performed for total particulate matter, metallic elements, ozone, and oxides of nitrogen using the standard NIOSH methods at the time of this study. These methods are listed in Table 4 along with the current accepted methods.

RESULTS

The results from the GMAW and GTAW studies are shown in Tables 5 and 6. Results are given for all analytes both outside and inside the welding helmet. Results for the metals, although measured as the total quantity of each individual element, are expressed in the form for which occupational exposure limits have been established. This conversion, to the oxide forms for aluminum and magnesium, was made to permit easy comparison with the occupational exposure

limits and to simplify interpretation of the results. Note that most of the metals in the weld fume would have been present as the oxides.

The airborne concentration of each analyte was calculated from the flow rates of the sampling pumps and the duration of each test. All results are reported as time-weighted averages over the 100 min of arc time. Results are given as the geometric mean of five duplicate tests, with the exception of the 2219/2319 alloy combinations where only three tests were conducted. The geometric standard deviations are shown in parentheses.

A concern was raised after completion of the studies that the ozone generated during welding may have reacted with the short pieces of Tygon tubing (23.5 cm) in the sampling train. A series of 11 tests were conducted where ozone was passed through 23.5 cm of either Teflon or Tygon tubing. Ozone concentrations ranged from 0.27 to 15.8 ppm. The concentrations measured after passing through the Tygon tubing were $86 \pm 20\%$ of those measured for the Teflon tubing. The differences were not concentration dependent. Therefore, the use of Tygon resulted in the loss of some ozone, and the reported concentrations were lower than those actually generated. However, the relative ratios of the concentrations outside and inside the welding helmet were considered valid.

DISCUSSION

Unless otherwise noted, the discussion below focuses on results measured outside the welding helmet. The lower concentrations measured inside of the helmet and, in some cases, the greater variability in the results made statistical analyses difficult.

GMAW VS. GTAW

As discussed above, the more turbulent transfer method employed in GMAW should generate higher concentrations of welding fume. The higher weld speed of GMAW, which results in a greater amount of filler metal deposited and a greater amount of base metal melted per unit of time, should also result in higher concentrations of fumes. In these tests, the speed for GMAW was almost 2.5 times that of GTAW.

In general, the concentrations of particulate matter generated by GMAW were higher than for GTAW when the mannequin was in the same position. More specifically, the concentrations generated from the 5556/5356

Fig. 6 Welding helmet with inside sample media

alloy combination, the only base/filler alloy combination welded using both methods in the same mannequin position, were significantly higher (8- to 50-fold) for GMAW ($p < 0.0001$ for the Argon shield gas and $p = 0.012$ for the Argon-Helium shield gas). Similar results were found for particulate matter inside the welding mask.

Because the filler metal is transferred as a spray in GMAW, the filler alloy would be expected to contribute more to the particulate emissions than the base alloy. Base alloy 6061 (1.09% magnesium) was welded using GMAW in the initial position with two different filler alloys: 4043 (0.01% magnesium) and 5356 (4.69% magnesium). The fume generated from the 6061/4043 alloy combination only contained 0.08 mg/m^3 of magnesium oxide, while the fume from the 6061/5356 alloy combination contained 2.0 mg/m^3 of magnesium oxide. This was a significant difference ($p = 0.024$), particularly considering that the total amounts of particulate matter generated were similar (24.9 and 34.3 mg/m^3 , respectively, $p = 0.31$). The magnesium dioxide in the welding fume was generated almost entirely from the filler wire with very little contribution from the magnesium in the base alloy. Similar results were found inside the welding mask and have been reported elsewhere.^[3]

When these two alloy combinations were welded using GTAW, the difference in the amount of magnesium oxide present in the welding fumes was less dramatic (0.23 vs. 1.03 mg/m^3) but still significant ($p = 0.047$). The decreased contribution from the filler alloy would be expected considering the nature of filler metal transfer in GTAW.

Ozone is formed when atmospheric oxygen is struck by ultraviolet light from the arc. The quantity of ozone produced depends on the wavelength and intensity of the ultraviolet light. Other factors include the intensity of the arc, the shield gas, and the amount of welding fume generated.^[8,9] GTAW would be expected to generate higher concentrations of ozone due to the greater intensity and length of the arc. Only the 5456/5356 alloy combination

Total particulates	S-349	Polyvinylchloride filter (5.0 μm pore size)	Gravimetric	0500
Metals	P&CAM 173	Mixed cellulose ester filter (0.8 μm pore size)	Atomic Absorption/ICP	7300
NO	P&CAM 154	Triethanolamine treated molecular sieve	Colorimetric	6014
NO ₂	P&CAM 231	Triethanolamine treated molecular sieve	Colorimetric	6014
Ozone	P&CAM 154	Impinger with 1% KI	Colorimetric	ID 214 (OSHA)

was welded using both processes in the same mannequin position. The results show an insignificant difference between GMAW and GTAW when argon is used (1.54 vs. 1.26 ppm, $p = 0.11$) and small, significant difference when helium-argon is used (0.31 vs. 0.59 ppm, $p = 0.039$).

The nitrogen oxides, NO and NO₂, were generated from atmospheric nitrogen due to the intense heat of the arc. As with ozone, GTAW would be expected to produce the higher concentrations. However, results from the 5456/5356 alloy combination show no significant difference between GMAW and GTAW with the exception of NO₂ when helium-argon was used as the shield gas ($p = 0.008$).

The unexpected results found for the gaseous emissions, comparable values for GMAW and GTAW, could be an artifact of the welding equipment and shield gas flow. The volumetric flow rate of shield gas was lower for GTAW than for GMAW. However, the gas velocity would be dependent on the size of the gas nozzle in the welding gun. A higher gas velocity would tend to shield the arc better and sweep emissions away from the arc. This could cause a relative increase in the amount of ozone generated due to the shorter residence time of the generated ozone in the heated area around the arc, and decreased contact of the ozone with welding fume. Thermal and chemical decomposition of the ozone would therefore be reduced. Conversely, increased velocity of the shield gas would reduce the concentration of atmospheric nitrogen in the arc, thereby reducing the generation of nitrogen oxides.

The velocities of the shield gases in this particular situation, which were not measured, may have been such that any inherent differences between the two welding processes may have been negated.

Shield Gas

The 5456/5356 alloy combination was welded not only with both processes but also with two different shield gases: helium-argon (75:25) and argon. The helium-argon shield gas reduced particulate matter generation from GMAW when compared with argon shield gas. The concentration of particulate matter was dramatically reduced from 611 mg/m³ to 101 mg/m³ ($p = 0.0001$). Similar results were found inside the helmet. The differences found for GTAW, however, were not significant ($p = 0.45$).

The fact that the addition of helium had a large effect on GMAW but not on GTAW could be due to differences in the filler metal transfer mechanisms. A change in the shield gas could result in changes in plasma temperature, the rate of oxidation at the weld point, or the electrical acceleration of the filler metal spray. Any such change would have a greater effect on GMAW where the filler metal is sprayed across the arc.

Switching to helium-argon caused a significant reduction in the generation of ozone for both GMAW ($p = 0.001$) and GTAW ($p = 0.002$). Similar results were found for NO ($p = 0.007$ and 0.044, respectively) and for NO₂ ($p = 0.03$ and 0.01, respectively).

The reduction in ozone generation with helium-argon was expected. Ozone generation is dependent on the intensity and wavelength of the ultraviolet radiation generated by the arc plasma. The intensity of the radiation from argon plasma is much stronger than from helium plasma.^[10,11] In addition, with helium, there is a shift away from the ultraviolet light (<240 nm) needed to generate ozone toward longer wavelengths.^[11]

Alloying Elements

Alloys containing elements with lower melting and boiling points or elements that are more reactive would be expected to produce higher concentrations of particulate matter. Table 7 lists the properties of the metals present in the test alloys. Metals like magnesium, zinc, and copper would be more likely to volatilize and contribute to the particulate matter. Magnesium, beryllium, and titanium would more readily oxidize and, therefore, add to the welding fume. The 2219/2319 alloy combination (both alloys contain more than 6% copper), the 5456/5356 alloy combination (both alloys contain more than 4% magnesium), and the 1100/1100 alloy combination (essentially pure aluminum) were all welded under the same conditions: GMAW, final position for the mannequin, and argon shield gas. The 2219/2319 and 5456/5356 alloy combinations produced more particulate matter ($p = 0.09$ and 0.0001, respectively) than the 1100/1100 alloy combination. (Copper analyses are not included in Table 5. Copper exposures were not a focus of this study and analyses for copper were not performed.)

Because magnesium has lower melting and boiling points and is more reactive than copper, the 5456/5356

alloy combination would be expected to produce more particulate matter than the 2219/2319 alloy combination. There was a significant difference between the two alloy combinations (611 vs. 260 mg/m³, respectively, $p = 0.005$).

The particular sample of filler alloy 5356 used in these studies was selected because it contained 0.0007% beryllium.

Because of its higher reactivity, beryllium should readily oxidize and be present in the weld fume. However, all results from this filler alloy showed beryllium emissions of <0.2 µg/m³ even though the concentration of particulate matter exceeded 600 mg/m³.

Table 7 Alloying elements, physical and chemical properties

Metal	Melting point (°C)	Boiling point (°C)	Electrochemical potential (V)
Aluminum, Al	660	2327	−1.68

Vanadium, V	1917	3380	−1.13
Chromium, Cr	1900	2642	−0.74

Position of the Welder

The position that the welder takes in relationship to the work can move the welder into or out of the weld plume. Two different positions for the mannequin were used during these welding studies. The initial position, which was more upright, resulted in lower exposures to particulate matter. The results for particulate matter from the 2219/2319 alloy combination, the only combination welded in both positions, were more than 5-fold lower (47.7 vs. 260 mg/m³, $p = 0.011$) in the initial position. However, the differences in gaseous emissions were not significant between the two positions.

The effect of the welding position on fume concentrations was expected. The position of the welder, the position of the sampling media^[12] and the position of the workpiece^[13] have all been noted as a factor in exposures to welding fume. The lack of a difference for the gaseous emissions may be related to how they are formed and/or dispersed. Ozone can be produced some distance away from the arc. The gaseous emissions may also be swept farther from the arc and farther from the plume by the shield gas than the heavier particulate matter.

Welding Helmet

The welding helmet, while not designed as personal protection equipment for the reduction of fumes, can lower the exposure of the welder to particulate emissions. The percentage reductions for each test are shown in Table 8. The values ranged from insignificant to greater than 99% and are generally higher for GTAW and when the concentrations of the particulate matter are lower. The least significant reductions occurred with the mannequin in the initial position.

Table 8 Percentage of reduction in particulate matter inside welding helmet

Table 3. Percentage of reduction in particulate matter inside welding helmet					
Base/filler	Shield gas	Total particulate (mg/m ³)		Reduction (%)	Significant Difference
		Outside	Inside		
GMAW—Initial Position					
2219/2319	Argon	47.7	23.1	52	No, p = 0.16
6061/4043	Argon	24.9	12.0	52	Yes, p = 0.035
6061/5356	Argon	34.3	14.1	59	No, p = 0.089
GMAW—Final Position					
1100/1100	Argon	84.3	59.1	30	Yes, p = 0.018
2219/2319	Argon	260	121	53	Yes, p = 0.025
5456/5356	Argon	611	261	57	Yes, p =<0.0001
5456/5356	Helium-Argon	101	0.89	>99	Yes, p = 0.007
GTAW—Final Position					
5456/5356	Argon	12.2	0.09	>99	Yes, p =<0.0001
5456/5356	Helium-Argon	12.8	<0.04	>99	Yes, p = 0.013
6061/4043	Argon	6.52	0.33	95	Yes, p = 0.03
6061/5356	Argon	18.5	0.80	>99	Yes, p = 0.0004

Similar results were seen in Table 9 for the gaseous emissions: ozone, NO, and NO₂. Reductions ranged from insignificant to 85%. Again, the least significant reductions occurred with the mannequin in the initial position; however, overall, the amount of reduction was less and fewer sample sets actually showed a reduction, only 55% compared with 82% of the sets for particulate matter.

Lower concentrations of welding fumes and gases inside the welding helmet have been observed in other studies.

Goller et al.^[12] reported reductions of iron oxide ranging from 29% to 64% depending on the particular location at which the outside sample was collected. All of the samples were collected on production welders. Alpaugh et al.,^[14] using a mannequin that exhaled clean air, found reductions in the concentrations of iron oxide ranging from 86% to 99%. Lesser reductions were seen for gaseous emissions.

However, Liu et al.^[15] and Harris et al.,^[16] collecting samples on welders in relatively enclosed areas, observed

only minimal differences between fume concentrations outside and inside the welding helmet. They found significant reductions only at relatively high ($>20 \text{ mg/m}^3$) levels of particulate matter.

Several explanations have been proposed for the widely varying results reported in the literature, including the effect of the body position of the welder. The variation in the levels of reduction seen between the initial and final position of the mannequin in this study would support that explanation.

CONCLUSIONS

The emission studies were designed to represent conditions that could be encountered in a production weld shop.

- Cross draft air movement was minimal. However, welding areas were designed to allow updraft convection currents.
- Large open spaces were present over the welding areas.
- Sampling was conducted for 100 min of arc time, which was estimated to represent a full day's work at this type of facility.

From this study, the following observations can be made.

- Different arc welding processes produce different levels of particulate matter, metal oxides, and gaseous emissions. GMAW generally produces higher concentrations of particulate matter.
- Different base/filler alloy combinations produce different levels of particulate matter, metal oxides, and gaseous emissions.
- The filler alloy is the major contributor to the particulate matter, particularly for GMAW. The supplier's material safety data sheet should therefore be consulted for technical data, compositional information, and precautionary measures.
- Use of filler alloys containing up to 0.0007% beryllium did not result in emissions greater than $0.2 \mu\text{g/m}^3$.
- The position of the welder can have a significant impact on the level of exposures to airborne emissions.
- A standard, curved-chin, welding helmet can reduce emissions inside the helmet. However, the level of reduction may be highly variable and can be dependent on the position of the welder, the welding process, and the particular analyte.
- Ventilation and engineering controls may be required in certain situations to reduce exposures. This is particularly important in confined or poorly ventilated spaces.

Welding emissions can change with welding process, alloy combinations, and environmental conditions. To accurately

evaluate welding exposures, an assessment by an industrial hygienist would be required. Using appropriate work practices, engineering controls, and personal protective equipment, emissions generated during the welding of aluminum alloys can be adequately controlled.

Additional studies have been sponsored by The Aluminum Association. These studies evaluated the emissions for additional aluminum alloys during GMAW, GTAW, plasma arc cutting, and grinding. The results from those studies will be covered in future articles.

Abstract

This article discusses the effects of various modifications on the properties of aluminum alloys for structural applications. The effect of reinforcing particles on the mechanical properties of wrought 6063 aluminum alloy arising from our previous works is extensively discussed to identify the most promising reinforcing particles. It also discusses the improvement in mechanical properties of 1200 aluminum alloy using silicon carbide particulates. The effect of micro-alloy additions on the mechanical properties is also outlined in this article based on the results from our previous experimental works. Effect of combining heat treatment and deformation on the mechanical properties of wrought aluminum alloys is also presented. Results presented show that particle reinforcement, deformation, and microelemental additions to aluminum alloy result in significant improvement in mechanical properties of the alloys considered. Addition of reinforcing particles of barite, silicon carbide, iron fillings, and electric arc furnace dust are found to impart improved tensile strength to aluminum alloy. The most outstanding finding is that synergy between particle addition, deformation, and heat treatment has a good prospect in the production of improved aluminum alloy materials for automotive applications.

Keywords: Aluminum; Alloy addition; Composites; Deformation; Particle reinforcement.

INTRODUCTION

Metal matrix composites (MMCs) have light metallic base matrix such as aluminum, magnesium, or titanium with fibers, particulates, or whiskers as reinforcement. Composites produced from any of the matrix-reinforcement combination possess excellent properties, namely, thermal stability, high Young's modulus, and high compression and tensile strengths. Components made from these composites are currently used in aircraft, satellites, jet engines, missiles, diesel engine pistons, tank armors, high performance cutting tools, automotive disc brakes, drive shafts, cylinder liners, high power, high-density multi-chip modules in electronics and power electronic modules. The unlimited variations in MMC component arise from the possibility of combining various material systems (metal–ceramic–nonmetal). The most popular matrix for MMC is aluminum. Its low density, ability to be strengthened

by precipitation, good corrosion resistance, high thermal and electrical conductivities, and high damping capacity make aluminum very attractive as matrix for composites in most structural applications. The aluminum matrix composites have a superior advantage of being processed and shaped by conventional metal working techniques, such as extrusion and rolling.

The excellent properties of aluminum matrix composite are functions of

- a) Reinforcement.
 - Type.
 - Size.
 - Orientation.
 - Surface condition.
- b) Matrix chemical composition.
- c) Reinforcement chemical composition.
- d) Mechanical/thermal treatment.

This article discusses the effects of reinforcing particles on the mechanical properties of wrought 6063 aluminum alloy. It also discusses the improvement in mechanical properties of 1200 aluminum alloy using silicon carbide particulates (SiCp) as most matrices in earlier studies have been on A356, 2xxx, and 6xxx series alloys. Few studies have also been reported on the 7xxx series alloys reinforced with SiCp. The most common alloying elements added to commercial wrought aluminum alloys, singly or in combinations, are copper, silicon, manganese, magnesium, zinc, chromium, and nickel.

PARTICLE REINFORCEMENT

Aluminum has been reinforced with ceramic particles such as Al_2O_3 , ZrO_2 , SiC_p , iron fillings, electric arc furnace (EAF) dust, graphite, mica, and barite particles.^[1,19,22,25,48,68,71,77]

Effect of Addition of Alumina

Alumina has been recently researched as one of the reinforcing additives to aluminum. Alumina is found to be useful in improving high temperature and wear properties of aluminum alloys. Gudlur et al.^[42] recently studied the mechanical response of Al– Al_2O_3 composites using powder metallurgy. About 100% pure wrought aluminum alloy of 10 μm size was mixed with Al_2O_3 powder in a ball mill, pressed, and sintered at 600°C for 2 h. Samples were subjected to resonant ultrasound spectroscopy and uniaxial compressive strength. Elastic modulus between 51–62 GPa were achieved depending on the processing method. Porosities and segregation of particles were seen in the SEM images. The authors concluded that the processing method significantly affects the microstructural characteristics and consequently the mechanical characteristics. Another study by Su et al.^[85] indicates that tensile strength higher than 200 MPa can be achieved with Al_2O_3 nanoparticles in AA2024 alloys to study the effect of nano-sized Al_2O_3 particles on the tensile properties of AA2024 alloy using conventional stir casting methods with ultrasonic treatment. AA2024 powder of 80 μm sized and 99% purity was used to form composites with Al_2O_3 nano-sized powders. Results show that tensile and yield strengths above 200 and 150 MPa, respectively, can be achieved with 1.0 wt.% of the Al_2O_3 . However, tensile elongation decreased considerably with increase in Al_2O_3 .

Stir casting process has also been used to process A356-nano Al_2O_3 composites.^[54] Different weight fractions of nano-alumina and Al particles were incorporated into A356 alloy using a mechanical stirrer and samples were tested for mechanical properties. The study reports highest ultimate tensile strength of 182 MPa and highest ductility of 2.9% depending on the fraction of Al_2O_3 incorporated. It was suggested that the grain boundary refinement and effective

load transfer achieved are attributable to uniformly distributed and well-bonded Al_2O_3 particles. A similar study was conducted by Sajjadi et al.^[80] using the same material but different mixing process. Stirring speed and filler size were varied. Fillers were also treated in inert atmosphere before incorporation. Compressive strength and surface hardness were the mechanical properties tested. The authors reported highest compressive strength of 610 MPa. The authors agree with Mazahery et al.^[54] that incorporation of Al_2O_3 led to significant grain refinement, which contributes to the high compressive strength. Excellent properties have also been recorded by other authors. Gudlur et al.^[41] achieved an elastic modulus of 90 GPa using powder metallurgy at room temperature and modulus above 45 GPa at temperatures above 450°C. Yield strength of 141 MPa has also been recorded by Hossein-Zadeh et al.^[45] for Al nano-sized Al_2O_3 with stir casting under controlled atmosphere using magnesium as a wetting agent. A recent study by Garbiec et al.^[37] also shows tensile strength up to 160 MPa, tensile modulus of 100 GPa, and compressive strength of 247 MPa using spark plasma sintering. Using electromagnetic stir casting, Kumar et al.^[51] achieved a tensile strength of 148 MPa for A359 alloy incorporated with micron sized Al_2O_3 . Chou et al.^[27] obtained highest bending strengths of 482 MPa for Al_2O_3 /A356, 463 MPa for Al_2O_3 /6061, and 418 MPa for Al_2O_3 /1050 alloy composites using squeeze casting technique. The yield strengths for Al_2O_3 /A356, Al_2O_3 /6061, and Al_2O_3 /1050 were 235, 131, 103 MPa, respectively. In another study, Chu and Wu^[28] using squeeze casting achieved bending strength of 521 MPa and bending modulus of 102 GPa. Akbari et al.^[13] study gave a tensile strength of 265 MPa with commercial casting using nano-sized Al_2O_3 . Prielipp et al.^[74] achieved a 370% increase in fracture strength and a 150% increase in fracture toughness through gas pressure metal infiltration of Al_2O_3 in aluminum. Another study by Mazen and Ahmed^[55] showed that hot pressing followed by hot extrusion, a strength improvement of 64%–100% compared to the matrix material strength, can be obtained from wrought aluminum alloy filled Al_2O_3 . McCormick et al.^[56] showed that Al– Al_2O_3 composites manufactured using liquid metal infiltration method experienced increased in yield stress and attributed this to the strengthening effect in the aluminum matrix due to increase in the dislocation density. Gudlur et al.^[40] in another study using powder metallurgy realized an elastic modulus of ~80 GPa with alumina–aluminum composite. Production of 2024 aluminum alloy MMCs reinforced with Al_2O_3 particles up to 30 wt.% by Kok^[50] using vortex method and subsequent application of pressure realized a 57% improvement in tensile strength compared to virgin aluminum. The highest tensile strength obtained from this study was 110 MPa. The mechanism of strengthening with Al_2O_3 particles lies in the fact that they act to refine the grain size of α -aluminum by nucleating small grains and hence increase in amount of grain boundary during the solidification process.^[51] A summary of the

production techniques for Al-Al₂O₃ composites is shown in Table 1.

Effect of Addition of Barite Particles

Barite is the naturally occurring mineral form of barium sulfate. It has a high specific gravity of 4.5 and very low solubility. It is nontoxic and chemically and physically inert. These properties make it valuable for commercial use in various industries. Ground Barite is used mostly as an inert volume and weight filler in oil well drilling mud and as extender and heavy additive in the paint, paper, and rubber industries. Barite is also used as a filler or extender in cloth, ink, and plastics products. It is also used in radiography (“barium milkshake”), copper deoxidization, anode rotors lubrication in X-ray tubes, spark-plug alloys, and as expensive pigments in coatings. It is extracted by both surface and underground mining, followed by simple physical processing methods to produce correctly sized product and to remove extraneous materials. Barites are supplied in a variety of forms, and the price depends on the amount of processing. For filler applications, higher prices are demanded following intense physical processing

by grinding and micronizing. The opportunity to develop superior products for the aerospace and motor vehicle industries, and recreational applications, has sustained the interest in advanced composites.

Our study on the use of barite, as shown in Fig. 1, has shown that the increased addition of barite caused the precipitation of third phase (AlFeSi) crystals that enhanced the elongation of the alloy. When fine crystals of Mg₂Si were clustered incoherently at grain boundaries, elongation increased as dislocation motions were enabled through weak interface between clusters. In this alloy, Mg and Si combined to form the chemical compound Mg₂Si, which is the primary hardening phase. The strength of the alloy was dependent on the role of Mg₂Si precipitates while ductility depended on the amount of Mg and Si in solid solution and the size and distribution of Mg₂Si precipitates. The use of as-mined barite particles additions to AA6063 aluminum alloy has shown that strength, hardness, and elongation can be promoted above what is obtainable with SiCp additions as the strength and hardness of some metallic alloys may be enhanced by the formation of extremely small uniformly dispersed particles of a second phase within the matrix.

Effect of Addition of Silicon Carbide Particles

Aluminum-silicon carbide is a metal–ceramic composite material consisting of silicon carbide particles (SiCp) dispersed in a matrix of aluminum alloy. It combines the benefits of high thermal conductivity of metal and low coefficient of thermal expansion (CTE) of ceramic. The silicon carbide improves the stiffness and wear resistance of the resulting composite. The toughness and ductility are reduced by the ceramic dispersoids. With its composite features, Al–SiC is an advanced packaging material for high technology thermal management. Al–SiC is compatible with a wide range of metallic and ceramic substrate and plating materials used in microelectronic packaging for aerospace, automotive, and microwave applications. Al–SiC allows for a new packaging technology that can replace traditional W–Cu, Mo, BeO, Mo–Cu, AlN, AlSi, and Al_2O_3 . Silicon carbide, boron carbide, and aluminum oxide are the main particulate reinforcements that have been used for excellent combinations of specific strength and stiffness at ambient and elevated temperatures. The SiCp are also produced as a by-product of the processes used to make whiskers of these materials.^[84] Studies have also shown that aluminum MMC reinforced with silicon carbide (SiCp) particles have up to 20% improvement in yield strength, lower CTE, higher modulus of elasticity and improved wear resistance than the corresponding non-reinforced matrix alloy systems.^[79,93] For these reasons, they are currently being used in a number of specialty products such as brake discs and bicycle frames. The strength improvements for AA6063 aluminum alloy reinforced with particles is shown in Table 2.

It has now been shown that addition of SiCp to wrought 1200 aluminum alloy can significantly increase its strength and elongation characteristics.^[7] The presence of Al_3Fe crystals and incoherent precipitation of intermetallics have been observed to improve elongation. About 186% and 187% improvement in ultimate tensile strength (UTS) was obtained in as-cast and normalized samples with 40 vol.% and 50 vol.% of SiCp, respectively, while the elongations also improved to 13% and 15%, respectively. For a combination of strength and elongation as

required in wrought alloys, addition of 20 vol.% SiCp gave 127% improvement in strength and elongation of 23% for sample normalized. In another study, it was observed that application of reactive wetting of the SiC particles^[3] led to the increase in ductility of the Al–SiC composite, which was greatly compromised in the previous study. Other authors also prove that the use of SiC in aluminum alloys greatly improves the mechanical characteristics. El-Kady and Fathy^[33] recorded a compressive strength of 601 MPa from wrought aluminum alloy–SiC composite produced via powder metallurgy followed by extrusion. Another study by Melgi and Purohit^[58] used stir casting to produce LM6–SiC composite and recorded a tensile strength of 250 MPa and a ductility of 2%. Rahman and Rashed^[76] produced SiC filled composites with wrought aluminum alloy as the matrix using stir casting and recorded a tensile strength of 77.56 MPa. AA6061–SiC stir cast composites produced by Moses et al.^[64] was found to give a tensile strength of 210 MPa. Extruded wrought Al–SiC composite produced by Ma et al.^[53] also recorded a tensile strength of 278 MPa and yield strength of 175 MPa. Zakeri and Vakili-Ahrari^[98] work achieved a peak tensile strength of 212 MPa using three shaping methods, namely, conventional powder metallurgy, hot press, and hot extrusion. Mohanakumara et al.^[61] incorporated SiC particles into AA1100 with magnesium as the wetting agent using stir casting method. The cast ingots were later extruded and tested. They reported tensile and yield strength up to 345 and 310 MPa, respectively. High ductility up to 24% was also observed. Table 3 shows fabrication methods adopted for the production of some particles reinforced with aluminum alloys.

Effect of Addition of Boron Carbide

One of the most important ceramic particles used in improving the stiffness of aluminum is boron carbide. Boron carbide (B_4C) has a density of 2.52 g/cm³, a hardness slightly lower than that of diamond with excellent thermal stability and remarkable chemical inertness.^[62,70] It is widely believed that it can substitute SiC in areas where high stiffness and wear resistance are required. Oñoro et al.^[70] investigated the effect of boron carbide in AA6061 and AA7015 alloys using hot extrusion technique and recorded highest tensile strength of 380 MPa for AA7015 and 340 MPa for AA6061 composites. Mohanty et al.^[62] reported very poor flexural strength but flexural modulus as high as 180 GPa for AA1100–boron carbide composites produced via powder metallurgy. Similar results were also recorded by Yücel and Tekin^[97] for AA7075 and wrought aluminum alloy with boron carbide fillers produced using explosive consolidation. Stir casting method was applied by Shirvanimoghaddam et al.^[81] to A356–boron carbide composites and highest tensile strength of 210 MPa was achieved. B_4C reinforced with aluminum composites have also been fabricated by microwave heating of the mixture

of B₄C and aluminum powders.^[39] The maximum bending strength of 238 MPa and compressive strength of 330 MPa were achieved.

Effect of Addition of Magnesium Oxide

Magnesium oxide (MgO) is a refractory material having a melting point of about 2780°C. It is known for its good thermal shock resistance, compressive strength, hardness, low thermal conductivity, and excellent thermodynamic stability. Its density (3.58 g/cm³) is higher than that of aluminum and possesses very high Young's modulus (320 GPa). Because of its excellent stability and surface hardness, MgO is considered a good material for reinforcing aluminum matrix in a bid to improve its stiffness characteristics. Baghchesara and Abdizadeh^[18] reported the effect of MgO addition on the mechanical properties of aluminum. A356 matrix was reinforced with nanoscale MgO particles and fabricated via powder metallurgy. Reinforcing the Al matrix alloy with MgO particles resulted in compressive strength of 288 MPa, that is, ~130% improvement over the virgin A356 alloy. A similar research was done with A356 using stir casting method by Yar et al.^[96] A356 matrix was reinforced with nanoparticle MgO and fabricated via stir casting method at various casting temperatures. Highest tensile and compressive strengths above 800 and 900 MPa, respectively, were

achieved. Magnesium oxide provides overall improvement in mechanical properties solely due to hindrance to dislocation movement. This is because the ceramic particles have very high melting points and have very poor reactivity at temperatures where aluminum is processed either by powder metallurgy or stir casting.^[18]

Effect of Addition of EAF Dust

Another particle of note is the EAF dust. Thousands of tons of EAF dusts are generated in metallurgical plants each year. These waste dusts are not easily disposed since they are considered toxic owing to the presence of Pb, As, and Cr oxides in small amounts, which are formed at high temperatures above the steel bath and in the off-gas systems. The major elements in EAF dusts are iron, zinc, calcium, manganese, magnesium, and silicon in the form of simple or mixed oxides. The most prominent of these are iron, manganese, and silicon in oxide form. Addition of steel dust powder to the 6063 aluminum alloy^[4] produced marked effect on the tensile strength, ductility, and hardness properties of the alloy. UTS also increased by about 40% to that of conventional 6063 Al alloy. This was due to the combined effect of grain refinement propelled by increase in iron content and the formation, precipitation, and distribution of hard intermetallic compounds (Al₁₂(Fe,Mn)₃Si) at the grain boundaries of the Al alloy during solidification. The ductility of the Al-Si-based alloy was influenced positively by the amount of steel dust addition.

Effect of Addition of Iron Fillings

Iron filings (steel particles) are mostly a by-product of the grinding, filing, or milling of finished iron products, so its history largely tracks the development of iron. In the machine shop, it is generated as a waste product.^[12] The iron and steel processing industry produces iron filings in abundance and it constitutes environmental problems as it is nonbiodegradable. Research on the addition of steel containing particles to aluminum has shown that significant increase in tensile properties can be achieved.^[32,69] Rolled and tempered samples with 15 wt.% mild steel particles show 45.59% increase in tensile strength over virgin AA6063 alloy in rolled and tempered condition.^[1] The combined effect of grain refinement propelled by increase in iron content and the formation, precipitation, and distribution of hard intermetallic phases (AlFeSi and Mg₂Si) at the grain boundaries of the Al alloy during solidification is responsible. Refs. [4,46,49,66,82] earlier pointed out that the presence of Fe and Fe containing intermetallics promote grain refinement of α -aluminum matrix and subsequent strengthening due to the combined effect of precipitation and the presence of hard particles in the matrix. This explains why there is an increase in tensile strength, hardness, and impact energy of the composites

with an increase in the filler particles up to a tolerable percentage before declining. Iron oxide (Fe_2O_3) has also been used as a reinforcement in aluminum matrix.

Effect of Addition of Titanium Carbide

TiC is an attractive ceramic particle for Al matrix composites due to its high hardness, elastic modulus, low density, good wettability with molten aluminum, and its low chemical reactivity.^[88] It is known to be a great instrument for grain refining.^[15] Premkumar and Chu^[73] used an in situ process to produce fine TiC particulates in molten aluminum alloy. Carbon-bearing gas was introduced into Al-Ti alloy melt, thereby forming TiC particles in the melt. Highest yield strength, tensile strength, and elastic modulus obtained were 470 MPa, 495 MPa, and 85 GPa, respectively. Yang et al.^[95] investigated the production of Al-TiC composite using stir casting. Powdered Al, Ti, and C were used for the formation of the composites. Tensile strength of 148 MPa was obtained, which is 52% improvement over the virgin aluminum. Hot consolidation process has been used to produce Al-TiC composites by Mohapatra et al.^[63] The TiC used was synthesized directly from the titanium ore by carbothermic reduction process through thermal plasma technique and added to Al by hot consolidation. Highest compressive strength of 360 MPa (320% over virgin Al), Elastic modulus of 89 GPa (27% over virgin ingot), and yield strength of 201 MPa (388% over virgin Al) were recorded. Tong and Ghosh^[89] investigated the fabrication of in situ TiC reinforced with aluminum matrix composites. Tensile strength as high as 369 MPa, yield strength of 242 MPa, and elastic modulus of 23 GPa were recorded for some samples depending on the production route. AA6082/TiC composites has also been produced by stir casting and characterized for their mechanical properties.^[87] Tensile strength of 265 MPa at 10% TiC was recorded as the highest. The key advantage in the use of TiC as reinforcement in Al matrix is the fact that TiC is thermodynamically stable than all other intermetallics formed during the solidification of the composite. This not only prevents the formation of deleterious brittle intermetallic particles such as Al_3Ti but enhances the hardness and lightness of the composite.^[63] This also makes room for ease of production using conventional methods. They are also easily dispersed around the grains leading to good mechanical and wear properties as illustrated by Harti et al.^[43] (see Fig. 2).

Effect of Addition of Zirconium Oxide

Zirconia is one of the most important refractory materials with high melting point (2680°C). ZrO_2 possesses low CTE, good thermal shock resistance, low thermal conductivity, and excellent thermodynamic stability. It also possesses excellent mechanical characteristics including density (5.76 g/cm³), Young's modulus (190 GPa), and

Fig. 2 Image of Al-6% TiC^[43]

hardness (1200 HV).^[19] The use of zirconia as a reinforcement is expected to lead to improvement in tensile properties; however, it will increase the weight of the resulting composite. Prasad and Rao^[72] investigated the effect of zirconia particle addition on tensile properties of LM24 alloy using vortex casting method and recorded tensile strength of 197 MPa, that is, 60% improvement over the virgin material. In the work, ductility was observed to be greatly impaired due to the presence of hard zirconia particles. A356–zirconia particle composite was also fabricated by Baghchesara et al.^[19] using vortex method. The study realized an improvement in tensile strength (232 MPa) with yield strength of 95 MPa. Microwave sintering was used to fabricate wrought Al alloy–zirconia composite by Khodai et al.^[48] and a compressive strength of 120 MPa was measured. Hemanth^[44] also investigated the effect of addition of zirconia to LM13 alloy using disintegrated melt deposition followed by hot extrusion. Tensile strength of 262 MPa, ductility of 7.4%, and yield strength of 171 MPa were recorded. The use of ZrO_2 is very beneficial in aluminum matrix composite because of their ability to nucleate Al grains during solidification and restrict growth of recrystallized Al grains. In addition, there is good interfacial interaction between ZrO_2 and α -aluminum matrix.^[44,68] This is illustrated in Fig. 3.^[68]

Effect of Addition of Graphite Particles

Graphite has been recognized as a high-strength, low-density material that can be used to improve stiffness and tensile strength of wrought aluminum alloys. Their addition to aluminum resulted in improved technological properties, namely, low coefficient of friction, low wear rate, superior gall resistance, high seizure resistance, high damping capacity, and good machinability.^[22] A380-graphite composite has been processed using stir casting and characterized.^[22] Tensile strength up to 270 MPa was recorded with excellent wear resistance.

Fig. 3 SEM of Al-ZrO₂^[68]

Etter et al.^[35] also investigated the formation of Al-graphite composite using gas pressure infiltration method. Wrought aluminum alloy of 99% purity was used as matrix and a maximum flexural strength of 105 MPa was obtained, which is 50% improvement over the virgin aluminum. Indirect squeeze casting process was also experimented by Etter et al.^[34] Porous isotropic graphite was performed with about 14.5 vol.% porosity were infiltrated with AlSi₇Ba and AlSi₁₂ separately, and flexural strength was determined at room temperature. The infiltration enhanced the flexural strength by a factor of 2 (120 MPa). The strengthening mechanism of graphite is generally attributed to hindrance to dislocation. Graphite lacks the ability to go into chemical reaction with α -aluminum matrix at the processing temperature of aluminum.

ALLOY ADDITION

Research has shown that addition of alloying elements to MMCs leads to improvement in some properties of the composite. The Cu additions on the structural features and mechanical properties of Al-Si-Cu alloy have shown increment in the strength of these alloys due to its influence on the precipitation behavior of the aluminum during age-hardening treatment.^[16,17,30,67,94] Yield stress, hardness, and microhardness increase with an increase in Cu content regardless of the alloy composition. Increase in Cu content to 2 wt % leads to changes in α -AlSi eutectic structure resulting in UTS and ductility improvements.^[30] Addition of Ti has also been found to lead to >80% increase in surface hardness of Al-Si alloy.^[99] This action was attributed to the grain refinement caused by the formation of Al₃Ti intermetallic particles. Chen et al.^[26] also investigated the production of Al₃Ti in AA7075 and its effect on mechanical properties. The results indicated 9% improvement in UTS and 10% improvement in ductility with 1% addition in Ti. Gao et al.^[36] also reported a 10% and 17% increase in tensile and yield strengths, respectively, for Al-13% Si alloy with 3% Ti addition. The formation of AlTi intermetallic

particles was seen as the reason for increase in mechanical properties of these alloys. Toptan et al.^[90] also reported the use of Ti to form a wetting layer between α -aluminum matrix and B₄C in Al-B₄C composite. The wetting issue was solved by the formation of very thin TiC and TiB₂ reaction layers.

The yield stress, UTS, and hardness of aluminum 6063 alloy improve with addition of 14–16 vol.% Zn, and impact energy is significantly improved above 16 vol.% Zn additions. For structural purposes, the addition of zinc above the allowable content in 6063 aluminum alloy will improve the strength, yield stress, impact energy, and elongation responses.^[100] The ductility of the alloy depends on the amount of Mg and Si in solid solution and on the size and distribution of the Mg₂Si particles.^[94] The addition of Cu in the matrix significantly depresses the precipitation of other intermetallics in the matrix surface resulting in increment in both UTS and yield stress. Cu addition in the range of 2–4 vol.% will increase the tensile strength and impact energy without diminishing the hardness. This is a way to make brittle intermetallics embedded in FCC matrix ductile, which should be of interest to the auto industry.^[5]

DEFORMATION

Over the years, deformation processing of materials has been of great importance as knowledge of the interrelationship among the process parameters, microstructure, and material properties will enhance the quality of the product. Deformation processing depends on the microstructure of the starting material, the geometry of the deformation zone, the temperature, the strain rate employed, and the frictional conditions. The microstructure of the material being processed determines the extent of microstructural damage likely to be caused by mechanisms such as cavity formation at hard particles, cracking at grain-boundary triple junctions, and flow localization due to adiabatic cracking. Matrix particles are known to influence cavity formation, while particles at the grain boundaries affect wedge cracking. Comparing the mechanical responses of the specimens to the deformation processes, the tensile strength of the specimens is more significantly improved with forging than with cold rolling, even at the same thickness reduction.^[20] The rate of fall in specimen elongation during forging is lower than during cold rolling. This implies that the strain-hardening exponent in forging is low, with low uniform elongation. In contrast, this could be attributed to the second-phase particles and other precipitates in the aluminum matrix becoming evenly distributed during rolling.

The chances of damage to the second-phase particle size are higher in forging than in rolling. Thus, there is high concentration of formed cavities at hard second-phase particles during deformation by rolling, which will reduce the UTS in comparison to forged specimens. The flow

localization, more feasible in cold-rolled specimens than in forged specimens, will cause reduction in UTS. When gaseous pores are present, during deformation, the reduction in volume and the changes in the configuration of individual gaseous pores would cause an increase in the tensile strength of the matrix. The mechanical properties of materials depend, to a large extent, on the microstructure of the starting material. This is because the starting material controls the structural damage caused during deformation processing. The following damage mechanisms are known^[78] to be important in materials containing hard particles, namely, cavity formation at particles, which is important at ambient temperatures and high strain rates and cracking at grain-boundary triple junctions, which occur at low strain rates and high (recrystallization) temperatures and flow localization that results from adiabatic heating. This is important at very high strain rates. Reduced ductility in alloys is due to structural damage arising from any of these mechanisms. During plastic deformation and strain hardening of particle filled alloys, only the matrix deforms and not the hard particles. This leads to the formation of cavities around the undeformed particles. Size reduction through forging and rolling at room temperature would increase dislocation motion while still improving the UTS and Rockwell hardness number characteristics of the material. However, forging is more effective in this regard. The forging process destroys grain boundaries much more than does rolling, and it also causes the gaseous pores to move by spreading them along the forging direction, thus reducing the rate of crack growth and damage.

The upset forging of AA6063 alloys^[20] at different temperatures shows that at room temperature the UTS and Rockwell Hardness number increase, as the range of reduction from processing increases from 0–50 pct. However, the ductility decreases correspondingly, which is indicative of a low strain-hardening exponent. The gaseous pores in the as-cast structure spread when forged, while rolling does nothing to the casting defect. The pore elongation and thinning promoted superior strength, Rockwell hardness number, and ductility in the forged sample as compared to cold-rolled specimen. In another study, the difference in the effect of forging and rolling on AA6063 was also investigated.^[8] The study indicated that rolling achieved significant improvement in tensile strength than forging. Rolled samples were found to possess 68% difference in tensile strength over that of forged samples. This is attributed to the high effect of strain hardening occurring in rolling than in forging.

During precipitation hardening, it has been shown that cold deformation before quenching and aging of Al-Si-Cu-Mg may offer improved strengthening compared to the conventional method.^[23,24,29,31,38,59,60,65,83] The increased strengthening is due to the high rate of precipitation-induced supersaturated solid solution of θ'' , θ' , and θ precipitates. The cold deformation prior

to aging enhances nucleation of precipitates resulting in relative increase in hardness.^[92] The mechanical and thermal treatment effects on the anisotropic responses of the structural aluminum alloy^[2] revealed that the microstructures of the alloy consist of precipitates of Mg_2Si and intermetallic phases like $AlCu_2$ and $AlSiFeMg$ in the α -aluminum matrix. Mg_2Si crystals dominated the α -aluminum matrix, with fine crystals of $AlCu_2$ and $AlSiFeMg$ evenly distributed in the matrix. Precipitation hardening strengthens the alloy due to $AlCu_2$, Mg_2Si , and $AlSiFeMg$ precipitates that are formed. The precipitates severely strained the α -aluminum matrix resulting in an increased hardness and UTS of the alloy. The presence of iron (>0.5%) has a tendency to reduce the strength and hardness of the alloy in heat-treated conditions. However, the formation of α -FeSi occasioned by the silicon content (1.18%) prevented the decline in these properties.^[75] The matrix contains fine crystals of Mg_2Si and $AlSiFeMg$ in approximately equal volume fractions with crystals of Mg_2Si appearing in the grain boundaries while $AlCu_2$ and $AlCuMgFe$ crystals are fairly distributed in the matrix. When crystals of $AlSiFeMg$ and $AlCu_2$ phases are found alternating with the α -aluminum crystals, increase in hardness and impact energy over the aged samples will occur. When aged, the Mg_2Si crystals would increase in volume fraction, while intermetallics such as $AlCu_2$ and $AlSiFeMg$ formed would be reabsorbed into the solution. The presence of $AlCu_2$ and $AlSiFeMg$ leads to an increase in hardness property of the Al-Si-Cu-Mg alloy,^[86] which can be precipitated by quenched and as-cast samples. The presence of incoherent Mg_2Si precipitates would cause increase in impact energy. At 90° orientations, strong precipitation of Mg_2Si crystals would occur in any other direction. This was also observed in Adeosun et al.,^[10] where Mg_2Si crystals were found to grow in 90° direction of cast AA6063 alloy during aging. Mg_2Si nucleates heterogeneously, which means it should nucleate in preferred directions.

Further studies on the synergy of the SiCp addition on 6063 aluminum alloy,^[21] ambient rolling, and heat treatment revealed that strength and ductility of this alloy could be improved. Increase in the volume fraction of SiC resulted in enhanced strength over the conventional 6063 aluminum alloy. The SiCp presence at grain boundaries increases dislocation density during deformation and results in appreciable work hardening leading to higher tensile strength. The strength and ductility of SiCp reinforced with 6063 aluminum alloy would improve by work hardening and precipitation hardening. Cold rolling causes an increase in dislocation density. This disorders the structure and increases the strength at the expense of ductility. The ductility of the sample depends on the amount of Mg and Si in the solid solution and on the size and distribution of Mg_2Si crystals. Tempering, on the other hand, tends to reverse this condition. When the

grain boundaries are filled with SiCp even with reduction in reinforcement volume, the strength characteristics would be enhanced. Hard particles in the grain boundaries serve as hindrances to dislocation movement that leads to increase in force needed to create deformation. Such good mechanical properties are important for applications in structures, sporting goods, automotive engineering, and aerospace industry.

The combined effect of particle addition and deformation processing of AA1200 alloy was also investigated.^[9] The study featured the addition of steel particles to AA1200 alloy using stir casting followed by cold forging and annealing. Tensile strength of 280 MPa and ductility of 1.75 were achieved with the addition of 106 μm sized steel particles and 10% reduction and subsequent annealing. This represents a 100% improvement over as-received samples. It was noticed that grain refinement occurrence was motivated by increase in iron content, and precipitation and distribution of hard AlFeSi-related intermetallic compounds at the grain boundaries of Al alloy during solidification. This phenomenon was found to contribute strongly to the increase in mechanical properties of the composite material.

The combined processing action of deformation, heat treatment, and alloying additions on the properties of aluminum alloys has shown that some level of improvement is achievable on Al-Ti alloy.^[11] Rolled, quenched, and tempered alloys containing titanium in the range of 1.7%–2.2% demonstrated improved tensile strength by 24.7%, yield strength by 28%, elastic modulus by 38.3% and hardness by 20.5%. The Al_3Ti phase being the most stable precipitate in the $\alpha\text{-Al}$ matrix is responsible for the significant improvement in the alloy's mechanical properties. However, rolled, quenched, and normalized alloys show decline in mechanical characteristics due to coarsening of the main reinforcing phase, Al_3Ti , coupled with a rather superfluous ductility, which is above 47%.

CONCLUSION

It has been shown that particulates, deformation, and microelemental additions to aluminum alloy result in significant improvement in mechanical properties of the base alloy. Particles of barite, silicon carbide, iron fillings, and EAF dust are found to be good reinforcement for improving the tensile strength of aluminum alloy. Alloy additions such as zinc and copper are also found to increase tensile and impact strength of the alloy without decreasing the surface hardness property. Deformation is found to be very effective in improving tensile strength when it is combined with heat treatment. Synergy between particle addition, deformation, and heat treatment shows good prospects in the production of improved aluminum alloy materials for automotive applications.

X-Ray Diffraction Analysis of the Microstructure of Precipitating Aluminum-Based Alloys

E. J. Mittemeijer

Abstract

The performance of metallic materials is predominantly determined by their microstructure. The term microstructure is comprised of phase distribution, grain size and shape, lattice defect concentrations and distribution, of the material of interest. In this article an overview is provided of the use of x-ray diffraction (XRD) for microstructural characterization of aluminum alloys. Topics in this review include: the lattice parameter, precipitation kinetics, microstrain, and crystallite size and microstrain from diffraction line broadening.

Keywords: Crystallite; Lattice parameter; Microstrain; Microstructure; Precipitation.

INTRODUCTION: THE ROLE OF THE MICROSTRUCTURE

The performance of metallic materials as used in practice is predominantly determined by their microstructure. The notion “microstructure” (beautifully described by the actually not translatable German word: “Gefüge”) comprises the phase distribution, the grain constitution (size and shape distributions), and (lattice) defect concentrations and distributions, etc., of the specimen/workpiece concerned. Knowing and understanding the imperfectness of real materials is a prerequisite to understanding material behavior in practice.

Very often heat treatment of metallic alloys is applied to optimize the microstructure in view of mechanical, chemical, or electrical properties. Heat treatments of supersaturated, unstable, or metastable alloys can lead to precipitation of intermediate and (eventually) equilibrium precipitates. The considerate choice of a path in the time–temperature plane is made with a view to the property sought.

Characterization of the microstructure and thus (selection of) the (precise) heat treatment is impossible without the application of x-ray diffraction (XRD) techniques. The classical application of XRD in materials science involves phase identification. The diffraction pattern can be utilized as a “fingerprint” for the presence of phases. The success of XRD for phase identification relies to a large extent on the availability of the powder diffraction file of the International Centre for Diffraction Data (ICDD) that contains (typically, peak-intensity and peak-position) data of more than 130,000 substances. However, XRD can do much more.

The position of a diffraction line (peak position) and the shape and width of a diffraction line, the so-called

diffraction-line broadening (peak width), can be used to determine many important microstructural parameters, such as the concentration of the alloying element dissolved in the matrix phase, the crystallite size (of the precipitating phase), the macro- and microstrains, and the concentration of (lattice) defects as vacancies and dislocations. Obviously, the precipitation sequence in a supersaturated alloy is influenced by the amount and type of lattice defects (strains and dislocations) and the supersaturation.

In this chapter an overview is presented of the power of XRD for microstructural characterization of Al-based alloys. Al–Si and Al–Mg alloys are used as model systems. Silicon and magnesium are often added as alloying elements for aluminum. They show contrasting effects: equilibrium solubility in Al of Si is low (about 1.6 at.% at 850 K) and of Mg is high (about 18.9 at.% at 723 K); starting from a supersaturated solid solution, silicon precipitates as pure Si (diamond lattice) directly in the Al-matrix without occurrence of intermediate precipitates, whereas the equilibrium precipitate β (about Al_3Mg_2 ; fcc lattice) develops in the Al-matrix as the end stage of a precipitation sequence via Guinier-Preston zones and intermediate precipitates. The production route of the alloy determines the microstructure before heat treatment. Two extremes can be considered for realizing the supersaturated solid solution: *liquid quenching* (from melt spinning) and conventional, *solid quenching*. With a view to the amount of alloying element dissolved and the amount of retained defects, liquid quenched and solid quenched alloys can be rather different.

XRD results from such prepared Al–Si and Al–Mg alloys will be used here to emphasize especially those microstructural aspects that seem to be neglected and which can be well analyzed by XRD, in, for example, the role of excess vacancies and the macro- and micro-strains. The XRD methods and techniques themselves will not be

discussed extensively, as this has been done in textbooks and review papers to which the reader will be referred at the appropriate places.

THE LATTICE PARAMETER OF AL-BASED ALLOYS: ANALYSIS OF DIFFRACTION-LINE POSITION

The lattice parameter can be determined from diffraction-line positions (peak maximum or centroid). Such values of the lattice parameter are (intensity absorption weighted) averages over the diffracting volume. Local variations in the lattice parameter express themselves through broadening of the diffraction lines (see discussion in “Crystallite size and microstrain: Analysis of diffraction-line broadening” section). Lattice-parameter determination from peak positions can be performed with high accuracy on a diffractometer or with a Guinier camera in combination with some extrapolation procedure as the Nelson-Riley extrapolation.^[1] The accuracy reached is about 1×10^{-5} nm. Therefore, during a phase transformation the determination of the lattice-parameter change can be as powerful as the determination of changes of mass and length, both of which can also occur with great precision.

The Amount of Dissolved Solute: Analysis of Precipitation Kinetics

The simplest relation between the lattice parameter, a_A , of phase A and the amount of dissolved alloying element B, x_B , is a linear one:

$$a_A = a_{A,0} + p x_B \quad (1)$$

where $a_{A,0}$ is the lattice parameter of pure A. Note that the lattice parameter can be affected by the presence of macrostrain. Then a direct interpretation of the measured value for the lattice parameter in terms of the composition of the diffracting phase is not possible (see discussion in “The amount of macrostrain” section).

Equation 1 could be interpreted as a so-called Végard equation. The Végard relationship represents a linear interpolation between the lattice parameters of the pure components, if based on the same type of lattice (thus in the case of Al-Si a linear interpolation between the lattice parameters of fcc Al and of imaginary fcc Si).^[2] Yet, Végard relationships often do not hold: thus a linear equation may occur, but, in the relevant composition range, with a slope different from the Végard one (this holds for Al-Si^[3]), or a parabolic relationship must be used that provides a satisfactory description for a number of systems crystallizing in the cubic system.^[4]

Once the lattice parameter has been determined, it can be used to obtain a value of the dissolved amount

of alloying element B applying, for example, Eq. 1, or a more complicated one (see above discussion). Then the progress of precipitation upon isothermal annealing a supersaturated alloy can be expressed as:

$$f = (x_{B,0} - x_{B,t}) / (x_{B,0} - x_{B,t=\infty}) \quad (2)$$

where f ($0 < f < 1$) indicates the degree of transformation and the additional subscripts to x_B denote the times concerned (0 = initial situation, t = actual state, and $t = \infty$ represents the end (fully) precipitated state). The degree of transformation as derived from XRD data is shown as a function of annealing time at various temperatures for a liquid quenched Al-Si and a liquid quenched Al-Mg alloy in Figs. 1, 2 and 5. On the basis of such results the precipitation kinetics can be quantified, by fitting some model to the f - t dependencies observed. For a review on the quantitative description of solid-state transformation kinetics.^[5] Without recourse to a specific kinetic model, one can deduce the effective^[5] activation energy of the process, E .^[6] In the case of isothermal annealing, the variable β , given by:

$$\beta = kt = k_0 \exp(-E/RT) \quad (3)$$

with k_0 as pre-exponential factor and R as the gas constant, can be adopted as the path variable in the T - t plane (cf. “Introduction: The role of the microstructure” section). This means that the mechanism of the transformation does not change in the temperature-time window investigated. Then the activation energy can be simply determined from the lengths of time between two fixed stages of transformation, f_1 and f_2 , measured at a number of temperatures (f_1 may be taken equal to the initial value: 0). It follows from Eq. 3:

Fig. 1 The reaction parameter, defined as $1-f$ (see Eq. 2), for the precipitation of a liquid quenched AlSi 2.4wt% alloy as function of aging time at the temperatures indicated. The amounts of silicon dissolved initially (at $t = 0$) are 1.67 at.% Si, 1.75 at.% Si, and 1.17 at.% Si for the specimens annealed at 397 K, 425 K, and 448 K, respectively

Fig. 2 The lattice parameter of the Al-matrix, a_{Al} , for the precipitation of a liquid quenched AlMg 16.7 at.% alloy as a function of aging time at the temperatures indicated. All magnesium is dissolved initially (at $t = 0$). In these experiments precipitation of the β' intermediate phase (hexagonal unit cell; semi-coherent with the matrix) occurs.^[10] The degree of transformation can be calculated on the basis of Eq. 2 from the lattice-parameter data; see Fig. 5

$$\ln(t_{f_2} - t_{f_1}) = E/RT - \ln(k_0) + \ln(\beta_{f_2} - \beta_{f_1}) \quad (4)$$

The effective activation energy follows from the slope of the straight line obtained by plotting $\ln(t_{f_2} - t_{f_1})$ vs. $1/T$. Examples of such plots are shown in Fig. 3 for liquid quenched Al-Mg alloys.

The determination of E from f as a function of t for the case of nonisothermal annealing for a number of constant heating rates, as could be performed on a diffractometer supplied with a heating stage, is possible. The corresponding procedure is a full pendant of the one for isothermal annealing as given above by Eqs. 3 and 4.^[6]

Until now it was tacitly assumed that the precipitation process occurs homogeneously throughout the specimen. However, inhomogeneous precipitation is well possible. As a result a lattice-parameter distribution occurs that is revealed by a pronouncedly asymmetric line broadening and in outspoken cases the diffraction lines of the decomposing matrix even become doubly or multiply peaked. An example is shown in Fig. 4 for a liquid quenched Al-Mg alloy. Clearly, two peak maxima occur for the same reflection. Microscopical analysis of the microstructure showed that abundant grain-boundary precipitation had occurred in conjunction with precipitation in the bulk of the grains. The difference between the rates of grain boundary and bulk precipitation causes development of appreciable regions in the Al-matrix grains adjacent to the grain boundaries that are relatively poor in Mg solute, whereas the regions in the bulk of the Al-matrix grains are still relatively rich in Mg solute. Thus the development of doubly peaked diffraction lines can be understood. At

Fig. 3 Determination of the activation energy for the β' precipitation process in two liquid quenched AlMg alloys (cf. Fig. 2) on the basis of Eq. 4. t_{f_1} is taken equal to zero ($f_1 = 0$); t_{f_2} is determined for $f_2 = 0.002$. Then a plot of $\ln(t_{f_2})$ vs. $1/T$, where T is the annealing temperature, leads to a straight line, the slope of which gives the activation energy

Fig. 4 Inhomogeneous precipitation in a liquid quenched AlMg 10.5 at.% alloy as revealed by the occurrence of asymmetric line broadening. The Al 422 line profile is shown for the liquid quenched condition (a) and after aging for 4 h at 500 K (b). Line profiles were recorded by x-ray diffractometry using Cu $K\alpha$ radiation and are shown after smoothing and elimination of the α_2 component

high supersaturation the rate of bulk precipitation can be relatively strongly enhanced and the appearance of two maxima for a single reflection is suppressed. The inhomogeneous nature of the precipitation process can then still be recognized if the shape of the broadened diffraction line is analyzed. Consider the behavior of w_1/w_2 during the precipitation process (see Fig. 5), where w_1 and w_2 represent the low-angle and high-angle half widths of the diffraction-line profile. In the beginning stages of the precipitation process only a minor part of the Al-matrix is depleted of Mg solute, corresponding to a relatively small value of the lattice parameter. This solute depleted material will diffract at relatively high values of the diffraction angle, thereby causing a tail at the high-angle side of the reflection considered and thus w_1/w_2 can be smaller than 1 (cf. Fig. 5). In later stages of the precipitation process a minor amount of the Al-matrix is still relatively rich in Mg solute, corresponding to a relatively large value of the lattice parameter. This material will diffract at relatively small values of the diffraction angle, thereby causing a tail at the low-angle side of the reflection considered and this w_1/w_2 can be larger than 1 (cf. Fig. 5). Other causes of line broadening (as precipitate-misfit strain does also occur; cf. “Crystallite size and microstrain: Analysis of diffraction-line broadening” section) may affect the outspokenness of the effect discussed here.

Fig. 5 The reaction parameter, defined as $1 - f$ (see Eq. 2), for the precipitation of a liquid quenched AlSi 16.7 at.% alloy as function of aging time at the temperatures indicated (see Fig. 2). The corresponding behavior of the ratio w_1/w_2 is also shown, where w_1 and w_2 represent the low-angle and high-angle half widths of the Al 220 diffraction-line profile (Cu $K\alpha$ radiation)

The Amount of Excess Vacancies

Vacancies are “frozen in place” when metallic alloys are quenched. Thus excess vacancies, i.e., vacancies in surplus of the equilibrium amount, can occur. The volume of a vacancy is smaller than that of an atom and can be estimated as about one half the volume of an atom.^[7] Hence the introduction of vacancies in a lattice lowers the lattice parameter. Conversely, if excess vacancies are annihilated upon holding at a certain temperature, this is associated with an increase of the lattice parameter. Vacancies play an important role in precipitation processes: for example, they can facilitate diffusion and/or can be used for misfit accommodation by their deposition at the interface of a developing precipitate.

The presence of excess vacancies makes itself visible in liquid quenched Al-based alloys by the occurrence of sudden increase in the lattice parameter before appreciable precipitation starts (Table 1 and Fig. 6).^[8] The amount of annihilated excess vacancies can be estimated as follows.

Conceiving the alloy with vacancies as a “binary” alloy composed of metal atoms and vacancies and adopting a Végard-like relation for the lattice parameter a of the metal–vacancy alloy, it follows that:

$$a = c_v a_v + (1 - c_v) a_m \tag{5}$$

where a_v is the fictitious vacancy lattice parameter, c_v is the vacancy fraction, and a_m is the lattice parameter of the alloy in the absence of vacancies. Assuming the vacancy volume as half the atomic volume (see above), it holds that:

$$a_v = 2^{-1/3} a_m \tag{6}$$

Table 1 The sudden increase of the lattice parameter of the Al matrix of liquid quenched Al-based alloys, Δa , observed upon annealing before appreciable precipitation starts, and the corresponding change in the vacancy concentration, Δc_v , calculated using Eq. 7

Composition		Aging temperature (K)	Δa ($\times 10^5$ nm)	Δc_v ($\times 10^4$)
Alloy (at.%)	Al matrix (at.%)			
2.30 Si	1.41 Si	399 $\pm$ 4	3	4
10.6 Si	3.53 Si	399 $\pm$ 4	7	8
3.18 Mg	3.18 Mg	404 $\pm$ 4	4	5
10.5 Mg	10.5 Mg	404 $\pm$ 4	6	7
10.5 Mg	10.5 Mg	411 $\pm$ 2	6	7
12.8 Mg	12.8 Mg	411 $\pm$ 4	10	12
16.7 Mg	16.7 Mg	404 $\pm$ 4	34	40
16.7 Mg	16.7 Mg	411 $\pm$ 2	50	59

Fig. 6 Annihilation of excess vacancies. The change of the Al-matrix lattice parameter as a function of aging time at the temperatures and for the alloys indicated. Note that for the AlMg alloys all Mg is in solid solution, whereas for the AlSi 10.6 at.% alloy only 3.53 at.% Si is dissolved

Hence, it is obtained from Eqs. 5 and 6 for the change of the lattice parameter Δa due to a change of the vacancy concentration Δc_v :

$$\Delta a = (2^{-1/3} - 1)a_m \Delta c_v \quad (7)$$

Results for Δc_v calculated in this way from the measured lattice-parameter increases upon short-time annealing have also been given in Table 1. As a rule of thumb the vacancy concentration in a pure metal is estimated to be about 1% at the melting temperature. The results shown in Table 1 clearly indicate that the amount of excess vacancies strongly depends on the amount of solute which can be ascribed to a solute concentration dependent on the apparent free enthalpy of vacancy formation.

The Amount of Macrostrain

The lattice parameter observed at room temperature for the Al-matrix in a fully precipitated Al-Si alloy is significantly greater than the expected equilibrium value. Extensive investigation of this new phenomenon^[11] initially led to the conclusion that the effect is due to the hydrostatic component of the elastic distortion of the matrix by the precipitates. Later work showed that a similar phenomenon occurs upon precipitation in nitrated ferrite.^[12] Because the change of the matrix lattice parameter can be used for analyzing precipitation kinetics (see “Introduction: The role of the microstructure” section), understanding and correction for this effect is desired.

The elastic distortion of a crystal by a point imperfection has been considered by Eshelby.^[13,14] This theory does

not work well to explain the change of the lattice parameter upon dissolving an alloying element in a matrix, where the point defects are the solute atoms. The reason is that electronic interactions between solute and solvent atoms can be more important than elastic deformation in this case. However, this theory can be well suited to describe the elastic distortions due to a misfitting precipitate in a matrix, where electronic interactions do not play a role.

Consider a system of spherical particles/inclusions B in a continuous matrix A . Assuming elastically isotropic materials and n inclusions per unit volume, the fractional lattice-parameter change of the finite matrix, $\Delta a_A/a_A$, is given by:^[11,15]

$$\Delta a_A/a_A = 4C_A \{ \epsilon / (1 + \epsilon)^3 \} y_B \quad (8)$$

where $C_A = (\mu_A K_B / K_A) / (3K_B + 4\mu_A)$ is an elastic constant, with μ , and K as shear and bulk moduli, and y_B is the volume fraction of particles B experiencing the linear misfit ϵ with the matrix. In the model the distinction between a finite and an infinite matrix is essential: the image force to be applied to the external surface of the finite matrix, to assure that a stress-free bounding surface occurs, induces the hydrostatic component of stress responsible for the volume change of the matrix and thus the corresponding change of the average lattice parameter.

Obviously the inclusions themselves are also subjected to the hydrostatic component of stress discussed above. For the lattice-parameter change of the inclusions, $\Delta a_B/a_B$, it is shown that:^[15]

$$\Delta a_B/a_B = -4C_B \epsilon (1 - y_B) \quad (9)$$

where $C_B = \mu_A / (3K_B + 4\mu_A)$ is an elastic constant. Clearly, the change of the lattice parameter for the inclusions is opposite to that for the matrix.

Two sources of misfit can be indicated. First, the specific volume of the precipitate can be different from that of the matrix. For example, the volume of a silicon atom as dissolved in the fcc Al matrix is about 23% smaller than as precipitated as Si in its diamond-like lattice. Second, upon cooling after partial or complete precipitation thermal misfit between precipitates and the matrix is generated because of the difference between the thermal expansion coefficients of the matrix and precipitates. Indeed, the last case provided the first evidence for the macrostrain effect discussed here.^[11]

The measured lattice parameter of the aluminum matrix of a liquid quenched Al-11wt.%Si alloy as a function of aging time at 425 K is shown in Fig. 7. Upon annealing, dissolved Si precipitates and the lattice parameter increases. After completed precipitation the lattice parameter, as measured at room temperature, has attained a constant value, which is larger than the equilibrium value of the (now) pure Al-matrix. This difference can be explained on the basis discussed above: the

Fig. 7 The lattice parameter of the Al matrix as observed at room temperature for a liquid quenched AlSi 11wt% alloy as a function of annealing time at 425 K. The bold dashed line indicates the equilibrium value of the lattice parameter of pure aluminum. The positive deviation from this value observed for the AlSi alloy after completed precipitation is caused by the thermal misfit between the Si particles and the Al matrix developing upon cooling after the precipitation annealing. The dashed thin line shows the lattice parameter of the Al matrix after correction for the effect due to the difference in thermal shrink

elastic distortion caused by the thermal misfit between precipitates and the matrix, due to cooling from the precipitation temperature to room temperature, causes the enhancement of the matrix lattice parameter. The linear misfit parameter ϵ (cf. Eq. 8) can be given for this case as $\Delta\alpha\Delta T$, where $\Delta\alpha$ and ΔT denote the difference in linear thermal expansion coefficient and the difference in temperature, respectively. Then a plot of $\Delta a_{\text{Al}}/\Delta T$ vs. y_b should fall on a straight line that passes through the origin (cf. Eq. 8), as is observed (Fig. 8). Similarly, one expects that the lattice parameter of the Si precipitates is smaller than the equilibrium value (cf. Eq. 9). This is indeed observed.^[9,15]

The precipitation induced misfit can be very large, as holds for the Al–Si system, for example (see above). Then full elastic accommodation of this misfit cannot be expected. Maxima in the Al-matrix lattice parameter of precipitating Al–Si alloys have been observed in conjunction with lattice parameter minima for the Si precipitates.^[15] These lattice-parameter maxima and minima have values smaller than that calculated by application of Eqs. 8 and 9: during precipitation considerable relaxation of the precipitation induced stresses takes place.

The discussion in this section implies that during precipitation the lattice parameter of the matrix may not be straightforwardly interpreted in terms of the solute content

Fig. 8 $\Delta a_{\text{Al}}/\Delta T$ as a function of the volume fraction silicon precipitated (y_b in Eq. 8), where Δa_{Al} is the change of the lattice parameter of the Al matrix due to the thermal misfit, induced by cooling over a temperature range ΔT , between the Si precipitates and the Al matrix. See Eq. 8

that is still dissolved in the matrix; i.e., Eq. 1 cannot be applied without more calculation. Instead it holds that:

$$a_A = a_{A,0} + p \cdot x_B + \Delta a^{\text{thermal}} + \Delta a^{\text{prec}} \quad (10)$$

Values for $\Delta a^{\text{thermal}}$ and Δa^{prec} may be estimated using the model given by Eqs. 8 and 9 as long as the misfit is accommodated fully elastically. On the basis of Eqs. 8–10, the unknowns x_B and y_b can be calculated from the measured lattice parameter and the known overall composition of the specimen.

CRYSTALLITE SIZE AND MICROSTRAIN: ANALYSIS OF DIFFRACTION-LINE BROADENING

The analysis of diffraction-line broadening is one of the most powerful methods to quantitatively analyze defects in crystalline materials. Values for crystallite-size and microstrain parameters can be obtained according to a variety of methods. A review is presented in Ref. [16]. The methods differ with respect to the severity of the assumptions made. The more rigorous methods employ the difference in order dependence of size and strain broadenings to separate them. Often two orders of a reflection are the minimum needed, but are not available (for example, the second order of a reflection may be too weak and cannot be measured accurately enough within a reasonable time). Then single-line methods may be applied, but these are subject to assumptions. Perhaps the most widely used and well-known single-line method assumes that the line-profile shape can be described by a Voigt function.^[16,17] A Voigt function is a convolution of a Cauchy function and a Gaussian function. From the profile

to be investigated the integral breadth (i.e. peak area/peak height) of the Cauchy and Gaussian components of the only structurally broadened profile are obtained. In practice, size broadening is often considered to result into Cauchy-shaped profiles, whereas strain broadening gives rise to Gaussian-shaped profiles. Then, one can apply Eq. 11^[16,17] for the determination of crystallite-size and strain parameters

$$D_{\text{eff}} = \lambda / (\beta_c^f \cos \theta) \quad \text{and} \quad e = \beta_g^f / (k \tan \theta) \quad (11)$$

where D_{eff} and e denote the effective crystallite size perpendicular to the diffracting planes and an average microstrain in the same direction, respectively, and β_c^f and β_g^f are the integral breadths of the Cauchy and Gaussian components of the only structurally broadened profile, f . The constant k is usually taken as 4.^[16] Note that the broadening due to the instrumental conditions (including the wavelength distribution) has to be removed before the structural line broadening can be analyzed. This can be achieved by recording reflections of a standard specimen not exhibiting structural line broadening.^[16]

The microstrain parameter e can be conceived as a measure for the root mean square strain, $\langle e_0^2 \rangle^{1/2}$. In order to replace e by $\langle e_0^2 \rangle^{1/2}$ in Eq. 11, the constant k has to have a value that depends on the particular strain distribution in the specimen. For many cases $k = 4$ provides a fair estimate: for example, (a) if a Gaussian microstrain distribution occurs with Gaussian strain broadening, k equals $2\sqrt{(2\pi)}$,^[16] and (b) for the case of a misfitting spherical precipitate in a matrix it appears (on the basis of line-profile simulations) that k equals about 5.5.^[18]

Crystallite Size and Microstrain in Initial and Final Microstructures

XRD measurements performed on liquid quenched Al–Si alloys showed that the Al matrix gave rise to a dominant strain broadening, whereas the initially present Si particles (not all Si is dissolved in the Al-rich matrix at the start of annealing) gave rise to both size and strain broadening. Since $1/E$, where E is Young's modulus, for Al is larger in a [100] direction than in a [211] direction, one may expect that the microstrain is larger in a [100] direction than in a [211] direction (see Fig. 10 at $t = 0$). Similarly it can be understood that for Si the microstrain in a [311] direction is larger than in a [111] direction (see Fig. 11 at $t = 0$).

After completed precipitation where it can be assumed that the precipitation induced misfit has been entirely relaxed, cooling down to room temperature from the precipitation temperature induces thermal misfit between the precipitates B and the matrix A . On the basis of the model discussed in “Crystallite size and microstrain: Analysis of diffraction-line broadening” section it can be straightforwardly calculated that in this case^[19]

$$\langle e_0^2 \rangle^{1/2} = \left\{ (2\sqrt{5})/5 \right\} C'_A \{ \varepsilon / (1 + \varepsilon)^3 \} \sqrt{y_B} \quad (12)$$

with $C'_A = 3K_B / (3K_B + 4\mu_A)$ as the elastic constant. Again adopting the following expression for the linear misfit parameter, $\varepsilon = \Delta\alpha\Delta T$ (see “Crystallite size and microstrain: Analysis of diffraction-line broadening” section), it follows that a plot of $\langle e_0^2 \rangle^{1/2} / \Delta T$ vs. $y_B^{1/2}$ should result in a straight line. This agrees with the experimental finding (Fig. 9).

It should be noted that the amount of energy stored in the specimen by only the elastic accommodation of thermal misfit can be appreciable. For the system of misfitting spherical precipitate in a matrix the stored energy per unit volume of the matrix A is given by:^[19,20]

$$E_A = (15/2) \mu_A \langle e_0^2 \rangle \quad (13)$$

For the Al–Si system and $\Delta T = 150$ K it follows that $\varepsilon = 3.1 \times 10^{-3}$. Then, combining Eqs. 12 and 13, it is obtained for the stored energy density $E_A \approx 600 y_B$ KJ/m³. This can be compared with the stored energy density corresponding to a dislocation density of 10^{14} m⁻² in Al which equals about 100 kJ/m³.

Finally, it is remarked that storage at room temperature of Al-based alloys allows significant relaxation of misfit stresses. Already in the first few days of storage at room temperature appreciable stress relaxation takes place; after 12 years at room temperature less than 50% of the original misfit is still accommodated elastically.^[21]

Crystallite Size and Microstrain During Precipitation

The change of the microstrain in the Al matrix and in the Si particles during precipitation in a liquid quenched Al–Si alloy is shown in Figs. 10 and 11. At the start of annealing

Fig. 9 The microstrain in the Al matrix of fully aged AlSi alloys per Kelvin difference between aging and room temperature, $\langle e_0^2 \rangle^{1/2} / \Delta T$, as a function of the square root of the volume fraction of Si phase, $y_{\text{Si}}^{1/2}$. See Eq. 12

Fig. 10 The microstrain, $\langle e_0^2 \rangle^{1/2}$, of the Al matrix of a liquid quenched AlSi 13wt% alloy as a function of aging time at 445 K. Results derived from two reflections, Al 400 and Al 422, are shown

Fig. 11 The microstrain, $\langle e_0^2 \rangle^{1/2}$, of the Si phase particles in the Al matrix of a liquid quenched AlSi 13wt% alloy as a function of aging time at 445 K. Results derived from four reflections, Si 111, Si 220, Si 311, and Si 422, are shown

quenched-in stresses disappear, which causes a decrease of the microstrain. Then, upon precipitation, precipitation induced stresses appear, which are not dissipated readily. Of course, the fraction of the volume affected by the precipitation stresses will be larger for the minority Si phase than for the Al matrix. Hence, after the initial decrease of the microstrain in the Si phase, the microstrain increases again; see especially the results for the [111] direction in Fig. 11. After completed precipitation no further precipitation induced (transformation) strains are induced and relaxation becomes dominant (see Fig. 11 for $t > 8\frac{1}{4}$ h at 445 K). The microstrain that remains after extensive aging is due to the thermal misfit induced by cooling from the precipitation/aging temperature to room temperature where the

diffraction measurements were performed (for discussion, see "Introduction: The role of the microstructure" section and Ref. [19]).

Upon aging the crystallite size of the silicon precipitates increases (see Fig. 12). The size in a [111] direction is the smallest, suggesting that the Si particles prefer to align their {111} planes parallel to the interface with the Al matrix. At the start of the precipitation the average crystallite size increases slowly as new precipitates nucleate (note that not all Si is dissolved in the (supersaturated) Al-rich matrix at the start of annealing). During coarsening, after completed precipitation, small precipitates dissolve in favor of larger precipitates. The silicon atoms have to cover larger distances in the coarsening stage than in the precipitation stage. Consequently, the growth rate in the coarsening stage is smaller than in the precipitation stage and decreases continuously upon increasing annealing time (see Fig. 12; note the logarithmic time scale of the abscissa in Fig. 12).

CONCLUSION

X-ray diffraction analysis is a powerful method to describe the changing microstructure in Al-based alloys upon precipitation. Two characteristics of the diffraction pattern play a major role: (a) the diffraction-line position and (b) the diffraction-line profile shape and width.

The diffraction-line position allows determination of the dissolved solute content in the matrix. However, it is not normally realized that the diffraction-line position in supersaturated alloys is also influenced by the presence of quenched-in excess vacancies (especially important for liquid quenched alloys) and the hydrostatic component of

Fig. 12 The crystallite size of the silicon phase particles in the AlSi 13wt% alloy as a function of aging time at 445 K. Results derived from four reflections, Si 111, Si 220, Si 311, and Si 422, are shown

stress due to the misfit between the matrix and the second phase particles. Two sources of such misfit can occur: (a) the precipitation induced misfit (differences in atomic volume between dissolved and precipitated stage), and (b) the thermal misfit due to the difference in thermal expansion coefficient of matrix and second-phase particles. Evidence for these effects has been summarized in this overview and the procedure for correction for these effects on the lattice parameter has been described.^[15]

Once the lattice-parameter value has been corrected for macrostrain and vacancy effects, if such corrections are necessary, the composition of the matrix phase can be determined, provided the dependence of lattice parameter on composition is known. The analysis of the lattice parameter as a function of temperature and time thereby becomes a method for the determination of precipitation kinetics as powerful as more usual methods, such as dilatometry. It should be noted that the analysis of changes in the integrated intensity of one or more reflections, in order to determine the increase or decrease of the amount of a phase, is usually less sensitive and less accurate than the analysis of lattice-parameter change.

The basic model for the quantitative assessment of the misfit strain/stress effects has been presented: a misfitting spherical inclusion in a *finite* matrix.^[11] Predictions of this model agree well with the experimental observations. On this basis the precipitation kinetics of supersaturated Al-based alloys can be determined from lattice-parameter measurements after correction for macrostrain effects due to the misfit between the matrix and the precipitates.

Diffraction analysis is the only technique that allows the simultaneous determination of both macro- and microstrains. The macrostrain represents the average strain in the diffracting volume, which is of macroscopical size, i.e., of specimen dimensions. The microstrain represents the local (atomic) variation in lattice spacing, e.g., due to the volume misfit between precipitates and matrix. The most practical method to analyze the structural line broadening appears to be the single-line Voigt method used in the work discussed here.^[16,17] (This method has been included in commercial software packages: see the Philips diffraction software.) For rigorous analysis the constraint of assumed profile shape has to be relieved. Then computer simulation of the occurring diffraction-line broadening and fitting to the observed diffraction-line profiles can be performed. On this basis the usually modest asymmetry of the microstrain broadening can be understood and analyzed.^[18]

Analysis of the crystallite size from various reflections of the precipitating phase allows determination of the developing morphology of the precipitates. X-ray diffraction, as compared to transmission electron microscopy, has the advantage of providing statistical averages for the specimen; such averages are needed to understand and predict material behavior in practical applications.

The importance of the microstrain for practical applications may be recognized by indicating that the stored

energy density in the Al-matrix by only the elastic accommodation of the thermal misfit developing upon cooling, as derived from the diffraction-line broadening, can be of the same order of magnitude as the stored energy density in a cold worked metal.
